# Preface

This book is based on lectures regularly taught in the fourth and fifth year graduate courses in transport phenomena and chemical reactor modeling, and in a post-graduate course in modern reactor modeling at the Norwegian University of Science and Technology, Department of Chemical Engineering, Trondheim, Norway. The objective of the book is to present the fundamentals of the single-fluid and multi-fluid models for the analysis of single- and multiphase reactive flows in chemical reactors with a chemical reactor engineering rather than mathematical bias. Organized into 13 chapters, it combines theoretical aspects and practical applications and covers some of the recent research in several areas of chemical reactor engineering. This book contains a survey of the modern literature in the field of chemical reactor modeling.

This monograph consists of three parts printed in three volumes:

Part I: Single Phase Fundamentals.

Part II: Multiphase Fundamentals.

Part III: Applications.

In part I most of the fundamental theory of single phase reactive flows is presented. In part II most of the fundamental theory of multiphase reactive flows is presented. In both parts a few numerical model simulation application examples are given to elucidate the link between theory and applications. In part III the chemical reactor equipment to be modeled are described. Several engineering models are introduced and discussed. A survey of the frequently used numerical methods, algorithms, and schemes is provided. A few practical engineering applications of the modeling tools are presented and discussed. The working principles of several experimental techniques employed in order to get data for model validation are outlined.

I hope this book can serve as a guide for my future Ph.D. students, as well as other interested scientists, to get a thorough introduction to this field of research without spending too much of their invaluable time searching for and reading a large number of books and papers.

Comments on the contents of the book:

In [Chap. 1](#), a survey of the elements of transport phenomena for single phase multi-component mixtures is given. This theory serves as basis for the

development of most chemical engineering models as well as the multiphase flow concepts to be presented in the following chapters. The first part of the chapter considers single phase Newtonian fluid flows for multi-component mixtures. In the second part of the chapter the governing equations are applied to turbulent flows.

**Chapter 2** contains a summary of the basic concepts of kinetic theory of dilute and dense gases. This theory serves as basis for the development of the continuum scale conservation equations by averaging the governing equations determining the discrete molecular scale phenomena. This method is an alternative to, or rather both a verification and an extension of, the continuum approach described in **Chap. 1**. These kinetic theory concepts also determine the basis for a group of models used describing granular flows, further outlined in **Chap. 4**.

**Chapter 3** contains a survey of a large number of books and journal papers dealing with the basic theory of multi-fluid flow modeling. Emphasis is placed on applying the multi-fluid model framework to describe reactive flows. In the more advanced textbooks the basic multi-component multiphase theory is introduced in a rather mathematical context, thus there is a need for a less demanding presentation easily accessible for chemical reaction engineering students.

**Chapter 4** contains a summary of the basic theory of granular flow. These concepts have been adopted describing particulate flows in fluidized bed reactors. The theory was primarily used for dense bed reactors, but modified closures of this type have been employed for more dilute flows as well. Compared to the continuum theory presented in the previous chapter, the granular theory is considered more complex. The main purpose of introducing this theory, in the context of reactor modeling, is to improve the description of the particle (e.g., catalyst) transport and distribution in the reactor system.

In **Chap. 5**, an outline of the basic theory of the required closure laws and constitutive equations is provided. The first sections describe models for the interfacial transport phenomena occurring in multiphase reactive systems. An overview of the important models for the different forces acting on a single particle, bubble, or droplet is given. Model modifications due to swarm or cluster effects are discussed. In the following sections the standard theories for interfacial heat and mass transfer are examined. In the last section the literature controversy originating from the fact that with the present level of knowledge, there is no general mathematical theory available to determine whether the 3D multi-fluid model is *well posed* as an initial-boundary value problem, is examined.

In **Chap. 6** the derivation of the classical reactor models is examined starting out from the microscopic heat and species mass balances. In chemical reactor engineering the idealized models like the plug flow reactor (PFR)—and continuous stirred tank reactor (CSTR) models are well known from basic courses in chemical reaction engineering. For non-ideal flows the dispersion models (DMs) are frequently used. These standard models are deduced from the local heat and species mass balances employing a cross-sectional area averaging procedure. Similar, but not identical, models can be obtained by simplifying the governing local transport equations. Two models for chemical reaction equilibrium calculations are examined.

In **Chap. 7**, a brief summary of the agitation and fluid mixing technology is given. The main emphasis is placed on examining the modern strategies used to model the momentum transfer from the impeller to the fluid. The methods are sketched and the basic equations are listed. A few model simulation examples are presented.

In **Chap. 8**, the basic bubble column constructions and the principles of operation of these reactors are described. The classical models for two- and three phase simple bubble column reactors are defined based on heat and species mass balances. The state of the art on fluid dynamic modeling of bubble column reactors is then summarized including a few simulations of reactive flows.

In **Chap. 9**, an outline of the basic theory of the population balance equation is provided. Three different modeling frameworks are defined, the macroscopic formulation, the local continuum, and the kinetic theory formulations. The macroscopic model is formulated directly on the macroscopic scales, enabling a suitable framework for practical engineering calculations. In this framework simple and inaccurate numerical approximations, quadrature rules and merged functions have become integrated parts of many such macroscopic closure laws. Since these numerical approximations are difficult to split from the physical parts of the closure laws and the fundamental functions can be hard to extract from the merged functions, the more popular macroscopic closures for bubble coalescence and breakage rates are also discussed in this chapter. The more rigorous local formulations are presented and future reactor analysis should preferably be based on these concepts, enabling more accurate closure laws to be formulated and more optimized solution methods to be used. The status on population balance modeling of bubble coalescence and breakage phenomena is summarized.

**Chapter 10** contains a literature survey of the basic fluidized bed reactor designs, principles of operation, and modeling. The classical two- and three phase fluidized bed models for bubbling beds, risers, and circulating fluidized beds are defined based on heat and species mass balances.

In **Chap. 11**, an overview of the basic designs, principles of operation, and modeling of fixed packed bed reactors is presented. The basic theory is applied to describe the performance of particular chemical processes operated in fixed packed bed reactors.

In **Chap. 12**, a group of finite volume solution algorithms for solving the multi-fluid model equations is described. The basic single-phase finite volume method solution strategies, spatial discretization schemes, and ODE solution methods in time are examined. The selected multiphase algorithms are extended versions of the single-phase SIMPLE-like algorithms. However, alternative algorithms can be found in the literature. Some of these methods are briefly outlined in this chapter. Moreover, several numerical methods for solving the population balance equation for dispersed flows are outlined. Finally, several solution methods for the resulting algebraic discretization equations are mentioned.

In **Chap. 13**, a survey of several frequently used experimental techniques for characterization of dispersed multiphase flows is provided. The working principle

of these techniques are outlined. The application of these techniques to chemical reactor flows is critically examined.

The book may be used as a reference book of the multi-fluid theory, or for teaching purposes at different educational levels. For example, at the graduate level, an introductory graduate course in single phase transport phenomena can be based on Chap. 1 (and parts of Chap. 2). Suitable numerical solution methods for the governing single phase equations can be found in Chap. 12. An introduction to reactor modeling can be based on Chaps. 6–11. The material in Chaps. 2–5 the multiphase parts of Chap. 12 and Chap. 13 may be better suited at the postgraduate level. Taking these three courses in sequence, I hope the Ph.D. students get the necessary knowledge to give useful future contributions in this field of science.

I have received a great deal of help from numerous persons over the 30 years of association with this subject, in formulating and revising my views on both reactor modeling and chemical reactor engineering. I would like to acknowledge the inspiring discussions I have had with colleagues at NTNU during my work on this book. Moreover, I wish to thank the Ph.D. students who have taken my graduate subjects and thus read the lecture notes carefully and supplied me with constructive criticisms (among other comments) and suggestions for further improvements on the text. It is fair to mention that my students, especially Dr.-Ing. Lars Hagesæther, Prof. Dr.-Ing. Carlos A. Dorao, Dr.-Ing. Håvard Lindborg, Dr.-Ing. Hans Kristian Rusten, Dr.-Ing. Cecilie Gotaas Johnsen, Ph.D., Zhengjie Zhu, Ph.D. Luciano E. Patruno, Ph.D. Federico Sporleder, Ph.D. Kumar Ranjan Rout, Ph.D. Zhongxi Chao, and M.Sc. Jannike Solsvik, have contributed to this book in many ways. This includes technical contributions either in a direct or indirect way, and reading parts of the draft manuscript. Finally, I must thank B.Sc. Itishree Mohallick for drawing many of the figures in the book.

|                    |                                                                               |
|--------------------|-------------------------------------------------------------------------------|
| $A$                | Hamaker constant (J)                                                          |
| $A$                | Chemical component in general reaction                                        |
| $A$                | Empirical model parameter (—)                                                 |
| $A$                | Linear algebraic system matrix in WRM                                         |
| $A$                | Macroscopic surface area defining the control volume (m <sup>2</sup> )        |
| $A$                | Model parameter (—)                                                           |
| $A$                | Shorthand notation for advective term                                         |
| $A$                | System matrix of linear system in DQMOM                                       |
| $A$                | The tube cross-section area (m <sup>2</sup> )                                 |
| $a$                | An empirical parameter in F-OPT theory (—)                                    |
| $a$                | Coefficient in the FVM discretization equation                                |
| $a$                | Non-linear function in PDE classification theory                              |
| $a$                | Parameter in linear growth velocity model                                     |
| $a$                | Stoichiometric coefficients in general reaction (—)                           |
| $a$                | The distance from scatterer to the detector in LDT arrangement (m)            |
| $A(t, \mathbf{r})$ | Generalized variable dependent on time and space                              |
| $A_0$              | Catchment area (m <sup>2</sup> )                                              |
| $A_0$              | Valve opening area (m <sup>2</sup> )                                          |
| $a_0$              | Parameter in prescribed velocity profile in laminar boundary layer theory (—) |
| $A_1$              | Surface of phase 1 in two phase system (m <sup>2</sup> )                      |
| $a_1$              | Parameter in prescribed velocity profile in laminar boundary layer theory (—) |
| $A_2$              | Surface of phase 2 in two phase system (m <sup>2</sup> )                      |
| $a_2$              | Parameter in prescribed velocity profile in laminar boundary layer theory (—) |
| $a_3$              | Parameter in prescribed velocity profile in laminar boundary layer theory (—) |

|              |                                                                                                                      |
|--------------|----------------------------------------------------------------------------------------------------------------------|
| $a_C(\dots)$ | Coalescence frequency or the fraction of particle pairs of two states that coalesce per unit time (1/s)              |
| $A_h$        | Heat exchange surface of reactor (m <sup>2</sup> )                                                                   |
| $A_I$        | Interface area (m <sup>2</sup> )                                                                                     |
| $A_i$        | Prefactor in the Arrhenius- or Van't Hoff equations                                                                  |
| $a_I$        | Interfacial area density denoting the interface area per unit volume (m <sup>2</sup> /m <sup>3</sup> )               |
| $a_i$        | RHS of transport equation for weights in DQMOM                                                                       |
| $a_i$        | Coefficient in generic algebraic equation in TDMA outline                                                            |
| $a_i$        | Components of the diagonal of the Jacobi matrix in PD algorithm                                                      |
| $a_i$        | Constants in MWR truncated series expansion approximation of the solution function                                   |
| $a_j$        | Recurrence coefficient for the family of Jacobi polynomials                                                          |
| $a_n$        | Mie coefficient                                                                                                      |
| $A_P$        | Projected area, average projected area of particle area distribution on a plane normal to the flow (m <sup>2</sup> ) |
| $A_r$        | Chemical affinity of reaction $r$ (kJ/kmol)                                                                          |
| $A_S$        | Particle surface, average surface calculated from a particle surface distribution (m <sup>2</sup> )                  |
| $a_{ij}$     | Coefficients in algebraic system matrix $\mathcal{A}$                                                                |
| $B$          | Baffle width (m)                                                                                                     |
| $B$          | Chemical component in general reaction                                                                               |
| $B$          | Coefficient consisting of inverted Maxwell–Stefan diffusivities (s/m <sup>2</sup> )                                  |
| $B$          | Displacement factor (–)                                                                                              |
| $B$          | Model parameter (–)                                                                                                  |
| $B$          | Model parameter in logarithmic velocity profile (–)                                                                  |
| $b$          | A function of geometrical arrangement of PDA (1/°)                                                                   |
| $b$          | Bubble zone or region                                                                                                |
| $b$          | Constant of integration in laminar boundary layer theory (–)                                                         |
| $b$          | Constant term in the FVM discretization equation                                                                     |
| $b$          | Impact parameter (m)                                                                                                 |
| $b$          | Non-linear function in PDE classification theory                                                                     |
| $b$          | Parameter in linear growth velocity model                                                                            |
| $b$          | Stoichiometric coefficients in general reaction (–)                                                                  |
| $B(\dots)$   | Net birth term in population balance equation                                                                        |
| $B_0$        | Permeability (m <sup>2</sup> )                                                                                       |
| $b_B(\dots)$ | Particle breakup frequency (s <sup>–1</sup> )                                                                        |
| $B_i$        | Factor in the Arrhenius- or Van't Hoff equations                                                                     |
| $b_i$        | RHS of transport equation for weighted abscissas in DQMOM                                                            |

|                   |                                                                                                             |
|-------------------|-------------------------------------------------------------------------------------------------------------|
| $b_i$             | Coefficient in generic algebraic equation in TDMA outline                                                   |
| $b_i$             | Components of the diagonal of the Jacobi matrix in PD algorithm                                             |
| $b_j$             | Recurrence coefficient for the family of Jacobi polynomials                                                 |
| $b_n$             | Mie coefficient                                                                                             |
| $B_{B,i}$         | Birth rate due to breakup in bubble class $i$ ( $\frac{1}{\text{sm}^3}$ )                                   |
| $B_{C,i}$         | Birth rate due to coalescence in bubble class $i$ ( $\frac{1}{\text{sm}^3}$ )                               |
| $B_{dd}(x)$       | Kolmogorov second order velocity structure function ( $\text{m}^2/\text{s}^2$ )                             |
| $C$               | Capacitance matrix                                                                                          |
| $C$               | Chemical component in general reaction                                                                      |
| $C$               | Clearance of turbulent impeller from the tank bottom (m)                                                    |
| $C$               | Constant in velocity structure function formula,<br>$C = \frac{27}{55} \Gamma(\frac{1}{3}) C_k \approx 2.0$ |
| $C$               | Laminar impeller wall clearance (m)                                                                         |
| $C$               | Model parameter (—)                                                                                         |
| $C$               | Shorthand notation-notation for convective term                                                             |
| $C$               | Universal constant in the Kolmogorov two-third-law (—)                                                      |
| $c$               | Mole concentration of species ( $\text{mol}/\text{m}^3$ )                                                   |
| $c$               | Non-linear function in PDE classification theory                                                            |
| $c$               | Parameter in relation for the modulus of elasticity of the particulate phase (—)                            |
| $c$               | Particle speed in kinetic theory (m/s)                                                                      |
| $c$               | Speed of electromagnetic radiation propagation in a medium (m/s)                                            |
| $c$               | Stoichiometric coefficients in general reaction (—)                                                         |
| $c^*$             | Mole concentration scale in turbulent boundary layer theory (—)                                             |
| $c^+$             | Dimensionless mole concentration in turbulent boundary layer theory (—)                                     |
| $C_L^M$           | Magnus lift force coefficient (—)                                                                           |
| $C_L^S$           | Saffman lift force coefficient (—)                                                                          |
| $C_L^T$           | Slanted wake transversal lift force coefficient (—)                                                         |
| $C_0$             | Model coefficient (—)                                                                                       |
| $C_\mu$           | $k-\epsilon$ turbulence model parameter (—)                                                                 |
| $C_\omega$        | Empirical model constant (—)                                                                                |
| $C_b$             | Empirical parameter in two-phase $k-\epsilon$ turbulence model (—)                                          |
| $C_c$             | Molar concentration of species $c$ in mixture ( $\text{kmol}/\text{m}^3$ )                                  |
| $C_D$             | $k-\epsilon$ turbulence model parameter (—)                                                                 |
| $C_D$             | Drag coefficient (—)                                                                                        |
| $C_E$             | Empirical constant in LES model (—)                                                                         |
| $C_f(f_{v_{ij}})$ | Surface area increase coefficient (—)                                                                       |
| $C_f$             | Friction factor (—)                                                                                         |
| $c_i$             | Coefficient in generic algebraic equation in TDMA outline                                                   |

|                     |                                                                                                    |
|---------------------|----------------------------------------------------------------------------------------------------|
| $c_j$               | Recurrence coefficient for the family of Jacobi polynomials                                        |
| $C_K$               | Kinetic-energy velocity correction factor (—)                                                      |
| $C_k$               | Constant in the Kolmogorov five-third-law (—)                                                      |
| $C_L$               | Lift force (net) coefficient (—)                                                                   |
| $C_M$               | Momentum velocity correction factor (—)                                                            |
| $C_P$               | Specific heat at constant pressure (kJ/kg K)                                                       |
| $C_p$               | Laminar impeller off bottom clearance (m)                                                          |
| $C_p$               | Model parameter (—)                                                                                |
| $C_S$               | Smagorinsky constant (—)                                                                           |
| $C_S$               | Speed of sound (m/s)                                                                               |
| $C_V$               | Specific heat at constant volume (kJ/kg K)                                                         |
| $C_V$               | Virtual—or added mass force coefficient (—)                                                        |
| $c_0$               | Speed of light in the medium. In a vacuum<br>$c_0 = 2.998 \times 10^8$ (m/s)                       |
| $C_{\text{Diff}}$   | Model parameter (—)                                                                                |
| $C_{\varepsilon 3}$ | Model parameter (—)                                                                                |
| $C_{\varepsilon 1}$ | $k-\epsilon$ turbulence model parameter (—)                                                        |
| $C_{\varepsilon 2}$ | $k-\epsilon$ turbulence model parameter (—)                                                        |
| $C_{ij}$            | The electrical capacitance between two electrodes $i$ and $j$ is<br>given in Farads (F)            |
| $C_{W1}$            | Empirical wall lift force coefficient (—)                                                          |
| $C_{W2}$            | Empirical wall lift force coefficient (—)                                                          |
| $C_{wb}$            | Bubble wall friction force coefficient (—)                                                         |
| $Ca$                | Capillary number, $Ca = We/Re_P$ (—)                                                               |
| $D$                 | Auxiliary factor in multiphase fractional step method<br>implementation                            |
| $D$                 | Bubble deformation factor (—)                                                                      |
| $D$                 | Chemical component in general reaction                                                             |
| $D$                 | Diagonal similarity transformation in Golub–Welsch<br>algorithm                                    |
| $D$                 | Diameter (m)                                                                                       |
| $D$                 | Impeller diameter (m)                                                                              |
| $D$                 | Mass diffusion coefficient or diffusivity, binary<br>or multicomponent systems (m <sup>2</sup> /s) |
| $D$                 | Model parameter (—)                                                                                |
| $D$                 | Reactor diameter (m)                                                                               |
| $D$                 | Shorthand notation—notation for diffusive term                                                     |
| $d$                 | Inner diameter of CT system (m)                                                                    |
| $d$                 | Non-linear function in PDE classification theory                                                   |
| $d$                 | Particle diameter (m)                                                                              |
| $d$                 | Stoichiometric coefficients in general reaction (—)                                                |
| $d'$                | Diameter of daughter particle (m)                                                                  |
| $d''$               | Diameter of the smallest daughter particle (m)                                                     |

|                  |                                                                                                                             |
|------------------|-----------------------------------------------------------------------------------------------------------------------------|
| $D'_s$           | Effective mass based diffusion coefficient in the explicit expression for the Maxwell-Stefan flux ( $\text{m}^2/\text{s}$ ) |
| $D'_{sm}$        | Effective diffusion coefficient of species $s$ in Wilke mass flux ( $\text{m}^2/\text{s}$ )                                 |
| $D(\dots)$       | Net death term in population balance equation                                                                               |
| $d\hat{S}$       | Entropy of mixture (J/K)                                                                                                    |
| $D'_{gp}$        | Gas-particle turbulent dispersion coefficient ( $\text{m}^2/\text{s}$ )                                                     |
| $d_A$            | Surface average diameter (m)                                                                                                |
| $d_a$            | Major axis of an ellipsoidal bubble (m)                                                                                     |
| $d_b$            | Horizontal axis of a bubble (m)                                                                                             |
| $d_b$            | Minor axis of an ellipsoidal bubble (m)                                                                                     |
| $d_c$            | Critical bubble diameter (m)                                                                                                |
| $d_D$            | Drag diameter (m)                                                                                                           |
| $d_e$            | Equivalent bubble diameter (m)                                                                                              |
| $D_f$            | The distance between the fringes in LDA (nm)                                                                                |
| $D_h$            | Hydraulic diameter (m)                                                                                                      |
| $d_H$            | Maximum horizontal dimension of a deformable particle (m)                                                                   |
| $d_i$            | Coefficient in generic algebraic equation in TDMA outline                                                                   |
| $d_i$            | Diameter of particle in interval $i$ (m)                                                                                    |
| $d_p$            | Particle diameter in kinetic theory (m)                                                                                     |
| $d_p$            | The particle size (m)                                                                                                       |
| $d_r$            | Reactor diameter (m)                                                                                                        |
| $D_s$            | Effective diffusion coefficient for species $s$ in explicit Maxwell-Stefan flux expression ( $\text{m}^2/\text{s}$ )        |
| $d_S$            | Sauter mean diameter (m)                                                                                                    |
| $D_s^e$          | Effective diffusivity of species $s$ in explicit expression for the dusty gas model flux ( $\text{m}^2/\text{s}$ )          |
| $D_s^T$          | Multicomponent thermal diffusion coefficients (kg/ms)                                                                       |
| $d_t$            | Reactor tube diameter (m)                                                                                                   |
| $d_V$            | Maximum vertical dimension of a deformable particle (m)                                                                     |
| $d_V$            | Volume average or equivalent particle diameter (m)                                                                          |
| $d_{12}$         | Distance between the centers of two hard spheres at collision in kinetic theory (m)                                         |
| $d_{\text{eff}}$ | Effective bubble diameter (m)                                                                                               |
| $d_{\text{max}}$ | Maximum stable fluid particle (m)                                                                                           |
| $D_{B,i}$        | Death rate due to breakup in bubble class $i$ ( $\frac{1}{\text{s m}^3}$ )                                                  |
| $d_{b,i}$        | Bubble diameter measured in sample $i$ by PDA (m)                                                                           |
| $DC_i$           | Death rate due to coalescence in bubble class $i$ ( $\frac{1}{\text{s m}^3}$ )                                              |
| $d_{e,0}$        | Initial equivalent bubble diameter just above the distributor (m)                                                           |
| $d_{\text{max}}$ | Fixed maximum particle size (m)                                                                                             |
| $d_{\text{min}}$ | Fixed minimum particle size (m)                                                                                             |
| $D_{sm}$         | Wilke effective diffusion coefficient for species $s$ ( $\text{m}^2/\text{s}$ )                                             |

|                              |                                                                                                                                |
|------------------------------|--------------------------------------------------------------------------------------------------------------------------------|
| $D_{sr}$                     | Fick's law binary diffusivity for the species $s$ and $r$ mixture ( $\text{m}^2/\text{s}$ )                                    |
| $Da$                         | Damköhler number (—)                                                                                                           |
| $da$                         | Infinitesimal area on the sphere of influence denoting the face of the collision cylinder (in kinetic theory) ( $\text{m}^2$ ) |
| $da$                         | Infinitesimal surface element ( $\text{m}^2$ )                                                                                 |
| $Da_I$                       | Damköhler number, $Da_I = lr/u$ (—)                                                                                            |
| $dA_p$                       | Differential area used to define the radiation intensity, $dA_p = da \cos \theta$ ( $\text{m}^2$ )                             |
| $DEN$                        | Auxiliary parameter (denominator) in kinetic expression for steam reforming                                                    |
| $dl$                         | Element of arc length (m)                                                                                                      |
| $dl$                         | Height of collision cylinder (in kinetic theory) (m)                                                                           |
| $dl$                         | Length of collision cylinder in kinetic theory (m)                                                                             |
| $ds$                         | Arc length (m)                                                                                                                 |
| $dt$                         | Infinitesimal increment in time (s)                                                                                            |
| $dv$                         | Infinitesimal volume element ( $\text{m}^3$ )                                                                                  |
| $dV_{\text{cylinder}}$       | Volume of collision cylinders ( $\text{m}^3$ )                                                                                 |
| $dV_{\text{total}}$          | Total volume of collision cylinders in $d\mathbf{r} \text{ m}^3$                                                               |
| $dx$                         | Infinitesimal increment in $x$ -coordinate direction (m)                                                                       |
| $dy$                         | Infinitesimal increment in $y$ -coordinate direction (m)                                                                       |
| $dz$                         | Infinitesimal increment in $z$ -coordinate direction (m)                                                                       |
| $E$                          | Empirical wall law model parameter (—)                                                                                         |
| $E$                          | Energy of each photon (J)                                                                                                      |
| $E$                          | Heat flux emitted by a real surface ( $\text{W}/\text{m}^2$ )                                                                  |
| $E$                          | The photon energy (J)                                                                                                          |
| $E$                          | Total emissive power of thermal radiation ( $\text{W}/\text{m}^2$ )                                                            |
| $e$                          | Non-linear function in PDE classification theory                                                                               |
| $e$                          | Restitution coefficient in kinetic theory (—)                                                                                  |
| $e$                          | Thermal internal energy per unit mass of mixture ( $\text{kJ}/\text{kg}$ )                                                     |
| $e(\lambda)$                 | Kinetic energy of eddy with size $\lambda$ (J)                                                                                 |
| $e(d_i, \lambda)$            | Turbulent kinetic energy of an individual eddy of size $\lambda$ breaking a bubble of size $d_i$ (J)                           |
| $E(k, t)$                    | Three dimensional energy spectrum per unit mass ( $\text{m}^3/\text{s}^2$ )                                                    |
| $E(t)$                       | Contact time distribution function in penetration theory ( $\text{s}^{-1}$ )                                                   |
| $E(t)$                       | Normalized element age distribution function in surface renewal theory ( $\text{s}^{-1}$ )                                     |
| $E_k^\Gamma$                 | Interfacial energy transfer due to phase change ( $\text{J}/\text{m}^3\text{s}$ )                                              |
| $E_k^E$                      | Interfacial heat transfer ( $\text{J}/\text{m}^3\text{s}$ )                                                                    |
| $E_k^W$                      | Interfacial work by viscous and pressure forces ( $\text{J}/\text{m}^3\text{s}$ )                                              |
| $E_\lambda(\lambda)$         | Spectral emissive power of thermal radiation ( $\text{W}/\text{m}^2 \mu\text{m}$ )                                             |
| $E_{\text{eddies}}(\lambda)$ | Energy of discrete eddies of size $\lambda$ ( $\frac{\text{J}}{\text{m}^3[\text{m}]}$ )                                        |

|                               |                                                                                                                                                         |
|-------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------|
| $E_{\text{spectra}}(\lambda)$ | Energy of eddy wave function for eddies of size between $\lambda$ and $\lambda + d\lambda \left( \frac{\text{J}}{\text{m}^3 [\text{m}]} \right)$        |
| $E_{\text{total}}$            | Total energy associated with the center of mass of a thermodynamic system (kJ)                                                                          |
| $E_{\text{total}}$            | Total energy content within an arbitrary volume $V$ in the system (kJ)                                                                                  |
| $E_a$                         | Activation energy of sorbent (J/kmol)                                                                                                                   |
| $E_b$                         | Total thermal radiative power emitted by a blackbody ( $\text{W}/\text{m}^2$ )                                                                          |
| $E_c(k)$                      | Scalar spectrum in wave number space                                                                                                                    |
| $E_i$                         | Activation energy for reaction $i$                                                                                                                      |
| $E_i$                         | Internal energy associated with the center of mass of a thermodynamic system (kJ)                                                                       |
| $E_k$                         | Kinetic energy associated with the center of mass of a thermodynamic system (kJ)                                                                        |
| $E_p$                         | Potential energy associated with the center of mass of a thermodynamic system (kJ)                                                                      |
| $E_p$                         | Scalar potential energy function or potential (kJ)                                                                                                      |
| $E_p(\dot{q}, t)$             | Generalized potential energy of a given system in Lagrangian mechanics                                                                                  |
| $E_s(d)$                      | Minimum energy required to deform a bubble of size $d$ (J)                                                                                              |
| $e_s(d_i, d_j)$               | Increase of bubble surface energy required breaking the parent bubble $d_i$ into a daughter bubble $d_j$ and a second corresponding daughter bubble (J) |
| $E_T$                         | Total kinetic energy of the macroscopic fluid motion (J)                                                                                                |
| $E_{\lambda, b}$              | Spectral thermal radiative power emitted by a blackbody ( $\text{W}/\text{m}^2 \mu\text{m}$ )                                                           |
| $E_{\text{Total}}$            | Total energy of two colliding particles (kJ)                                                                                                            |
| $E_{k, \text{fluid}}$         | Kinetic energy (KE) of fluid surrounding a particle in virtual mass force analysis (J)                                                                  |
| $E_a$                         | Activation energy of reaction (J/kmol)                                                                                                                  |
| $E_o$                         | Eötvös number (—)                                                                                                                                       |
| $f(t, \mathbf{x})$            | Longitudinal autocorrelation function (—)                                                                                                               |
| $F$                           | Dimensionless drag coefficient (—)                                                                                                                      |
| $F$                           | Mass flux component in FVM discretization                                                                                                               |
| $F$                           | Net flux of property $\psi$ in elementary kinetic theory                                                                                                |
| $F$                           | The phase factor used in PDA ( $^\circ/\text{m}$ )                                                                                                      |
| $f$                           | Continuous number density probability in least squares method outline                                                                                   |
| $f$                           | Dimensionless constant in turbulent viscosity model (—)                                                                                                 |
| $f$                           | Friction factor (—)                                                                                                                                     |
| $f$                           | Non-linear function in PDE classification theory                                                                                                        |
| $f$                           | Surface force component (N)                                                                                                                             |

|                                                                  |                                                                                                                                            |
|------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------|
| $f$                                                              | Wave frequency associated with Taylor hypothesis (radians/s)                                                                               |
| $f(\dots)$                                                       | Distribution function in Hamiltonian mechanics                                                                                             |
| $f(\dots)$                                                       | Single distribution function in kinetic theory                                                                                             |
| $f(\mathbf{x})$                                                  | Quadratic function in CG definition                                                                                                        |
| $f(\zeta, \eta)$                                                 | Function defining a curve on a given surface, expressed in the curvilinear coordinates                                                     |
| $f(m, \mathbf{r}, t)$                                            | Particle distribution function with particle mass as inner coordinate $\left(\frac{1}{\text{m}^3 [\text{kg}]}\right)$                      |
| $f(t, \mathbf{r})$                                               | General scalar, vector or tensor valued function                                                                                           |
| $F(x, y)$                                                        | Explicit function defining a surface in 3D space, expressed in Cartesian coordinates                                                       |
| $f(x, y, z)$                                                     | Implicit function defining a surface in 3D space, expressed in Cartesian coordinates                                                       |
| $f^{(1)}(\mathbf{r}, \mathbf{c}, \mathbf{r}_1, \mathbf{c}_1, t)$ | Single distribution function in kinetic theory, $f \equiv f^{(1)}$                                                                         |
| $f^{(1)}(\mathbf{x}, \mathbf{r}, t)$                             | Single number distribution function denoting the number of particles per unit volume of the particle phase space at time $t$ (general)     |
| $f^{(1)}(d, \mathbf{r}, t)$                                      | Average single particle number density function using particle diameter as inner coordinate $\left(\frac{1}{[\text{m}] \text{m}^3}\right)$ |
| $f^{(1)}(d, t)$                                                  | Particle number density probability with $d$ as inner coordinate $\left(\frac{1}{\text{m}^3 [\text{m}]}\right)$                            |
| $f^{(2)}(\mathbf{r}, \mathbf{c}, \mathbf{r}_1, \mathbf{c}_1, t)$ | Pair distribution function in kinetic theory                                                                                               |
| $f_0$                                                            | Fixed frequency shift for one of the beams in dual beam LDA (1/s)                                                                          |
| $f_1$                                                            | Single distribution function for molecule of type 1 in kinetic theory                                                                      |
| $f_2$                                                            | Single distribution function for molecule of type 2 in kinetic theory                                                                      |
| $f_\lambda$                                                      | Number density of eddies of size between $\lambda$ and $\lambda + d\lambda \left(\frac{1}{\text{m}^3 \text{s} [\text{m}]}\right)$          |
| $f_b$                                                            | Area (volume) fraction of bed gas taken by bubble zone gas ( $\text{m}^2$ )                                                                |
| $f_e$                                                            | Area (volume) fraction of bed gas taken by emulsion zone gas ( $\text{m}^2$ )                                                              |
| $F_i$                                                            | Factor calculated from Arrhenius- or Van't Hoff equations                                                                                  |
| $f_i$                                                            | Incoming light frequency in Dual-beam LDA (1/s)                                                                                            |
| $f_i^0$                                                          | Fugacity of species $i$ in the mixture at the standard state (Pa)                                                                          |
| $f_k$                                                            | Auxiliary factor in PEA implementation                                                                                                     |
| $F_s$                                                            | Molar flow rate of species $s$ (mol/s)                                                                                                     |
| $f_s$                                                            | Scattering light frequency in Dual-beam LDA (1/s)                                                                                          |
| $f_w$                                                            | Bubble wake fraction (—)                                                                                                                   |

|                        |                                                                                                                                                            |
|------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $f_{D,\text{shifted}}$ | Shifted Doppler frequency of one of the beams in dual beam LDA (1/s)                                                                                       |
| $f_{d,m}$              | Length-based mass density function (kg/m <sup>3</sup> m)                                                                                                   |
| $f_D$                  | Darcy friction factor (–)                                                                                                                                  |
| $f_F$                  | Fanning friction factor (–)                                                                                                                                |
| $F_{in,\psi}$          | Total inflow of property $\psi$ into the calculation domain, used in convergence criterion                                                                 |
| $f_{sr}$               | Proportionality or friction coefficient (kg/m <sup>3</sup> s)                                                                                              |
| $f_{V_{ij}}$           | Breakage volume fraction, $f_{V_{ij}} = d_j^3/d_i^3$ (–)                                                                                                   |
| $ff$                   | Fouling factor (K m <sup>2</sup> /W)                                                                                                                       |
| $Fr$                   | Froude Number, $Fr = v^2/gL$ (–)                                                                                                                           |
| $g(t, \mathbf{x})$     | Transverse autocorrelation function (–)                                                                                                                    |
| $G$                    | Auxiliary factor in multiphase fractional step method implementation                                                                                       |
| $G$                    | Non-dimensional shear rate (–)                                                                                                                             |
| $G$                    | Specific Gibbs free energy expressed in terms of mole (kJ/kg)                                                                                              |
| $G$                    | Total irradiation of thermal radiation (W/m <sup>2</sup> )                                                                                                 |
| $g$                    | Acceleration of gravity (m/s <sup>2</sup> )                                                                                                                |
| $g$                    | Length of the relative velocity vector (m/s)                                                                                                               |
| $g$                    | Non-linear function in PDE classification theory                                                                                                           |
| $g$                    | Source function                                                                                                                                            |
| $g$                    | source term in least squares method outline                                                                                                                |
| $G_0$                  | Modulus of elasticity of the particulate phase (kg/m s <sup>2</sup> )                                                                                      |
| $g_0$                  | Constant initial value                                                                                                                                     |
| $g_0(r)$               | Radial distribution function, a configurational pair-correlation function in kinetic theory of solid particles (–)                                         |
| $G_\lambda(\lambda)$   | Spectral irradiation of thermal radiation (W/m <sup>2</sup> μm)                                                                                            |
| $g_l$                  | Interface Gibbs free energy per unit mass (J/kg)                                                                                                           |
| $g_i$                  | Auxiliary variable in PBE solution using finite volume sectional method                                                                                    |
| $g_k$                  | Gibbs free energy per unit mass (J/kg)                                                                                                                     |
| $g_{0,ij}$             | Binary radial distribution functions for multiple particle mixture (–)                                                                                     |
| $g_{\alpha\beta}$      | Metric tensor                                                                                                                                              |
| $Gr$                   | Grashof number, $Gr = l^3 \Delta \rho g / \rho \nu^2$ (–)                                                                                                  |
| $H$                    | H-property function in the Boltzmann H-theorem                                                                                                             |
| $H$                    | Liquid height in standard turbulent stirred tank (m)                                                                                                       |
| $H$                    | Specific enthalpy, mixture enthalpy per unit mass expressed in terms of temperature, pressure and the mass fractions of the species in the mixture (kJ/kg) |
| $H$                    | Stagnation enthalpy (J/kg)                                                                                                                                 |
| $H$                    | Wall distance in square duct (m)                                                                                                                           |
| $h$                    | Plank's constant = $6.6262 \times 10^{-34}$ (J s)                                                                                                          |

|                                |                                                                                                                                                                                      |
|--------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $h$                            | Film thickness (m)                                                                                                                                                                   |
| $h$                            | Grid spacing (m)                                                                                                                                                                     |
| $h$                            | Grid spacing in multigrid method outline                                                                                                                                             |
| $h$                            | Head in head form of energy balance (m)                                                                                                                                              |
| $h$                            | Specific enthalpy, mixture enthalpy per unit mass expressed in terms of temperature, pressure and the mass fractions of the species in the mixture, a fluid dynamic quantity (kJ/kg) |
| $H(\psi)$                      | Heaviside function                                                                                                                                                                   |
| $H(\mathbf{p}, \mathbf{q}, t)$ | Hamiltonian function in Hamiltonian mechanics                                                                                                                                        |
| $h(Re_P)$                      | Dimensionless function in particle drag expression (—)                                                                                                                               |
| $h_k^\Gamma$                   | Interfacial heat transfer due to phase change (J/m <sup>3</sup> s)                                                                                                                   |
| $h^*$                          | Specific enthalpy of ideal gas mixture (kJ/kg)                                                                                                                                       |
| $h_k^{\text{cond,conv}}$       | Combined convective heat transfer coefficient accounting for conductive and convective heat transfer (W/m <sup>2</sup> K)                                                            |
| $h_k^{\text{cond}}$            | Convective heat transfer coefficient accounting for conductive heat transfer (W/m <sup>2</sup> K)                                                                                    |
| $h^{\text{excess}}$            | Specific mixture excess enthalpy (kJ/kg)                                                                                                                                             |
| $h^{\text{excess}}$            | Specific residual enthalpy of mixture (kJ/kg)                                                                                                                                        |
| $h^{\text{idealmixture}}$      | Specific mixture enthalpy expressed in terms of enthalpies of pure real fluids (kJ/kg)                                                                                               |
| $H^{\text{mf}}$                | Height of fluidized bed at minimum fluidization state (m)                                                                                                                            |
| $h^{\text{rad}}$               | Heat transfer coefficient accounting for radiation transfer (W/m <sup>2</sup> K)                                                                                                     |
| $H_0$                          | Height of packed bed (m)                                                                                                                                                             |
| $h_0$                          | Initial film thickness (m)                                                                                                                                                           |
| $h_\alpha$                     | Lamé coefficients, metric coefficients, or scale factors                                                                                                                             |
| $H_B(\dots)$                   | Average breakage yield redistribution function $\left(\frac{1}{\text{m}^3(\mathbf{x})}\right)$                                                                                       |
| $h_C$                          | Effective swept volume rate (m <sup>3</sup> /s)                                                                                                                                      |
| $h_c$                          | Specific enthalpy associated with chemical species/component $c$ (kJ/kg)                                                                                                             |
| $h_f$                          | Final film thickness (m)                                                                                                                                                             |
| $h_f$                          | Wall film heat transfer coefficient (kW/(m <sup>2</sup> K))                                                                                                                          |
| $H_I$                          | Mean surface curvature (m <sup>-1</sup> )                                                                                                                                            |
| $h_I$                          | Interface enthalpy per unit mass (J/kg)                                                                                                                                              |
| $h_k$                          | Enthalpy per unit mass (J/kg)                                                                                                                                                        |
| $h_s$                          | Wall heat transfer coefficient for a known packet residence time (kW/(m <sup>2</sup> K))                                                                                             |
| $h_v$                          | Volumetric heat transfer coefficient (J m <sup>-3</sup> K <sup>-1</sup> )                                                                                                            |
| $h_w$                          | Overall wall heat transfer coefficient (kW/(m <sup>2</sup> K))                                                                                                                       |
| $h_{cd}$                       | Interfacial heat transfer coefficient (kW/(m <sup>2</sup> K))                                                                                                                        |
| $H_{GL}$                       | Suspension height (m)                                                                                                                                                                |
| $h_{gp}$                       | Gas to particle heat transfer coefficient (J m <sup>-2</sup> K <sup>-1</sup> )                                                                                                       |
| $I$                            | Global index associated with the collocation points                                                                                                                                  |

|                                        |                                                                                                               |
|----------------------------------------|---------------------------------------------------------------------------------------------------------------|
| $I$                                    | Identity matrix                                                                                               |
| $I$                                    | Integral                                                                                                      |
| $I$                                    | The electric current (A)                                                                                      |
| $I$                                    | The light intensity measured after penetrating a distance $z$ into the suspension in F-OPT ( $\text{W/m}^2$ ) |
| $I$                                    | The total scattered light intensity used in LD theory ( $\text{W/m}^2$ )                                      |
| $I$                                    | Time-average light intensity when radiating through a bubble mixture by LDA ( $\text{W/m}^2$ )                |
| $I$                                    | Time-average light intensity when radiating through bubble free liquid by LDA ( $\text{W/m}^2$ )              |
| $I$                                    | Turbulence intensity (—)                                                                                      |
| $i$                                    | Local index associated with the collocation points                                                            |
| $i$                                    | The complex index, $i = \sqrt{-1}$                                                                            |
| $I'$                                   | The intensity of pixel (i, j) in the first image in PIV theory ( $\text{W/m}^2$ )                             |
| $I''$                                  | The intensity of pixel (i + x, j + y) in the second image in PIV theory ( $\text{W/m}^2$ )                    |
| $I_0$                                  | The intensity of the incident light used in LD theory ( $\text{W/m}^2$ )                                      |
| $I_0$                                  | The light intensity emitting from the probe in F-OPT ( $\text{W/m}^2$ )                                       |
| $I_e$                                  | Total intensity of emitted thermal radiation ( $\text{W/m}^2$ )                                               |
| $I_i$                                  | Total intensity of incident thermal radiation ( $\text{W/m}^2$ )                                              |
| $I_i$                                  | Turbulence intensity measured by LDA (—)                                                                      |
| $I_Q$                                  | Global quadrature point index                                                                                 |
| $I_R$                                  | Relative turbulence intensity (—)                                                                             |
| $I_X$                                  | X-ray intensity measured in coulomb per unit mass (C/kg)                                                      |
| $i_z$                                  | Local collocation point index in $z$ -coordinate                                                              |
| $I_\gamma$                             | $\gamma$ -ray intensity measured in coulomb per unit mass (C/kg)                                              |
| $I_{\lambda,b}$                        | Spectral radiation intensity of blackbody emission ( $\text{W/m}^2 \text{ sr } \mu\text{m}$ )                 |
| $I_{\lambda,e}(\lambda, \theta, \phi)$ | Spectral intensity of emitted thermal radiation ( $\text{W/m}^2 \text{ sr } \mu\text{m}$ )                    |
| $I_{\lambda,i}(\lambda, \theta, \phi)$ | Spectral intensity of incident thermal radiation ( $\text{W/m}^2 \text{ sr } \mu\text{m}$ )                   |
| $I_{\text{ext}}$                       | The light extinction intensity in F-OPT ( $\text{W/m}^2$ )                                                    |
| $I_{\text{trans}}$                     | The transmitted light intensity in F-OPT ( $\text{W/m}^2$ )                                                   |
| $i_\xi$                                | Local collocation point index in $\xi$ -coordinate                                                            |
| $i_{q\xi}$                             | Local quadrature point index in $\xi$ -coordinate                                                             |
| $i_{q\zeta}$                           | Local quadrature point index in $\zeta$ -dimension                                                            |
| $i_{qz}$                               | Local quadrature point index in $z$ -coordinate                                                               |
| $J(ff)$                                | Approximate collision term in the Boltzmann equation as given by the Enskog expansion                         |
| $J$                                    | Jacobian determinant                                                                                          |
| $J$                                    | Global index associated with the polynomial order in the truncated series expansion of the solution           |
| $J$                                    | Symmetric tridiagonal matrix in Golub–Welsch algorithm                                                        |
| $J$                                    | Total radiosity of thermal radiation ( $\text{W/m}^2$ )                                                       |

|                      |                                                                                                                                     |
|----------------------|-------------------------------------------------------------------------------------------------------------------------------------|
| $j$                  | Local index associated with the polynomial order in the truncated series expansion of the solution                                  |
| $j$                  | The complex index, $j = \sqrt{-1}$                                                                                                  |
| $J_{k,s}^I$          | Interfacial species mass transfer due to phase change (kg/m <sup>3</sup> s)                                                         |
| $J_{k,s}^j$          | Interfacial species mass transfer due to ordinary diffusion (kg/m <sup>3</sup> s)                                                   |
| $J_j^{\alpha,\beta}$ | Jacobi polynomial of degree $j$                                                                                                     |
| $J_0$                | The Bessel function of the first kind of order zero                                                                                 |
| $J_1$                | The Bessel function of the first kind of order unity                                                                                |
| $J_\lambda(\lambda)$ | Spectral radiosity of thermal radiation (W/m <sup>2</sup> μm)                                                                       |
| $j_\xi$              | Local polynomial order index in truncated series expansion in $\xi$ -coordinate                                                     |
| $j_z$                | Local polynomial order index in truncated series expansion in $z$ -coordinate                                                       |
| $J_{i+1/2}$          | Auxiliary flux variable in PBE solution using finite volume sectional method                                                        |
| $K$                  | Equilibrium constant                                                                                                                |
| $K$                  | Generalized proportionality coefficient in the interfacial transfer flux relation                                                   |
| $K$                  | Model parameter (—)                                                                                                                 |
| $K$                  | Number of FEM elements that constitute a part of the domain                                                                         |
| $K$                  | Parameter in bubble size model for bubbling beds (—)                                                                                |
| $K$                  | Permeability constant in the Davidson–Harrison model characteristic of the particles and the fluidizing fluid (m <sup>3</sup> s/kg) |
| $K$                  | The gradient energy coefficient used in the phase field method                                                                      |
| $k$                  | An empirical parameter in F-OPT theory (—)                                                                                          |
| $k$                  | Constant in capture kinetics (1/s)                                                                                                  |
| $k$                  | Mean turbulent kinetic energy per unit mass (m <sup>2</sup> /s <sup>2</sup> )                                                       |
| $k$                  | Parameter in cyclone pressure drop relation (—)                                                                                     |
| $k$                  | Reaction rate constant                                                                                                              |
| $k$                  | The wave number (1/m)                                                                                                               |
| $k$                  | Thermal conductivity (kW/m K)                                                                                                       |
| $k$                  | Wave number (m <sup>-1</sup> )                                                                                                      |
| $K''$                | Model parameter (—)                                                                                                                 |
| $K'''$               | Model parameter (—)                                                                                                                 |
| $K(t - \tau)$        | Kernel function in history force expression (—)                                                                                     |
| $k^{\text{dilute}}$  | Conductivity parameter for the dilute limit in granular theory (kg/m s)                                                             |
| $k_p^{\text{kin}}$   | Kinetic thermal conductivities of the particle phase (W/m K)                                                                        |

|                     |                                                                                                      |
|---------------------|------------------------------------------------------------------------------------------------------|
| $k_c^{\text{stat}}$ | Thermal heat conductivity of gas phase in fluidized bed/<br>packed bed at static state (kW/m K)      |
| $k_d^{\text{stat}}$ | Thermal heat conductivity of dispersed phase in fluidized<br>bed/packed bed at static state (kW/m K) |
| $K_p^{\text{coll}}$ | Collisional diffusion coefficient ( $\text{m}^2/\text{s}$ )                                          |
| $K_p^t$             | Particle turbulent (or kinetic) diffusion coefficient ( $\text{m}^2/\text{s}$ )                      |
| $k_0$               | Wave number for the integral scale of turbulence ( $\text{m}^{-1}$ )                                 |
| $K_1$               | Empirical parameter in drag coefficient parameterization (—)                                         |
| $k_1$               | Reaction rate constant (1/s)                                                                         |
| $K_2$               | Empirical parameter in drag coefficient parameterization (—)                                         |
| $K_3$               | Empirical parameter in drag coefficient parameterization (—)                                         |
| $k_C$               | Cutoff wave number in LES ( $\text{m}^{-1}$ )                                                        |
| $k_d$               | Viscous Cutoff wave number in LES ( $\text{m}^{-1}$ )                                                |
| $k_d^m$             | Thermal conductivities of the particle phase (W/m K)                                                 |
| $K_G$               | Overall gas-side mass transfer coefficient (m/s)                                                     |
| $K_g$               | Empirical parameter in breakage kernel closure (—)                                                   |
| $K_i$               | Equilibrium constant for reaction $i$                                                                |
| $k_i$               | Reaction rate constant for reaction $i$                                                              |
| $K_L$               | Overall liquid-side mass transfer coefficient (m/s)                                                  |
| $k_p$               | Mass transfer coefficient associated with a pressure driving<br>force (m mole/J s)                   |
| $k_p$               | The imaginary part of the refractive index of the particle used<br>in LD theory (—)                  |
| $k_p$               | Turbulent kinetic energy analogue of the particulate<br>phase ( $\text{m}^2/\text{s}^2$ )            |
| $K_r$               | Overall rate coefficient ( $\text{kg}/\text{m}^3$ )                                                  |
| $k_{10}$            | Reaction rate constant (1/s)                                                                         |
| $k_{bc}$            | Bubble-cloud mass interchange coefficient ( $\text{m}^3/\text{m}^3 \text{ s}$ )                      |
| $k_{c,s}$           | Interfacial mass transfer coefficient (m/s)                                                          |
| $K_{eq}$            | Chemical reaction equilibrium constant                                                               |
| $k_{gp}$            | Gas-particle fluctuation covariance ( $\text{m}^2/\text{s}^2$ )                                      |
| $k_{gp}$            | Gas-particle fluctuation kinetic energy (covariance) ( $\text{m}^2/\text{s}^2$ )                     |
| $k_{mA}$            | Mass transfer coefficient m/s                                                                        |
| $k_{SGS,t}$         | Sub-grid scale kinetic energy per unit mass in LES ( $\text{m}^2/\text{s}$ )                         |
| $Kn$                | Knudsen number (—)                                                                                   |
| $L$                 | Height (m)                                                                                           |
| $L$                 | Length of reactor (m)                                                                                |
| $L$                 | Length scale of turbulence, or integral length scale of<br>turbulence (m)                            |
| $L$                 | Length scale, characteristic length (m)                                                              |
| $L$                 | The number of electrodes in EIT                                                                      |
| $L$                 | Mixing length (m)                                                                                    |
| $l$                 | The extinction distance in F-OPT (m)                                                                 |
| $l$                 | The path length through bubbly flow measured by LDA (m)                                              |

|                                      |                                                                                          |
|--------------------------------------|------------------------------------------------------------------------------------------|
| $l$                                  | Turbulence length scale (m)                                                              |
| $l$                                  | Upper horizontal boundary in laminar boundary momentum balance analysis (m)              |
| $L(\dot{\mathbf{q}}, \mathbf{q}, t)$ | Lagrangian function in Lagrangian mechanics                                              |
| $L_c$                                | Integral scale of scalar segregation (m)                                                 |
| $L_D$                                | Height of solids in downcomer (m)                                                        |
| $l_e$                                | Eddy size in the inertial subrange of the turbulence energy spectrum (m)                 |
| $l_I$                                | Line formed by the intersection of $A_I(t)$ with $A(t)$ (m)                              |
| $l_j$                                | Interfacial transport length for interface $j$ (m)                                       |
| $l_p$                                | Mean free path for particle in kinetic theory (m)                                        |
| $l_S$                                | Smagorinsky length scale (m)                                                             |
| $l_W$                                | Intersection of CV wall interface with the cross sectional plane (m)                     |
| $L_{\text{Total}}$                   | Total angular momentum of two colliding particles ( $\text{kg m}^2/\text{s}$ )           |
| $l_{k,s}$                            | Film thickness on the phase $k$ side of the interface (m)                                |
| $L_{mf}$                             | Height of the fixed bed at minimum fluidization conditions (m)                           |
| $l_{W,k}(t, z)$                      | Closed curve of phase $k$ in the cross section plane (m)                                 |
| $Le$                                 | Lewis number, $Le = \alpha/D$ (—)                                                        |
| $M$                                  | The images magnification factor used in PIV theory (—)                                   |
| $M$                                  | Total mass of mixture in CV (kg)                                                         |
| $M$                                  | Total mass of particulate system (kg)                                                    |
| $m$                                  | Empirical model parameter (—)                                                            |
| $m$                                  | Index indicating individual measurements in LDA                                          |
| $m$                                  | The complex refractive index of the particle used in LD theory (—)                       |
| $m_1$                                | Parameter in Davidson–Harrison two-zone model (—)                                        |
| $m_2$                                | Parameter in Davidson–Harrison two-zone model (—)                                        |
| $M_c$                                | Mass of species $c$ (kg)                                                                 |
| $m_c$                                | Mass of fluid enclosed in the volume of the particle in the pressure gradient force (kg) |
| $m_c$                                | Total mass associated with the center of mass of a binary particle system (kg)           |
| $M_I$                                | Net interface property term                                                              |
| $m_i$                                | Mass of one particle of type $i$ (kg)                                                    |
| $m_p$                                | Mass of a single particle (kg)                                                           |
| $m_V$                                | Virtual mass of a particle in virtual mass force analysis (kg)                           |
| $M_{sr}$                             | Molecular weight factor ( $\text{kg/kmol}$ )                                             |
| $m_{c,ij}$                           | Sum of mass of particle type $i$ and $k$ (kg)                                            |
| $M_{in,mass}$                        | Total inflow of mass into the calculation domain, used in convergence criterion          |
| $M_{w_c}$                            | Molecular weight of species $c$ ( $\text{kg/kmol}$ )                                     |
| $Ma$                                 | Mach Number, $Ma = v/C_S$ (—)                                                            |

|            |                                                                                                       |
|------------|-------------------------------------------------------------------------------------------------------|
| $Mo$       | Morton number (—)                                                                                     |
| $MTKE$     | Mean turbulent kinetic energy per unit mass, coincides with the $k$ quantity ( $m^2/s^2$ )            |
| $N$        | Impeller stirring rate (RPM)                                                                          |
| $N$        | Number of experiments, or realizations                                                                |
| $N$        | Number of particles contained in a given system in classical mechanics                                |
| $N$        | The number of electrodes in ECT                                                                       |
| $N$        | Total number of sampled particles measured by LDA                                                     |
| $N$        | Total number of species in a mixture                                                                  |
| $n$        | Empirical model parameter (—)                                                                         |
| $n$        | Number density in kinetic theory (number of particles/ $m^3$ )                                        |
| $n$        | Number of basis functions used in MWR solution approximation function                                 |
| $n$        | Number of equations in matrix system, or number of unknowns in algebraic equation system              |
| $n$        | Number of moles (kmol)                                                                                |
| $n$        | The refractive index (—)                                                                              |
| $n_1$      | Model constant (—)                                                                                    |
| $n_1$      | Parameter in capture kinetics (—)                                                                     |
| $n_2$      | Model constant (—)                                                                                    |
| $n_2$      | Parameter in capture kinetics (—)                                                                     |
| $N_\xi$    | Total number of sections or cells used in sectional methods                                           |
| $N_a$      | Avogadro's number                                                                                     |
| $n_c$      | The refractive index of the continuous phase (—)                                                      |
| $n_i$      | Number density in $i$ -th section or cell in sectional methods                                        |
| $n_i$      | Number density of particles in size class $i$ ( $\frac{1}{m^3}$ )                                     |
| $N_P$      | Particle number density (Number/ $m^3$ )                                                              |
| $N_p$      | Newton number, $N_p = P/\rho N^3 D^5$ (—)                                                             |
| $N_Q$      | Pumping number (—)                                                                                    |
| $N_q$      | Order of the quadrature approximation in PD algorithm                                                 |
| $N_s$      | Moles of species $s$ (mol)                                                                            |
| $N_{12}$   | Binary collision density, number of collisions per unit time and volume ( $1/s\ m^3$ )                |
| $Nu$       | Nusselt number, $Nu = hl/k$ (—)                                                                       |
| $O$        | Origo, an arbitrary reference point in space                                                          |
| $P$        | Impeller power consumption (W)                                                                        |
| $P$        | Wave period associated with Taylor hypothesis (s)                                                     |
| $p$        | Laminar impeller pitch (m)                                                                            |
| $p$        | Pressure (Pa)                                                                                         |
| $p'_{k,l}$ | Temporal deviation between the instantaneous pressure and the interfacial mean pressure variable (Pa) |
| $p(\dots)$ | Advanced particle distribution function ( $\frac{1}{ \mathbf{x} (\mathbf{r})m}$ )                     |

|                                                     |                                                                                                                                                       |
|-----------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------|
| $p(\mu)$                                            | Probability density (—)                                                                                                                               |
| $p(\xi, \mathbf{r}, \mathbf{v}_\xi, \mathbf{c}, t)$ | Extended distribution function in kinetic theory                                                                                                      |
| $P(\mathbf{r}, \mathbf{c}, t)$                      | Normalized distribution function, or probability density function                                                                                     |
| $p^{\text{kin}}$                                    | Kinetic pressure in granular theory ( $\text{N/m}^2$ )                                                                                                |
| $p_C^B$                                             | Coalescence probability due to buoyancy processes (—)                                                                                                 |
| $p_C^T$                                             | Coalescence probability due to turbulence processes (—)                                                                                               |
| $p_i^{(1)}(\dots)$                                  | Advance particle distribution function with multiple inner coordinates                                                                                |

| $R_L(s)$                | Auto-covariance ( $\text{m}^2/\text{s}^2$ )                                                                                                |
| $R_n$                   | Radius of curvature at the nose of the gas bubble (m)                                                                                      |
| $R_r$                   | Reactor radius (m)                                                                                                                         |
| $r_r$                   | Rate of generation for reaction $r$ defined independent of species, proportional to the extent of reaction ( $\text{kmol/m}^3 \text{ s}$ ) |
| $R_s$                   | Dimensionless energy source due to mean force acting on particles in granular flow (—)                                                     |
| $r_s$                   | Mass rate of production of species $s$ due to homogeneous chemical reaction ( $\text{kg/m}^3 \text{ s}$ )                                  |
| $R_{\text{cap}}$        | Capture rate                                                                                                                               |
| $R_{\text{CO}_2}$       | $\text{CO}_2$ capture rate ( $\text{kg/kg s}$ )                                                                                            |
| $r_{AB}$                | Linear correlation coefficient (—)                                                                                                         |
| $r_{ij}$                | Equivalent bubble radius (m)                                                                                                               |
| $R_{ij}(t, \mathbf{x})$ | Two-point correlation tensor ( $\text{m}^2/\text{s}^2$ )                                                                                   |
| $R_{n_{k,s}}$           | Volumetric species mass transfer rate ( $\text{kg/m}^3 \text{ s}$ )                                                                        |
| $R_{Q_k}$               | Volumetric heat transfer rate ( $\text{W/m}^3$ )                                                                                           |
| $R_{Q_{l,\lambda}}$     | Volumetric heat transfer rate due to condensation/vaporization ( $\text{W/m}^3$ )                                                          |
| $Re$                    | Reynolds Number, $Re = \rho v L / \mu$ (—)                                                                                                 |

|                |                                                                                                                                |
|----------------|--------------------------------------------------------------------------------------------------------------------------------|
| $Re_\kappa$    | Shear Reynolds number (–)                                                                                                      |
| $Re_\Omega$    | Rotation Reynolds number (–)                                                                                                   |
| $S$            | Action integral in classical or Lagrangian mechanics                                                                           |
| $S$            | Imaginary surface in phase space enclosing $\Omega$ , used in classical mechanics                                              |
| $S$            | Sensitivity (projection) matrix                                                                                                |
| $S$            | Specific entropy of mixture (kJ/kg K)                                                                                          |
| $s$            | Average surface renewal rate (s <sup>–1</sup> )                                                                                |
| $s$            | Model parameter (–)                                                                                                            |
| $s$            | Specific entropy of mixture (kJ/kg K)                                                                                          |
| $s$            | Time variable used calculating the autocorrelation, $s = t' - t$ .                                                             |
|                | Time difference between the two time instants at which the values of the time dependent velocity fluctuations are measured (s) |
| $S_\psi$       | Generalized source term                                                                                                        |
| $s_A(\psi, g)$ | Scattering cross section expressed in terms of $\mathbf{k}$ (m <sup>2</sup> )                                                  |
| $S_I$          | Perimeter (m)                                                                                                                  |
| $s_I$          | Interface entropy per unit mass (J/kg K)                                                                                       |
| $S_k$          | Momentum source term of phase $k$ (kg/m <sup>2</sup> s <sup>2</sup> )                                                          |
| $s_k$          | Entropy per unit mass (J/kg K)                                                                                                 |
| $S_p$          | The average displacement of the tracer particles in PIV (m)                                                                    |
| $S_s$          | Molar source term of species $s$ (kmol/(m <sup>3</sup> s))                                                                     |
| $S''_s$        | Mass source term of species $s$ (kg/(m <sup>3</sup> s))                                                                        |
| $S_W$          | Perimeter of the wall (m)                                                                                                      |
| $S_{1,2}$      | The two complex functions used in LD theory (–)                                                                                |
| $S_{C,\psi}$   | Constant part of the linearized source term in FVM discretization                                                              |
| $S_{k_c}$      | Turbulent kinetic energy production due to the movement of particles (kg/(m s <sup>3</sup> ))                                  |
| $S_{P,\psi}$   | Constant part of the linearized source term in FVM discretization                                                              |
| $Sc$           | Schmidt Number, $Sc = \mu/\rho D$ (–)                                                                                          |
| $Sh$           | Sherwood number, $Sh = k_c l/D$ (–)                                                                                            |
| $St_h$         | Stanton number for heat, $St_h = h/(C_P \rho v_{z,av}) = \frac{Nu}{Re Pr}$ (–)                                                 |
| $St_m$         | Stanton number for mass, $St_m = k_c/v_{z,av}$ (–)                                                                             |
| $T$            | Transpose                                                                                                                      |
| $T$            | Diameter of standard turbulent stirred tank (m)                                                                                |
| $T$            | Temperature (K)                                                                                                                |
| $T$            | The time for a particle to cross one fringe in LDA (s)                                                                         |
| $T$            | The total sampling time of F-OPT measurement (s)                                                                               |
| $T$            | Time period of Doppler bursts in PDA, $T = 1/f_D$ (s)                                                                          |
| $T$            | Time period over which time averaging is performed (s)                                                                         |
| $T$            | Tridiagonal matrix in Golub–Welsch algorithm                                                                                   |
| $t$            | Time coordinate (s)                                                                                                            |

|                                   |                                                                                                                            |
|-----------------------------------|----------------------------------------------------------------------------------------------------------------------------|
| $T(\dot{\mathbf{q}}, \mathbf{q})$ | Generalized kinetic energy in Lagrangian mechanics                                                                         |
| $T^*$                             | Temperature scale in turbulent boundary layer theory (—)                                                                   |
| $T^+$                             | Dimensionless temperature in turbulent boundary layer theory (—)                                                           |
| $T_{\text{Shaft}}$                | Shaft torque (W)                                                                                                           |
| $t_b$                             | Bubble breakage time (s)                                                                                                   |
| $T_{0,m}$                         | The gas contact period of the central sensor 0 for FPECPT (s)                                                              |
| $t_{\text{max}}$                  | Time between the first contact and the time when the film area between two colliding bubbles reaches its maximum value (s) |
| $t_{\text{total}}$                | The total sampling time of the central sensor 0 for FPECPT (s)                                                             |
| $T_n$                             | The pulse duration time caused by the bubble of probe sensor $n$ for FPECPT (s)                                            |
| $t_n$                             | The response delay time of probe sensor number $n$ in FPECPT (s)                                                           |
| $te$                              | Contact time in surface renewal and penetration theories (s)                                                               |
| $U$                               | overall heat transfer coefficient ( $\text{J}/\text{m}^2\text{s K}$ )                                                      |
| $u$                               | Integration variable in PBE source on flux form                                                                            |
| $u_b$                             | Average rise velocity of bubbles in a freely bubbling bed (m/s)                                                            |
| $u_e$                             | Interstitial gas velocity in the emulsion zone (m/s)                                                                       |
| $u_{bl, \text{rise}}$             | Rise velocity of a single bubble in a liquid (m/s)                                                                         |
| $u_{br,0}$                        | Ideal rise velocity of a single bubble in fluidized bed (m/s)                                                              |
| $U_{mf}$                          | Superficial gas velocity at minimum fluidization ( $\text{m}^3 \text{ m}^{-2} \text{ s}^{-1}$ )                            |
| $V$                               | Arbitrary macroscopic control volume fixed in space ( $\text{m}^3$ )                                                       |
| $V$                               | Combined abstract volume $V = V_x + V_r$                                                                                   |
| $V$                               | Speed of fluid flow $V =  \mathbf{v} $ (m/s)                                                                               |
| $V$                               | Tank volume ( $\text{m}^3$ )                                                                                               |
| $V$                               | The voltage signal when $\alpha_p \neq 0$ in F-OPT (V)                                                                     |
| $V$                               | Volume over which volume averaging is performed ( $\text{m}^3$ )                                                           |
| $v$                               | Kolmogorov micro velocity scale (m/s)                                                                                      |
| $v$                               | Flow of gas through a bubble in bubbling bed (m/s)                                                                         |
| $v$                               | Integration variable in PBE source on flux form                                                                            |
| $v$                               | Perturbation function used in variational method deriving the least-squares method                                         |
| $v$                               | Represents all admissible functions in the space $X(\Omega)$ of admissible functions in least squares method outline       |
| $v$                               | Speed of flow (m/s)                                                                                                        |
| $v^+$                             | Dimensionless velocity (—)                                                                                                 |
| $v^S$                             | Superficial velocity in tubular reactor (m/s)                                                                              |
| $V_0$                             | The voltage signal when $\alpha_p = 0$ in F-OPT (V)                                                                        |

|                       |                                                                                                                   |
|-----------------------|-------------------------------------------------------------------------------------------------------------------|
| $V_1$                 | Volume region of phase 1 in two phase system ( $\text{m}^3$ )                                                     |
| $V_2$                 | Volume region of phase 2 in two phase system ( $\text{m}^3$ )                                                     |
| $v_\infty$            | Terminal velocity (m/s)                                                                                           |
| $v_*$                 | Friction velocity (m/s)                                                                                           |
| $v_{\text{breakage}}$ | Characteristic velocity of the bubble breakage process (m/s)                                                      |
| $v_{\text{rms}}$      | Root-mean-square of the fluctuating velocity components, rms-velocity (m/s)                                       |
| $V_b$                 | Bubble volume ( $\text{m}^3$ )                                                                                    |
| $V_b$                 | Volume of bubble zone ( $\text{m}^3$ )                                                                            |
| $V_c$                 | Volume of cloud zone ( $\text{m}^3$ )                                                                             |
| $v_c^{mf}$            | Minimum fluidization velocity (m/s)                                                                               |
| $v_d$                 | Particle growth velocity (m/s)                                                                                    |
| $V_i$                 | Volume of a particle in class, group or phase $i$ ( $\text{m}^3$ )                                                |
| $V_l$                 | The potentials on the electrode $l$ (V)                                                                           |
| $V_p$                 | Volume of a single particle, or average of particle volume distribution ( $\text{m}^3$ )                          |
| $V_r$                 | Volume in physical space                                                                                          |
| $V_r$                 | Volume of gas in bubbling bed ( $\text{m}^3$ )                                                                    |
| $v_t$                 | Impeller tip speed (m/s)                                                                                          |
| $V_w$                 | Bubble wake volume ( $\text{m}^3$ )                                                                               |
| $V_x$                 | Abstract volume in internal property space                                                                        |
| $v_{\text{equa}}$     | Equatorial speed parameter used in experimental data analysis (m/s)                                               |
| $v_{\text{slip}}$     | Fluid-particle velocity slip (m/s)                                                                                |
| $v_{b, a}$            | The absolute bubble velocity measured by FPECPT (m/s)                                                             |
| $V_{bs}$              | Volume of solids in bubble zone ( $\text{m}^3$ )                                                                  |
| $V_{cs}$              | Volume of solids in cloud zone ( $\text{m}^3$ )                                                                   |
| $V_{es}$              | Volume of solids in emulsion zone ( $\text{m}^3$ )                                                                |
| $V_{p,i}$             | Volume of particle in class $i$ ( $\text{m}^3$ )                                                                  |
| $v_{p, n}$            | The velocity component in the plane of the laser beams, and perpendicular to their bisector measured by LDA (m/s) |
| $v_{z, \text{max}}$   | Maximum velocity at the center of a pipe (m/s)                                                                    |
| $W$                   | Impeller blade width (m)                                                                                          |
| $W$                   | Quadrature weight function                                                                                        |
| $W$                   | Weighting function in MWR discretization                                                                          |
| $W_s$                 | Solid feeding rate (kg/s)                                                                                         |
| $We$                  | Weber number, $We = \rho v^2 L / \sigma$ (—)                                                                      |
| $X$                   | Fractional conversion of SE-SMR reaction (—)                                                                      |
| $x$                   | Coordinate in Cartesian coordinate system (m)                                                                     |
| $x$                   | Fractional conversion of capture reaction (—)                                                                     |
| $X(\Omega)$           | Space of admissible functions, used in least squares method outline                                               |
| $X(\Omega)$           | Trial solution space                                                                                              |
| $X_k$                 | Phase indicator function                                                                                          |

|                                          |                                                                                                                   |
|------------------------------------------|-------------------------------------------------------------------------------------------------------------------|
| $x_s$                                    | Mole fraction of species $s$ in gas or liquid mixture (—)                                                         |
| $X_u$                                    | Sorbent particle fractional conversion at fully adsorbed state (—)                                                |
| $x_{p,n}$                                | The horizontal distance between probe sensors 0 and $n$ in FPECPT arrangement (m)                                 |
| $y$                                      | Coordinate in Cartesian coordinate system (m)                                                                     |
| $y$                                      | Distance from wall (m)                                                                                            |
| $Y(\Omega)$                              | Space for the norms measuring the residual in $\Omega$                                                            |
| $y^+$                                    | Distance from a wall measured in viscous lengths, or Reynolds number (—)                                          |
| $y_0$                                    | Distance between the wall and the particle (m)                                                                    |
| $y_{p,n}$                                | The vertical distance between probe sensors 0 and $n$ in FPECPT arrangement (m)                                   |
| $Z$                                      | Reactor height (m)                                                                                                |
| $z$                                      | Axial coordinate in cylindrical coordinate system (m)                                                             |
| $z$                                      | Coordinate in Cartesian coordinate system (m)                                                                     |
| $z$                                      | Position above the distributor (m)                                                                                |
| $z$                                      | The penetration depth in F-OPT (m)                                                                                |
| $Z_i$                                    | Overall collisional frequency for particles of type $i$ (1/s)                                                     |
| $Z_{s-r}$                                | Collision frequency for one molecule of species type $s$ colliding with target molecules of type $r$ ( $s^{-1}$ ) |
| $Z_{sr}$                                 | Collision density, the number of collisions between pairs of molecules $s$ and $r$ ( $m^{-3} s^{-1}$ )            |
| $A$                                      | Model parameter (—)                                                                                               |
| $\dot{m}$                                | The particle mass flow rate (kg/s)                                                                                |
| $\langle \omega_k \rangle_{A_I}^T$       | Interfacial mass flux weighted species mass fraction (—)                                                          |
| $\langle B_{B,j}(\mathbf{r}, t) \rangle$ | The $j$ -th moment of the population balance birth term due to breakage                                           |
| $\langle B_{C,j}(\mathbf{r}, t) \rangle$ | The $j$ -th moment of the population balance birth term due to coalescence                                        |
| $\langle c \rangle$                      | Particle mean speed in kinetic theory (m/s)                                                                       |
| $\langle D_{B,j}(\mathbf{r}, t) \rangle$ | The $j$ -th moment of the population balance death term due to breakage                                           |
| $\langle D_{C,j}(\mathbf{r}, t) \rangle$ | The $j$ -th moment of the population balance death term due to coalescence                                        |
| $\langle h_k \rangle_{A_I}^T$            | Interfacial mass flux weighted heat transfer (J/kg)                                                               |
| $\langle H_s \rangle_{A_I}$              | Surface average modified Henry's law constant for species $s$ in the mixture (—)                                  |
| $\langle I \rangle$                      | The average image intensity used in PIV theory ( $W/m^2$ )                                                        |
| $\langle k_c \rangle_L$                  | Length average mass transfer coefficient (m/s)                                                                    |
| $\langle N_i \rangle_{te}$               | Average mass transfer rate in surface renewal and penetration theories ( $mol/m^2 s$ )                            |
| $\langle v_{n,k}^{rel} \rangle_{A_I}$    | Normal interface velocity due to phase change (m/s)                                                               |
| $A_{pv,i}$                               | The PDA probe volume cross-section for sample $i$ ( $m^2$ )                                                       |

|                                 |                                                                                                                                                |
|---------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------|
| B                               | Model parameter (—)                                                                                                                            |
| $\bar{l}$                       | The separating distance between the two probes in F-OPT (m)                                                                                    |
| $\bar{v}_i$                     | Mean of velocity component $i$ measured by LDA (m/s)                                                                                           |
| $\tilde{D}_{sr}$                | Non-symmetric multi-component Fickian diffusivity for the $s$ and $r$ pair of gases [27]: Chap. 2, Curtiss and Bird (1999) (m <sup>2</sup> /s) |
| $\tilde{G}_s$                   | Partial mass Gibbs free energy for species $s$ (kJ/kg)                                                                                         |
| $\tilde{H}_c$                   | Partial specific enthalpy of species $c$ in the mixture (kJ/kg)                                                                                |
| $\tilde{h}_c$                   | Partial specific enthalpy of species $c$ in the mixture, a fluid dynamic quantity (kJ/kg)                                                      |
| CFL                             | Courant number, used in the Courant–Friedrichs–Lewy necessary stability condition for hyperbolic equations                                     |
| covar ( $v_i, v_j$ )            | Covariance between the $i$ and $j$ velocity components measured by LDA (m <sup>2</sup> /s <sup>2</sup> )                                       |
| $\Delta s$                      | The volume average displacement of the particle images between the interrogation areas in the first and second images in PIV (m)               |
| $\Delta f$                      | The Doppler-shift of light waves in LDA (1/s)                                                                                                  |
| $\Delta t$                      | The time between two subsequent images in PIV (s)                                                                                              |
| $\Delta V_{ij}$                 | The electrical potential difference between two electrodes $i$ and $j$ (V)                                                                     |
| $\dot{m}$                       | Total mass flow rate (kg/s)                                                                                                                    |
| $\dot{m}_k$                     | Interface mass transfer rate (kg/m <sup>2</sup> s)                                                                                             |
| $\dot{m}_s$                     | Mass flow rate of species $s$ (kg/s)                                                                                                           |
| $\dot{Q}$                       | Rate of heat added to the control volume $V$ (kJ/s)                                                                                            |
| $\dot{Q}_k^{\text{cond, conv}}$ | Combined convective heat transfer rate due to conduction and convection (W)                                                                    |
| $\dot{Q}_k^{\text{cond}}$       | Convective heat transfer rate due to conduction (W)                                                                                            |
| $\dot{Q}^{\text{rad}}$          | Radiation heat transfer rate (W)                                                                                                               |
| $\dot{Q}_\lambda$               | Spectral radiant heat transfer rate (W/μm)                                                                                                     |
| $\dot{W}$                       | Rate of work done on the control volume $V$ (kJ/s)                                                                                             |
| $\frac{dm(t)}{dt}$              | Particle growth rate related to mass change by condensation, evaporation and dissolution (kg/s)                                                |
| $\diamond$                      | Gibbs free energy expressed in terms of mole (kJ)                                                                                              |
| $G$                             | Gibbs free energy expressed in terms of mole (kJ)                                                                                              |
| $dV_{\text{cylinder}}$          | Volume of single collision cylinder in kinetic theory (m <sup>3</sup> )                                                                        |
| E                               | Generalized total energy of a given system in classical mechanics                                                                              |
| $f_s$                           | Ratio of initial to current total sorbent particle mass (—)                                                                                    |
| H                               | Height of BFB reactor (m)                                                                                                                      |
| H                               | Height of dense fluidized bed (m)                                                                                                              |
| $\dot{D}_{sr}$                  | Non-symmetric multi-component Fickian diffusivity for the $s$ and $r$ pair of gases [105] (m <sup>2</sup> /s)                                  |
| $\hat{C}_{sk}$                  | Multicomponent inverse diffusivities (s/m <sup>2</sup> )                                                                                       |

|                            |                                                                                                                                                                                                                                                                                                                         |
|----------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $\hat{D}_{sr}$             | Symmetric multi-component Fickian diffusivity for the $s$ and $r$ pair of gases [26]: <a href="#">Chap. 2</a> , Curtiss (1968), [27]: <a href="#">Chap. 2</a> , Curtiss and Bird (1999) ( $\text{m}^2/\text{s}$ )                                                                                                       |
| $\hat{F}$                  | Helmholtz energy (J)                                                                                                                                                                                                                                                                                                    |
| $\hat{f}_i$                | Fugacity of species $i$ in the mixture (Pa)                                                                                                                                                                                                                                                                             |
| $\hat{G}$                  | Gibbs free energy (J)                                                                                                                                                                                                                                                                                                   |
| $\hat{G}$                  | Gibbs free energy expressed in terms of mass (kJ)                                                                                                                                                                                                                                                                       |
| $\hat{H}$                  | Total mixture enthalpy (or enthalpy) expressed in terms of temperature, pressure and the masses of the various species in the mixture (J); or enthalpy expressed in terms of temperature, pressure and the mole numbers of the various species in the mixture (kJ)                                                      |
| $\hat{h}$                  | Total mixture enthalpy (or enthalpy) expressed in terms of temperature, pressure and the masses of the various species in the mixture, a fluid dynamic quantity (kJ); or enthalpy expressed in terms of temperature, pressure and the mole numbers of the various species in the mixture, a fluid dynamic quantity (kJ) |
| $\hat{R}[x, y]$            | The spatial cross-correlation used in PIV theory                                                                                                                                                                                                                                                                        |
| $\hat{S}$                  | Heat source term ( $\text{kJ}/(\text{m}^3 \text{ s})$ )                                                                                                                                                                                                                                                                 |
| $\hat{T}$                  | Non-dimensional temperature (–)                                                                                                                                                                                                                                                                                         |
| $\hat{P}_B(\dots)$         | Daughter size distribution function ( $\frac{1}{ \mathbf{x} }$ )                                                                                                                                                                                                                                                        |
| $\hat{p}_{k,l}$            | Deviation between the local instantaneous pressure and the interfacial area averaged pressure (Pa)                                                                                                                                                                                                                      |
| $a_i$                      | Activity of species $i$ in the mixture (–)                                                                                                                                                                                                                                                                              |
| $f_i^{\text{pure}}$        | Fugacity of pure species $i$ (Pa)                                                                                                                                                                                                                                                                                       |
| $J$                        | Jacobian determinant                                                                                                                                                                                                                                                                                                    |
| $J(\mathbf{f})$            | Source term in <a href="#">(4.187)</a>                                                                                                                                                                                                                                                                                  |
| $k$                        | Boltzmann constant (J/K)                                                                                                                                                                                                                                                                                                |
| $\ell$                     | Lagrange polynomial                                                                                                                                                                                                                                                                                                     |
| $\tilde{D}_{sK}^e$         | Effective Knudsen diffusivity of species $s$ in porous medium ( $\text{m}^2/\text{s}$ )                                                                                                                                                                                                                                 |
| $\tilde{D}_{sr}^e$         | Effective bulk diffusivity of binary pair $s - r$ in porous medium ( $\text{m}^2/\text{s}$ )                                                                                                                                                                                                                            |
| $\tilde{D}_{sk}$           | Maxwell–Stefan diffusivities ( $\text{m}^2/\text{s}$ )                                                                                                                                                                                                                                                                  |
| $\tilde{\mathcal{C}}_{ij}$ | Residual stress tensor in LES (Pa)                                                                                                                                                                                                                                                                                      |
| $\tilde{L}_{ij}$           | Leonard stress tensor in LES (Pa)                                                                                                                                                                                                                                                                                       |
| $\tilde{R}_{ij}$           | Residual stress tensor in LES (Pa)                                                                                                                                                                                                                                                                                      |
| $\tilde{S}_{ij}$           | The large scale strain-rate tensor in LES ( $\text{m}^2/\text{s}$ )                                                                                                                                                                                                                                                     |
| $M$                        | Mass (kg)                                                                                                                                                                                                                                                                                                               |
| $\hat{Y}(\Gamma)$          | Space for the norms measuring the residual in $\Gamma$                                                                                                                                                                                                                                                                  |
| $\mathbb{D}_{sr}$          | Symmetric multi-component Fickian diffusivity for the $s$ and $r$ pair of gases [9]: <a href="#">Chap. 2</a> , Bird et al. (2002) ( $\text{m}^2/\text{s}$ )                                                                                                                                                             |
| $\mathcal{A}$              | System matrix                                                                                                                                                                                                                                                                                                           |

| $\mathcal{F}$                   | A non-linear operator                                                                                                                                                                                                                                |
| $\mathcal{I}$                   | Source term in generalized Boltzmann type of equation representing the effects of particle coalescence, breakage and collisions                                                                                                                      |
| $\mathcal{J}(f; g)$             | Norm equivalent functional in least squares method outline                                                                                                                                                                                           |
| $\mathcal{L}$                   | Lower triangular matrix                                                                                                                                                                                                                              |
| $\mathcal{L}_j$                 | Weighted abscissas used in DQMOM                                                                                                                                                                                                                     |
| $\mathcal{M}$                   | Preconditioner in Krylov subspace methods outline                                                                                                                                                                                                    |
| $\mathcal{P}$                   | Process                                                                                                                                                                                                                                              |
| $\mathcal{R}$                   | Space domain                                                                                                                                                                                                                                         |
| $\mathcal{S}(\xi, z)$           | Overall source term due to breakage and coalescence                                                                                                                                                                                                  |
| $\mathcal{U}$                   | Upper triangular matrix                                                                                                                                                                                                                              |
| $\tilde{\mathcal{J}}$           | Matrix in Golub–Welsch algorithm for which the eigensystem are the Gauss–Lobatto quadrature points and weights                                                                                                                                       |
| $P$                             | Product difference matrix of order $(2N_q+1)(2N_q+1)$ in PD algorithm                                                                                                                                                                                |
| $P_\xi$                         | Polynomial order in $\xi$ -coordinate                                                                                                                                                                                                                |
| $P_z$                           | Polynomial order in $z$ -coordinate                                                                                                                                                                                                                  |
| $Y(\Omega)$                     | Space for the norms measuring the residual in $\Omega$                                                                                                                                                                                               |
| $N$                             | Number of components/species in the mixture (—)                                                                                                                                                                                                      |
| $n_p$                           | The real part of the refractive index of the particle used in LD theory (—)                                                                                                                                                                          |
| $Nu$                            | Nusselt number (—)                                                                                                                                                                                                                                   |
|                                 | Mean turbulent kinetic energy of an eddy of size $\lambda$ breaking a bubble of size $d_i$ (J)                                                                                                                                                       |
| $\bar{G}_s$                     | Partial molar Gibbs free energy for species $s$ (kJ/kmol)                                                                                                                                                                                            |

|                              |                                                                                                                                                                    |
|------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $\bar{p}$                    | Mean pressure, defined as the mean value of the normal stresses across any three orthogonal planes (Pa)                                                            |
| $\bar{v}_\lambda$            | Average velocity of eddies of size $\lambda$ (m/s)                                                                                                                 |
| $\bar{v}_{\text{drops}}$     | Mean turbulent velocity of droplet (m/s)                                                                                                                           |
| $\bar{v}_c$                  | Continuous phase circulation velocity (m/s)                                                                                                                        |
| $\bar{v}_{r,d_i}$            | Average rise velocity of particle of size class $i$ (m/s)                                                                                                          |
| $\bar{v}_{rel,t,ij}$         | Length of relative velocity between a pair of unlike bubbles (m/s)                                                                                                 |
| $\bar{v}_{t,d}$              | Average speed of particles of size $d$ due to turbulence (m/s)                                                                                                     |
| $\bar{v}_{t,i}$              | Mean turbulent bubble velocity (m/s)                                                                                                                               |
| $\frac{dv_c}{dr}$            | Average shear rate for the continuous phase (1/s)                                                                                                                  |
| $d$                          | Diameter of complementary daughter particle (m)                                                                                                                    |
| $Pr$                         | Prandtl number (—)                                                                                                                                                 |
| $R$                          | Universal gas constant (kJ/kmol K)                                                                                                                                 |
| $\tilde{P}'_g$               | Fluctuation pressure component of the undisturbed flow (Pa)                                                                                                        |
| $\tilde{P}_g$                | Local instantaneous pressure of the undisturbed flow (Pa)                                                                                                          |
| $\underline{\underline{CC}}$ | Symmetrical, traceless and non-divergent tensor in Enskog expansion                                                                                                |
| $\sigma_c^{\text{Re}}$       | Reynolds stress tensor (kg/(m s <sup>2</sup> ))                                                                                                                    |
| $A$                          | Turbulence anisotropy tensor in extended $k - \epsilon$ model (—)                                                                                                  |
| $B$                          | Tensor function in Enskog expansion                                                                                                                                |
| $e$                          | Unit tensor with components $e_{ij}$                                                                                                                               |
| $e_I$                        | Unit interface tensor                                                                                                                                              |
| $p$                          | Pressure tensor (Pa)                                                                                                                                               |
| $p^{\text{coll}}$            | Collisional pressure tensor (Pa)                                                                                                                                   |
| $p^{\text{kin}}$             | Kinetic pressure tensor (Pa)                                                                                                                                       |
| $p_d$                        | Total granular dispersed phase pressure tensor in kinetic theory (Pa)                                                                                              |
| $S$                          | Rate of shear tensor in kinetic theory (1/s)                                                                                                                       |
| $T$                          | The capillary tensor used in the phase field method (PF)                                                                                                           |
| $\mathbf{T}$                 | Total stress tensor (Pa); $\mathbf{T} = p\mathbf{e} + \boldsymbol{\sigma}$                                                                                         |
| $\tilde{\mathbf{T}}_g$       | Total stress tensor of the undisturbed flow (Pa)                                                                                                                   |
| $t_p$                        | The time average bubble contact time measured by F-OPT (s)                                                                                                         |
| $g_{\alpha\beta}$            | Local metric tensor                                                                                                                                                |
| $K_{\alpha\beta}$            | Curvature tensor (m <sup>-1</sup> )                                                                                                                                |
| $\underline{G}$              | Specific molar Gibbs free energy expressed in terms of mole (kJ/kmol)                                                                                              |
| $\underline{H}$              | Specific molar enthalpy, mixture enthalpy per unit mole expressed in terms of temperature, pressure and the mole fractions of the species in the mixture (kJ/kmol) |

|                                          |                                                                                                                                                                                              |
|------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $\underline{h}$                          | Specific molar enthalpy, mixture enthalpy per unit mole expressed in terms of temperature, pressure and the mole fractions of the species in the mixture, a fluid dynamic quantity (kJ/kmol) |
| $V$                                      | Volume (m <sup>3</sup> )                                                                                                                                                                     |
| $\bar{\mathbf{F}}_I$                     | Interfacial coupling term in two-phase $k - \epsilon$ turbulence model (N/m <sup>3</sup> )                                                                                                   |
| $\hat{\mathbf{n}}$                       | Discretized form of number density vector in sectional methods                                                                                                                               |
| $\langle \mathbf{n}_{k,s} \rangle_{A_I}$ | Surface average combined species mass transfer flux (kg/m <sup>2</sup> s)                                                                                                                    |
| $\langle \mathbf{v} \rangle_{N_i}$       | Number average velocity representative for particle size class $i$ (m/s)                                                                                                                     |
| $\mathbf{P}(\mathbf{p}, \mathbf{q}, t)$  | A set of generalized momenta in Hamiltonian mechanics                                                                                                                                        |
| $\mathbf{Q}(\mathbf{p}, \mathbf{q}, t)$  | A set of generalized coordinates in Hamiltonian mechanics                                                                                                                                    |
| $\dot{\mathbf{q}}$                       | Generalized velocities in Lagrangian Mechanics                                                                                                                                               |
| $\mathcal{C}$                            | Vector function in Enskog expansion                                                                                                                                                          |
| $\mathbf{A}$                             | Vector function in Enskog expansion                                                                                                                                                          |
| $\mathbf{a}$                             | Acceleration of a single particle (m/s <sup>2</sup> )                                                                                                                                        |
| $\mathbf{a}_\xi$                         | Generalized acceleration vector in property space                                                                                                                                            |
| $\mathbf{B}$                             | General vector or tensor valued function                                                                                                                                                     |
| $\mathbf{b}$                             | Constant vector in algebraic equation system                                                                                                                                                 |
| $\mathbf{b}$                             | Element-abundance vector (mole)                                                                                                                                                              |
| $\mathbf{C}$                             | Capacitance vector                                                                                                                                                                           |
| $\mathbf{C}$                             | Peculiar velocity (m/s)                                                                                                                                                                      |
| $\mathbf{c}$                             | Velocity of a single molecule or particle (m/s)                                                                                                                                              |
| $\mathbf{c}$                             | Velocity of light (m/s)                                                                                                                                                                      |
| $\mathbf{D}$                             | The electric displacement field measured in coulombs per square metres (C/m <sup>2</sup> )                                                                                                   |
| $\mathbf{d}$                             | Generalized diffusional driving force (m <sup>-1</sup> )                                                                                                                                     |
| $\mathbf{d}$                             | Source term of linear system in DQMOM                                                                                                                                                        |
| $\mathbf{E}$                             | The electric field strength vector measured in volt per metre (V/m)                                                                                                                          |
| $\mathbf{e}$                             | Error vector in multigrid method outline                                                                                                                                                     |
| $\mathbf{e}$                             | Unit vector with components $e_i$ in the $i$ ( $i = 1, 2, 3$ ) directions                                                                                                                    |
| $\mathbf{e}_i$                           | Unit vector in the direction of incoming light in LDA                                                                                                                                        |
| $\mathbf{e}_s$                           | Unit vector in the direction of scattered light in LDA                                                                                                                                       |
| $\mathbf{F}$                             | Linear algebraic system source vector used in WRM                                                                                                                                            |
| $\mathbf{F}$                             | Net force acting on a single particle (N)                                                                                                                                                    |
| $\mathbf{f}$                             | Solution vector used in WRM                                                                                                                                                                  |
| $\mathbf{f}$                             | Sum of forces acting on the mixture in the control volume (N)                                                                                                                                |
| $\mathbf{F}_{L,d}^W$                     | Wall lift force acting on a collection of dispersed particles per unit mixture volume (N/m <sup>3</sup> )                                                                                    |
| $\mathbf{F}_I$                           | Surface force per unit area (N/m <sup>2</sup> )                                                                                                                                              |

|                                 |                                                                                                                                          |
|---------------------------------|------------------------------------------------------------------------------------------------------------------------------------------|
| $\mathbf{F}_k$                  | Generalized drag force per unit mixture volume ( $\text{N/m}^3$ )                                                                        |
| $\mathbf{F}_L$                  | Lift force acting on a collection of particles per unit mixture volume ( $\text{N/m}^3$ )                                                |
| $\mathbf{F}_P$                  | Net force acting on a collection of particles per unit mixture volume ( $\text{N/m}^3$ )                                                 |
| $\mathbf{f}_S$                  | Total hydrodynamic surface force exerted by a fluid on a particle (N)                                                                    |
| $\mathbf{F}_V$                  | Virtual mass force acting on a collection of particles per unit mixture volume ( $\text{N/m}^3$ )                                        |
| $\mathbf{f}_W$                  | Net wall interaction force acting on a single particle (N)                                                                               |
| $\mathbf{f}_{Buo}$              | Buoyancy force on a single particle (N)                                                                                                  |
| $\mathbf{f}_B$                  | Basset history force acting on a single particle (N)                                                                                     |
| $\mathbf{f}_D$                  | Steady drag force acting on a single particle (N)                                                                                        |
| $\mathbf{f}_E$                  | Body forces (except gravity) acting on a single particle (N)                                                                             |
| $\mathbf{f}_G$                  | Body force due to gravity acting on a single particle (N)                                                                                |
| $\mathbf{f}_{hp}$               | Hydrostatic pressure force acting on a single particle (N)                                                                               |
| $\mathbf{F}_{ij}$               | Total binary particle–particle drag force between the two particle types ( $\text{N/m}^3$ )                                              |
| $\mathbf{F}_{ij}^{\text{flu}}$  | Binary particle–particle drag force derived from the fluid dynamic velocity difference between the two particle types ( $\text{N/m}^3$ ) |
| $\mathbf{F}_{ij}^{\text{fric}}$ | Empirical binary particle–particle frictional drag force between the two particle types ( $\text{N/m}^3$ )                               |
| $\mathbf{F}_{ij}^{\text{pec}}$  | Binary particle–particle drag force derived from the peculiar velocity difference between the two particle types ( $\text{N/m}^3$ )      |
| $\mathbf{F}_{L,V}$              | Combined lift-virtual mass force acting on a collection of particles per unit mixture volume ( $\text{N/m}^3$ )                          |
| $\mathbf{f}_L$                  | Lift force acting on a single particle (N)                                                                                               |
| $\mathbf{f}_{pg}$               | Pressure gradient force acting on a single particle (N)                                                                                  |
| $\mathbf{f}_p$                  | Force due to external pressure gradient acting on a single particle (N)                                                                  |
| $\mathbf{F}_{TD}$               | Turbulent dispersion force per unit volume ( $\text{N/m}^3$ )                                                                            |
| $\mathbf{f}_V$                  | Virtual- or added mass force acting on a single particle (N)                                                                             |
| $\mathbf{G}$                    | Image vector                                                                                                                             |
| $\mathbf{G}$                    | Velocity of the center of mass expressed in the laboratory frame (m/s)                                                                   |
| $\mathbf{g}$                    | External force per unit mass, or gravity force per unit mass ( $\text{m/s}^2$ )                                                          |
| $\mathbf{g}$                    | Relative particle velocity (m/s)                                                                                                         |
| $\mathbf{g}_\alpha$             | Tangent basis vectors in orthogonal coordinate systems                                                                                   |
| $\mathbf{G}_c$                  | Velocity of the center of mass expressed in the center of mass frame (m/s)                                                               |
| $\mathbf{H}$                    | Angular momentum vector for a system ( $\text{kg m}^2/\text{s}$ )                                                                        |

|                                  |                                                                                                                                             |
|----------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------|
| <b>H</b>                         | The magnetic field strength vector measured in amperes per metre (A/m)                                                                      |
| <b>h</b>                         | Angular momentum vector for a particle ( $\text{kg m}^2/\text{s}$ )                                                                         |
| <b>I</b>                         | Incident particle number flux or intensity in kinetic theory ( $1/\text{m}^2 \text{ s}$ )                                                   |
| <b>I<sub>k</sub></b>             | Generalized interfacial transfer flux                                                                                                       |
| <b>J</b>                         | Local instantaneous diffusive flux of the generalized quantity $\psi$                                                                       |
| <b>J</b>                         | The electric current density vector measured in ampere per square metre ( $\text{A}/\text{m}^2$ )                                           |
| <b>J<sub>s</sub><sup>*</sup></b> | Instantaneous diffusive molar flux of species $s$ in mixture ( $\text{kmol}/\text{m}^2 \text{ s}$ )                                         |
| <b>j<sub>m</sub></b>             | Volumetric flux of the mixture ( $\text{m}^3/\text{m}^2 \text{ s}$ )                                                                        |
| <b>J<sub>S</sub></b>             | Molecular entropy flux ( $\text{kJ}/\text{m}^2 \text{ s K}$ )                                                                               |
| <b>j<sub>s</sub></b>             | Instantaneous diffusive mass flux of species $s$ in mixture ( $\text{kg}/\text{m}^2 \text{ s}$ )                                            |
| <b>J<sub>12</sub></b>            | Impulse of the force exerted by particle 1 on particle 2 ( $\text{kg m/s}$ )                                                                |
| <b>j<sub>c</sub><sup>g</sup></b> | Multi-component mass diffusion flux due to external force ( $\text{kg}/\text{m}^2 \text{ s}$ )                                              |
| <b>j<sub>c</sub><sup>o</sup></b> | Ordinary multi-component mass diffusion flux ( $\text{kg}/\text{m}^2 \text{ s}$ )                                                           |
| <b>j<sub>c</sub><sup>p</sup></b> | Pressure gradient induced multi-component mass diffusion flux ( $\text{kg}/\text{m}^2 \text{ s}$ )                                          |
| <b>j<sub>c</sub><sup>T</sup></b> | Temperature gradient induced multi-component mass diffusion flux ( $\text{kg}/\text{m}^2 \text{ s}$ )                                       |
| <b>J<sub>Vd</sub></b>            | Volumetric flux of the dispersed phase relative to the velocity of the volume centre of the mixture ( $\text{m}^3/\text{m}^2 \text{ s}$ )   |
| <b>k</b>                         | Unit vector of the apse-line                                                                                                                |
| <b>M<sub>k</sub><sup>r</sup></b> | Interfacial momentum transfer due to phase change ( $\text{N}/\text{m}^3$ )                                                                 |
| <b>M<sub>k</sub><sup>T</sup></b> | Interfacial momentum transfer caused by stresses ( $\text{N}/\text{m}^3$ )                                                                  |
| <b>m<sub>c</sub></b>             | Instantaneous mass flux of molecules of species of type $c$ with respect to stationary coordinate axes ( $\text{kg}/\text{m}^2 \text{ s}$ ) |
| <b>M<sub>I</sub><sup>σ</sup></b> | Net surface tension force term ( $\text{N}/\text{m}^2$ )                                                                                    |
| <b>M<sub>k</sub></b>             | Interfacial momentum transfer to phase $k$                                                                                                  |
| <b>M<sub>k,l</sub></b>           | Interfacial momentum exchange between phases $k$ and $l$ ( $\text{kg}/\text{m}^2 \text{ s}^2$ )                                             |
| <b>M<sub>sr</sub></b>            | Momentum transferred from species $r$ to $s$ per collision ( $\text{kg m/s}$ , collision)                                                   |
| <b>n</b>                         | Number density vector in sectional methods                                                                                                  |
| <b>n</b>                         | Outwardly directed unit normal vector                                                                                                       |
| <b>n</b>                         | Species-abundance vector (mole)                                                                                                             |
| <b>n<sup>in</sup></b>            | Initial condition for number density vector in sectional methods                                                                            |

|                              |                                                                                                                            |
|------------------------------|----------------------------------------------------------------------------------------------------------------------------|
| $\mathbf{N}_I$               | Unit vector normal to $l_I(t)$ that is both tangent to and outwardly directed with respect to $A_I(t)$                     |
| $\mathbf{N}_s$               | Combined molar flux of species $s$ in gas or liquid mixture ( $\text{kmol/m}^2 \text{ s}$ )                                |
| $\mathbf{n}_s$               | Combined mass flux of species $s$ in gas or liquid mixture ( $\text{kg/m}^2 \text{ s}$ )                                   |
| $\mathbf{P}$                 | Momentum associated with a macroscopic CV ( $\text{kg m/s}$ )                                                              |
| $\mathbf{p}$                 | Generalized momenta in Hamiltonian mechanics                                                                               |
| $\mathbf{p}_m$               | Search direction in $m$ -th iteration in Krylov subspace methods outline                                                   |
| $\mathbf{P}_{sr}$            | Diffusive force per unit volume exerted by species $r$ on species $s$ ( $\text{N/m}^3$ )                                   |
| $\mathbf{q}$                 | Generalized coordinates in Lagrangian and Hamiltonian mechanics                                                            |
| $\mathbf{q}$                 | Heat flux vector ( $\text{kW/m}^2$ )                                                                                       |
| $\mathbf{q}^{\text{rad}}$    | Total radiant energy flux arriving at a surface element ( $\text{W/m}^2$ )                                                 |
| $\mathbf{q}^{\text{coll}}$   | Collisional granular heat flux ( $\text{kg/s}^3$ )                                                                         |
| $\mathbf{q}^{\text{kin}}$    | Kinetic granular heat flux ( $\text{kg/s}^3$ )                                                                             |
| $\mathbf{q}^c$               | Ordinary conductive heat flux, defined by Fourier's law ( $\text{kW/m}^2$ )                                                |
| $\mathbf{q}^d$               | Energy flux resulting from inter-diffusion of the chemical species ( $\text{kW/m}^2$ )                                     |
| $\mathbf{q}^o$               | Dufour energy flux resulting from a temperature gradient induced by mass diffusion of chemical species ( $\text{kW/m}^2$ ) |
| $\mathbf{q}^r$               | Radiative heat flux ( $\text{kW/m}^2$ )                                                                                    |
| $\mathbf{q}_d$               | Total granular heat flux in kinetic theory ( $\text{kg/s}^3$ )                                                             |
| $\mathbf{q}_I$               | Interface heat flux per unit length ( $\text{J/m}$ )                                                                       |
| $\mathbf{q}_V$               | Volumetric radiant energy flux ( $\text{W/m}^3$ )                                                                          |
| $\mathbf{q}_{A_s}$           | Radiant surface energy flux ( $\text{W/m}^3$ )                                                                             |
| $\mathbf{r}$                 | Position vector, locating a point in space ( $\text{m}$ )                                                                  |
| $\mathbf{r}$                 | Residual vector                                                                                                            |
| $\mathbf{r}_c$               | Position vector denoting the location of the center of mass ( $\text{m}$ )                                                 |
| $\mathbf{r}_i$               | Particle coordinates in Newtonian Mechanics ( $\text{m}$ )                                                                 |
| $\mathbf{r}_p$               | Particle position vector, locating the center of mass ( $\text{m}$ )                                                       |
| $\mathbf{T}$                 | Total torque applied to fluid mass in control volume ( $\text{Nm}$ )                                                       |
| $\mathbf{t}$                 | Torque on a single sphere ( $\text{Nm}$ )                                                                                  |
| $\mathbf{t}$                 | Unit tangent vector                                                                                                        |
| $\mathbf{t}^{(k)}$           | Tangent surface vector                                                                                                     |
| $\mathbf{t}_s$               | The unit tangent vector at a point on a streamline in the flow direction                                                   |
| $\mathbf{T}_{\text{Thrust}}$ | Propulsive force developed by a jet-propeller motor ( $\text{N}$ )                                                         |
| $\mathbf{u}$                 | Control volume surface velocity arising from the motion of the moving grid ( $\text{m/s}$ )                                |

|                              |                                                                                                                              |
|------------------------------|------------------------------------------------------------------------------------------------------------------------------|
| <b>u</b>                     | Generalized velocity in classical mechanics                                                                                  |
| <b>u</b>                     | Velocity of the control surface with respect to the coordinate reference frame (m/s)                                         |
| <b>v</b>                     | Local instantaneous mixture velocity, mass average velocity (m/s)                                                            |
| <b>v</b>                     | The average particle velocity in the interrogation area in PIV (m/s)                                                         |
| $\mathbf{v}_{d,s}'$          | Modified mass diffusion velocity for species $s$ (m/s)                                                                       |
| $\mathbf{v}_s^*$             | Species velocity of molecules of species $s$ generated by chemical reaction (m/s)                                            |
| $\mathbf{v}_{\text{drift}}$  | Fluid particle drift velocity (m/s)                                                                                          |
| $\mathbf{v}_c$               | Instantaneous number mean velocity of molecules of species type $c$ with respect to stationary coordinate axes (m/s)         |
| $\mathbf{v}_l$               | Interface velocity (m/s)                                                                                                     |
| $\mathbf{v}_i$               | Mass average velocity of particle class $i$ (m/s)                                                                            |
| $\mathbf{v}_i$               | Surface average velocity of particle class $i$ (m/s)                                                                         |
| $\mathbf{v}_j$               | $j$ -th eigenvector in PD algorithm                                                                                          |
| $\mathbf{v}_p$               | Particle velocity (m/s)                                                                                                      |
| $\mathbf{v}_p$               | The average particle velocity at the point of measurement in F-OPT (m/s)                                                     |
| $\mathbf{v}_r$               | External coordinate velocity (m/s)                                                                                           |
| $\mathbf{v}_r^{(i)}$         | $r$ -th moment average velocity in SQMOM                                                                                     |
| $\mathbf{v}_x$               | Internal coordinate velocity                                                                                                 |
| $\mathbf{v}_{\text{drift}}$  | Particle drift velocity (m/s)                                                                                                |
| $\mathbf{v}_{\text{slip},d}$ | Slip velocity for dispersed phase $d$ (relative to the continuous phase $c$ ) (m/s)                                          |
| $\mathbf{v}_\xi$             | Generalized velocity vector in property space                                                                                |
| $\mathbf{v}_{b,i}$           | Bubble velocity vector in sample $i$ measured by PDA (m)                                                                     |
| $\mathbf{v}_{c,d}$           | Instantaneous diffusion velocity for species $c$ , relative to the local motion of the mixture stream (m/s)                  |
| $\mathbf{v}_{i,d_i}$         | Size average velocity of particle class $i$ (m/s)                                                                            |
| $\mathbf{v}_{i,n_i}$         | Number average velocity of particle class $i$ (m/s)                                                                          |
| $\mathbf{v}_{i,V_i}$         | Volume average velocity of particle class $i$ (m/s)                                                                          |
| $\mathbf{v}_{Mk}$            | Diffusion velocity of phase $k$ , the velocity of phase $k$ relative to the velocity of the mass center of the mixture (m/s) |
| $\mathbf{v}_{\text{rel}}$    | Relative velocity between particles or phases (m/s)                                                                          |
| $\mathbf{v}_{rk}$            | Relative velocity between dispersed phase $k$ and continuous phase $c$ (m/s)                                                 |
| $\mathbf{v}_{Vk}$            | Drift velocity of phase $k$ , the velocity of phase $k$ relative to the velocity of the volume center of the mixture (m/s)   |
| <b>w</b>                     | Velocity of the fluid at the control surface with respect to the control surface (m/s)                                       |
| <b>x</b>                     | Internal property vector                                                                                                     |

|                                    |                                                                                                         |
|------------------------------------|---------------------------------------------------------------------------------------------------------|
| $\mathbf{x}$                       | Position vector defining the separation of two points in space (m)                                      |
| $\mathbf{x}$                       | Three coordinates in an arbitrary coordinate system fixed in space                                      |
| $\mathbf{x}$                       | True solution of matrix system: $\mathcal{A}\mathbf{x} = \mathbf{b}$                                    |
| $\mathbf{x}$                       | Vector of unknowns in algebraic equation system                                                         |
| $\mathbf{x}^\nu$                   | Intermediate solution of matrix system: $\mathcal{A}\mathbf{x}^\nu = \mathbf{b}$ after $\nu$ iterations |
| $\mathbf{x}^{\text{improved},\nu}$ | Corrected or improved solution in multigrid method outline                                              |
| $\mathbf{x}_m$                     | Approximate solution in $m$ -th iteration in Krylov subspace methods outline                            |
| $\mathbf{Y}$                       | Vector representing the continuous phase variables                                                      |
| $v_m$                              | Rate of change of particle mass in (4.187)                                                              |
| $v_T$                              | Rate of change of thermal temperature in (4.187)                                                        |
| $v_{br,j}$                         | The local time average bubble velocity measured by F-OPT (m/s)                                          |
| $d\mathbf{c}$                      | An infinitesimal element in a hypothetical velocity space containing the velocity $\mathbf{c}$          |
| $d\mathbf{k}$                      | Infinitesimal solid angle centered around the apse-line (steradians, sr)                                |
| $d\mathbf{r}$                      | An infinitesimal spatial space containing the point $\mathbf{r}$                                        |
| $J$                                | Jacobian                                                                                                |
| $r$                                | Parameter in (E.6)                                                                                      |

|             |                                                                                  |
|-------------|----------------------------------------------------------------------------------|
| $\alpha(T)$ | Total, hemispherical absorptivity of a surface (—)                               |
| $\alpha$    | A size parameter used in LD theory (—)                                           |
| $\alpha$    | Absorptivity, $\alpha = G_{\text{abs}}/G$ (—)                                    |
| $\alpha$    | Basis coefficients in truncated series expansion of the solution                 |
| $\alpha$    | Isothermal compressibility ( $Pa^{-1}$ )                                         |
| $\alpha$    | Parameter in definition of the family of Jacobi polynomials                      |
| $\alpha$    | Ratio of CO <sub>2</sub> -acceptor to catalyst mass                              |
| $\alpha$    | Relaxation parameter in Gauss–Seidel method                                      |
| $\alpha$    | Thermal diffusivity of conducting medium ( $m^2/s$ )                             |
| $\alpha^*$  | Parameter in relation for the modulus of elasticity of the particulate phase (—) |
| $\alpha_g$  | Time average void fraction of gas bubbles deduced from PDA measurements (—)      |
| $\alpha_i$  | Components of the continued fraction vector in PD algorithm                      |
| $\alpha_k$  | Instantaneous volume fraction of phase $k$ (—)                                   |
| $\alpha_m$  | Auxiliary factor at iteration $m$ in Krylov subspace methods outline             |

|                                                     |                                                                                                                                                                                                  |
|-----------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $\alpha_P$                                          | Relaxation factor in FVM discretization                                                                                                                                                          |
| $\alpha_{\lambda,\theta}(\lambda, \theta, \phi, T)$ | Spectral, directional absorptivity of a surface (–)                                                                                                                                              |
| $\alpha_\lambda(\lambda, T)$                        | Spectral, hemispherical absorptivity of a surface (–)                                                                                                                                            |
| $\alpha_{sr}$                                       | Onsager phenomenological coefficients (kg s /m <sup>3</sup> )                                                                                                                                    |
| $\bar{\rho}_d$                                      | Local bulk density in granular theory                                                                                                                                                            |
| $\beta$                                             | Bulk expansion coefficient (K <sup>–1</sup> )                                                                                                                                                    |
| $\beta$                                             | Constant in time-splitting method                                                                                                                                                                |
| $\beta$                                             | Empirical parameter ( $\beta \approx 2.0$ ) in the Kuboi mean square droplet velocity relation (–)                                                                                               |
| $\beta$                                             | Interfacial friction coefficient                                                                                                                                                                 |
| $\beta$                                             | Parameter in definition of the family of Jacobi polynomials                                                                                                                                      |
| $\beta$                                             | The local time average bubble fraction measured by F-OPT (–)                                                                                                                                     |
| $\beta_g$                                           | The gas time fraction measured by FPECPT (–)                                                                                                                                                     |
| $\beta_k$                                           | Time fraction (–)                                                                                                                                                                                |
| $\beta_m$                                           | Auxiliary factor at iteration $m$ in Krylov subspace methods outline                                                                                                                             |
| $\chi$                                              | Enskog free volume correction function                                                                                                                                                           |
| $\chi$                                              | Energy ratio, $\chi = \frac{e(d_i, \lambda)}{\bar{e}(d_i, \lambda)}$ (–)                                                                                                                         |
| $\chi$                                              | Variable in simplified PD algorithm solution in SQMOM                                                                                                                                            |
| $\chi(r)$                                           | Enskog's volume correction function in kinetic theory of dense gases (–)                                                                                                                         |
| $\Delta \bar{h}_{lg,s}^{\text{vap}}$                | Latent heat of vaporization of pure species $s$ in the multicomponent mixture (J/mol)                                                                                                            |
| $\Delta \Phi$                                       | The phase difference (shift) between a pair of Doppler burst signals in the PDA optical arrangement (°)                                                                                          |
| $\Delta E$                                          | Translational energy change during an inelastic collision (kg m <sup>2</sup> /s <sup>2</sup> )                                                                                                   |
| $\Delta E$                                          | Translational kinetic energy change during binary particle collision in kinetic theory (J)                                                                                                       |
| $\Delta h_{lg,\text{mix}}^{\text{vap}}$             | Latent heat of vaporization of the multicomponent mixture (J/kg)                                                                                                                                 |
| $\Delta L$                                          | Bubbling bed expansion (m)                                                                                                                                                                       |
| $\Delta p_C$                                        | Pressure drop through cyclone (Pa)                                                                                                                                                               |

| $\Gamma$                                              | Boundary                                                                                                                                                                                      |
| $\Gamma$                                              | Mean flux of molecules in elementary kinetic theory (number/m <sup>2</sup> s)                                                                                                                 |
| $\Gamma$                                              | Phase space symbol in classical mechanics                                                                                                                                                     |
| $\gamma$                                              | Energy dissipation rate term in the granular temperature equation (kg/m s <sup>3</sup> )                                                                                                      |
| $\gamma$                                              | Particle volume fraction (—)                                                                                                                                                                  |
| $\gamma$                                              | The electrical admittivity given in siemens per metre (S/m)                                                                                                                                   |

|                          |                                                                                                                                               |
|--------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------|
| $\Gamma(z)$              | Gamma function, a special function in advanced mathematics defined by means of an improper integral                                           |
| $\gamma_b$               | Volume fraction of solids in bubble zone with respect to the bubble volume (—)                                                                |
| $\gamma_c$               | Composition expansion coefficient associated with species $c$ (—)                                                                             |
| $\gamma_c$               | Volume fraction of solids in cloud zone with respect to the bubble volume (—)                                                                 |
| $\gamma_e$               | Volume fraction of solids in emulsion zone with respect to the bubble volume (—)                                                              |
| $\Gamma_i$               | The electrode $i$ surface ( $\text{m}^2$ )                                                                                                    |
| $\gamma_i$               | Activity coefficient for species $i$                                                                                                          |
| $\gamma_i$               | Element values of symmetric tridiagonal matrix $J$ in Golub–Welsch algorithm                                                                  |
| $\Gamma_k$               | Average interface mass transfer rate from phase $k$ due to phase change ( $\text{kg}/\text{m}^3 \text{ s}$ )                                  |
| $\gamma_k$               | Average occurrence of phase $k$ (—)                                                                                                           |
| $\Gamma_L$               | Lagrangian integral time scale (s)                                                                                                            |
| $\Gamma_\psi$            | General diffusion coefficient in FVM discretization                                                                                           |
| $\kappa$                 | Curvature ( $\text{m}^{-1}$ )                                                                                                                 |
| $\kappa$                 | Magnitude of fluid shear (1/s)                                                                                                                |
| $\kappa$                 | The extinction coefficient in F-OPT (—)                                                                                                       |
| $\kappa$                 | von Kàrmàn constant (—)                                                                                                                       |
| $\kappa$                 | Wavenumber associated with Taylor hypothesis (radians/m)                                                                                      |
| $\kappa_C()$             | Effective coalescence swept volume ( $\text{m}^3/\text{s}$ )                                                                                  |
| $\kappa_d$               | Total dispersed phase heat conductivity ( $\text{kW}/\text{m K}$ )                                                                            |
| $\kappa_d^{\text{coll}}$ | Collisional granular heat fluid conductivity ( $\text{kW}/\text{m K}$ )                                                                       |
| $\kappa_d^{\text{kin}}$  | Kinetic granular heat fluid conductivity ( $\text{kW}/\text{m K}$ )                                                                           |
| $A$                      | Quadrature weight matrix                                                                                                                      |
| $A$                      | Coefficient in the Zehner and Schlünder model for the convective heat transfer (—)                                                            |
| $A$                      | Model parameter (—)                                                                                                                           |
| $A$                      | Particle size ratio in bubble breakage kernel closure, $A = d_c/d$ (—)                                                                        |
| $\lambda$                | Dimensionless constant in bubble size model (—)                                                                                               |
| $\lambda$                | Distance between two points in the flow where the second order velocity structure function is depends on $\lambda$ and $\varepsilon$ only (m) |
| $\lambda$                | Eddy size ([m])                                                                                                                               |
| $\lambda$                | Laser light wavelength for LDA (nm)                                                                                                           |
| $\lambda$                | Length of electromagnetic radiation wave in a medium (m)                                                                                      |
| $\lambda$                | The wavelength (m)                                                                                                                            |
| $\lambda$                | Wavelength associated with Taylor hypothesis (m)                                                                                              |

|                                                 |                                                                                                                                           |
|-------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------|
| $\lambda_d$                                     | Slip parameter for wall boundary condition in granular theory (m)                                                                         |
| $\lambda_f(t)$                                  | Eulerian longitudinal integral length scale (m)<br>Eulerian longitudinal Taylor micro length scale, or longitudinal Taylor microscale (m) |
| $A_g(t)$                                        | Eulerian transverse integral length scale (m)                                                                                             |
| $\lambda_g(t)$                                  | Eulerian transverse Taylor micro length scale, or transverse Taylor microscale (m)                                                        |
| $A_i$                                           | $i$ -th section or cell in sectional methods                                                                                              |
| $\Delta_i$                                      | Particle size interval, section or class (m)                                                                                              |
| $\lambda_j$                                     | An eigenvalue of the tridiagonal matrix $T$ in Golub–Welsch algorithm                                                                     |
| $\langle \varepsilon_G \rangle_{\text{global}}$ | Effective global specific energy dissipation rate ( $\text{m}^2 \text{s}^{-3}$ )                                                          |
| $\mu$                                           | Mixture dynamic viscosity, or first viscosity coefficient ( $\text{kg/m s}$ )                                                             |
| $\mu$                                           | Particular realization of the process                                                                                                     |
| $\mu$                                           | Reduced mass (kg)                                                                                                                         |
| $\mu$                                           | Specific realization involved in ensemble averaging                                                                                       |
| $\mu$                                           | The linear absorption coefficient ( $1/\text{m}$ )                                                                                        |
| $\mu$                                           | The magnetic permeability given in henrys per metre (H/m)                                                                                 |
| $\mu_p^{\text{crit}}$                           | Critical state frictional viscosity for particle phase ( $\text{kg/m s}$ )                                                                |
| $\mu_p^{\text{fric}}$                           | Frictional viscosity for particle phase ( $\text{kg/m s}$ )                                                                               |
| $\mu_{\text{dilute}}$                           | Viscosity parameter for the dilute limit in granular theory ( $\text{kg/m s}$ )                                                           |
| $\mu_B$                                         | Mixture bulk viscosity, dilatational or second viscosity coefficient ( $\text{kg/m s}$ )                                                  |
| $\mu_c$                                         | Specific chemical potential of species $c$ (kJ/kg)                                                                                        |
| $\mu_j$                                         | $j$ -th moment of the number density function                                                                                             |
| $\mu_j$                                         | $j$ -th moment of the population density function                                                                                         |
| $\mu_j$                                         | Parameter in Golub–Welsch algorithm                                                                                                       |
| $\mu_j(r, t)$                                   | The $j$ -th moment of the population density function                                                                                     |
| $\mu_n$                                         | $n$ -th moment                                                                                                                            |
| $\mu_s$                                         | Partial mass Gibbs free energy for species $s$ (kJ/kg)                                                                                    |
| $\mu_t$                                         | Dynamic turbulent viscosity, or eddy viscosity ( $\text{kg/m s}$ )                                                                        |
| $\mu_{B,d}$                                     | Bulk viscosity parameter in granular theory ( $\text{kg/m s}$ )                                                                           |
| $\nu$                                           | Frequency of electromagnetic radiation wave ( $\text{s}^{-1}$ )                                                                           |
| $\nu$                                           | Mixture kinematic viscosity ( $\text{m}^2/\text{s}$ )                                                                                     |
| $\nu(\dots)$                                    | Average number of particles formed in the breakup processes (–)                                                                           |
| $\nu_{gp}^t$                                    | Gas-particle turbulent viscosity ( $\text{m}^2/\text{s}$ )                                                                                |
| $\nu_p^{\text{coll}}$                           | Collisional viscosity of particule phase ( $\text{m}^2/\text{s}$ )                                                                        |
| $\nu_p^t$                                       | Turbulent (or kinetic) viscosity of particule phase ( $\text{m}^2/\text{s}$ )                                                             |
| $\nu_{c,r}$                                     | Stoichiometric coefficient for element $c$ in reaction $r$ , negative for reactants, positive for products (–)                            |

|                                      |                                                                                                                                                |
|--------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------|
| $\nu_{SGS,t}$                        | Sub-grid kinematic viscosity in LES ( $\text{m}^2/\text{s}$ )                                                                                  |
| $\Omega(\psi)$                       | Net source term denoting the loss of the property $\psi$ caused by inelastic collisions                                                        |
| $\Omega$                             | Calculation domain                                                                                                                             |
| $\Omega$                             | Continuous size domain $\Omega = [0, \xi_{\max}]$ in sectional methods                                                                         |
| $\Omega$                             | Imaginary arbitrary volume in phase space, used in classical mechanics                                                                         |
| $\Omega$                             | Rotational speed, $\Omega =  \mathbf{\Omega} $ ( $\text{s}^{-1}$ )                                                                             |
| $\omega$                             | Angle between the velocity $\mathbf{C}$ and the normal vector $\mathbf{n}$ in collision cylinder analysis                                      |
| $\omega$                             | Angular velocity ( $\text{rad/s}$ )                                                                                                            |
| $\omega$                             | Interpolation formula parameter                                                                                                                |
| $\omega$                             | Rotational speed of the shaft ( $\text{rad/s}$ )                                                                                               |
| $\omega$                             | Species mixture mass fraction ( $-$ )                                                                                                          |
| $\omega$                             | The angular frequency of the applied current in ECT (radians/s)                                                                                |
| $\omega_B^T(d_i, \lambda)$           | Eddy-bubble collision probability density ( $\frac{1}{\text{s m}^3 [\text{m}]}$ )                                                              |
| $\omega_{B,\lambda}^T(d_i, \lambda)$ | Eddy-bubble collision probability density, differential because it is eddy-bubble interaction specific ( $\frac{1}{\text{s m}^3 [\text{m}]}$ ) |
| $\omega_\alpha$                      | Weight of the delta function centered at the characteristic particle size $\xi_\alpha$                                                         |
| $\Omega_{Shaft}$                     | Shaft angular velocity ( $\text{rad/s}$ )                                                                                                      |
| $\Omega_B$                           | Macroscopic breakage rate ( $\frac{1}{\text{s m}^3}$ )                                                                                         |
| $\Omega_B(d_i)$                      | Total breakage rate for particles of size $d_i$ ( $\frac{1}{\text{s m}^3}$ )                                                                   |
| $\Omega_C$                           | Macroscopic coalescence rate ( $\text{s}^{-1} \text{ m}^{-3}$ )                                                                                |
| $\omega_C$                           | Bubble–bubble collision density ( $\frac{1}{\text{m}^3 \text{s}}$ )                                                                            |
| $\omega_C^B$                         | Buoyancy collision density ( $\frac{1}{\text{s m}^3}$ )                                                                                        |
| $\omega_C^T$                         | Collision density caused by turbulent motion and expressed in the framework of a discrete numerical scheme ( $\frac{1}{\text{s m}^3}$ )        |
| $\omega_C^{LS}$                      | Collision density due to laminar shear ( $\frac{1}{\text{s m}^3}$ )                                                                            |
| $\Omega_{\mu,1}$                     | Collision integral for viscosity in kinetic theory ( $-$ )                                                                                     |
| $\omega_{B(d_i, \lambda_j)}$         | Eddy-bubble collision rate ( $\frac{1}{\text{s m}^3}$ )                                                                                        |
| $\omega_C$                           | Modified particle collision density ( $\frac{1}{\text{m}^3 \text{s} [\text{m}] [\text{m}]}$ )                                                  |
| $\Omega_{D,11}$                      | Collision integral for self-diffusion in kinetic theory ( $-$ )                                                                                |
| $\Omega_{D,12}$                      | Collision integral for diffusion in kinetic theory ( $-$ )                                                                                     |
| $\omega_{ff}$                        | Modified particle collision density ( $\frac{1}{\text{m}^3 \text{s} [\text{m}] [\text{m}]}$ )                                                  |
| $\omega_f$                           | Single particle collision density ( $\frac{1}{\text{s} [\text{m}]}$ )                                                                          |
| $\Omega_{k,1}$                       | Collision integral for thermal conductivity in kinetic theory ( $-$ )                                                                          |
| $\Phi(f)$                            | Presumed PDF ( $-$ )                                                                                                                           |
| $\Phi_{\text{viscous}}$              | Viscous dissipation function ( $\text{s}^{-2}$ )                                                                                               |
| $\Phi$                               | Basis (or trial) functions in truncated series expansion                                                                                       |

|                                   |                                                                                                                                                  |
|-----------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------|
| $\Phi$                            | Perturbation function in Enskog expansion                                                                                                        |
| $\Phi$                            | Potential energy per unit mass ( $\text{m}^2/\text{s}^2$ )                                                                                       |
| $\Phi$                            | The phase field or order parameter used in the phase field method                                                                                |
| $\phi$                            | Blade attachment angle ( $^\circ$ ) or (rad)                                                                                                     |
| $\phi$                            | Coefficient in the Zehner and Schlünder model for the convective heat transfer (—)                                                               |
| $\phi$                            | Local instantaneous source term of the generalized quantity $\psi$                                                                               |
| $\phi$                            | Model parameter                                                                                                                                  |
| $\phi$                            | Polar angle                                                                                                                                      |
| $\phi$                            | Polar coordinate                                                                                                                                 |
| $\phi$                            | Potential function in time-splitting method                                                                                                      |
| $\phi$                            | The electrical potential distribution or voltage (V)                                                                                             |
| $\phi$                            | Unknown variable in TDMA outline                                                                                                                 |
| $\phi(r)$                         | Limiter function in TVD schemes                                                                                                                  |
| $\Phi_{\text{eff}}$               | Effective global energy dissipation function ( $\text{s}^{-2}$ )                                                                                 |
| $\Phi_I(\frac{y}{\delta_v})$      | Non-dimensional function characteristic for the inner log-law or inertial sub-layer (—)                                                          |
| $\phi_i$                          | Fugacity coefficient for species $i$                                                                                                             |
| $\Phi_o(\frac{y}{\delta})$        | Non-dimensional function characteristic for the outer layer (—)                                                                                  |
| $\phi_r$                          | The off-axis angle in the PDA optical arrangement ( $^\circ$ )                                                                                   |
| $\phi_s$                          | Sphericity of solid particles (—)                                                                                                                |
| $\Phi_v(\frac{y}{\delta_v})$      | Non-dimensional function characteristic for the viscous sub-layer (—)                                                                            |
| $\phi_{1,2}$                      | The normalized cross-correlation function in F-OPT theory (—)                                                                                    |
| $\Phi_{\text{total}}$             | Entropy production rate ( $\text{kJ}/\text{m}^3 \text{ s K}$ )                                                                                   |
| $\phi_{I,c}$                      | Rate of production of the quantity $\psi_k$ per unit mass at each point on $A_I$                                                                 |
| $\Pi_{\varepsilon_g}$             | Interaction term in $\varepsilon_g$ model equation for gas phase ( $\text{kg}/\text{m s}^4$ )                                                    |
| $\Pi_{gp}$                        | Interaction term in $k_{gp}$ transport equation ( $\text{kg}/\text{m s}^3$ )                                                                     |
| $\pi_{i,j}$                       | Weighted breakage function                                                                                                                       |
| $\Pi_{kg}$                        | Interaction term in $k_g$ model equation for gas phase ( $\text{kg}/\text{m s}^3$ )                                                              |
| $\psi$                            | Generalized conserved quantity                                                                                                                   |
| $\psi$                            | Microscopic molecular property of dilute gas (referred to a single molecule) in elementary kinetic theory                                        |
| $\psi$                            | Polar angle                                                                                                                                      |
| $\psi$                            | The elevation angle in the PDA optical arrangement ( $^\circ$ )                                                                                  |
| $\psi$                            | Variable in simplified PD algorithm solution in SQMOM                                                                                            |
| $\psi(\mathbf{r}, \mathbf{c}, t)$ | A generalized physical function that denotes a property of the molecules located at time $t$ near $\mathbf{r}$ with a velocity near $\mathbf{c}$ |

|                                   |                                                                                                                  |
|-----------------------------------|------------------------------------------------------------------------------------------------------------------|
| $\psi(\mathbf{r}, \mathbf{c}, t)$ | Generalized particle property function located near $\mathbf{r}$ , with a velocity near $\mathbf{c}$ at time $t$ |
| $\rho$                            | A parameter used in LD theory (—)                                                                                |
| $\rho$                            | Instantaneous field mass density ( $\text{kg/m}^3$ )                                                             |
| $\rho$                            | Spectral reflectivity, $\rho = G_{\text{ref}}/G$ (—)                                                             |
| $\rho$                            | The electric charge density measured in coulombs per cubic metre ( $\text{C/m}^3$ )                              |
| $\rho_L(s)$                       | Autocorrelation coefficient (—)                                                                                  |
| $\rho_p$                          | Mass density of particle (kg)                                                                                    |
| $\sigma_k$                        | $k$ minus; $\epsilon$ turbulence model parameter (—)                                                             |
| $\sigma$                          | Stefan–Boltzmann constant, $= 5.67 \times 10^{-8} \text{ (W/m}^2 \text{ K}^4\text{)}$                            |
| $\sigma$                          | The electrical conductivity given in siemens per metre ( $\text{S/m}$ )                                          |
| $\sigma$                          | Variable in simplified PD algorithm solution in SQMOM                                                            |
| $\sigma'_{A_T}$                   | Alternative total (scattering) collision cross section ( $\text{m}^2$ )                                          |
| $\sigma_1$                        | Collision diameter used in kinetic theory (m)                                                                    |
| $\sigma_A(\Omega)$                | Differential scattering cross section ( $\text{m}^2$ )                                                           |
| $\sigma_I$                        | Surface tension ( $\text{N/m}$ )                                                                                 |
| $\sigma_i$                        | Standard deviation or rms velocity measured by LDA ( $\text{m/s}$ )                                              |
| $\sigma_i^2$                      | Unbiased variance of $\bar{v}_i$ measured by LDA ( $\text{m}^2/\text{s}^2$ )                                     |
| $\sigma_s(d)$                     | Surface restoring pressure of a bubble of size $d$ (Pa)                                                          |
| $\sigma_t(d)$                     | Average deformation stress for bubbles of size $d$ (Pa)                                                          |
| $\sigma_\epsilon$                 | $k$ – $\epsilon$ turbulence model parameter (—)                                                                  |
| $\sigma_{A_T}$                    | Total scattering cross section ( $\text{m}^2$ )                                                                  |
| $\sigma_A$                        | Standard deviation, the squared root of the variance (—)                                                         |
| $\sigma_A^2$                      | Variance, a statistical measure of the dispersion of data about the mean (—)                                     |
| $\sigma_{sr}$                     | Characteristic Lennard-Jones diameter ( $\text{\AA}$ )                                                           |
| $\sigma_{sr}$                     | Characteristic Lennard-Jones energy (J)                                                                          |
| $\tau$                            | Kolmogorov micro time scale (s)                                                                                  |
| $\tau$                            | A geometric parameter used in LD theory (—)                                                                      |
| $\tau$                            | Average residence time of the elements in surface renewal theory (s)                                             |
| $\tau$                            | The cross-correlation time delay between two signals in F-OPT theory (s)                                         |
| $\tau$                            | Time domain                                                                                                      |
| $\tau$                            | Time variable in history force expression (s)                                                                    |
| $\tau$                            | Tortuosity of porous medium (—)                                                                                  |
| $\tau$                            | Transmissivity, $\tau = G_{\text{trans}}/G$ (—)                                                                  |
| $\tau_p^c$                        | Characteristic particle–particle collision time (s)                                                              |
| $\tau_g^t$                        | Time scale of large turbulent eddies in gas phase (s)                                                            |
| $\tau_{gp}^t$                     | Interaction time between particle motion and gas fluctuation or eddy life time seen by a particle (s)            |

|                      |                                                                                                                                                |
|----------------------|------------------------------------------------------------------------------------------------------------------------------------------------|
| $\tau_1$             | Collision time of molecules of type 1 (s)                                                                                                      |
| $\tau_\omega$        | Time scale of scalar concentration fluctuations (s)                                                                                            |
| $\tau_b$             | Time constant associated with a bubble in $k - \epsilon$ turbulence model for bubbly flow [104]: Chap. 8, Lopez de Bertodano et al. (1994) (s) |
| $\tau_e$             | Eddy turnover time scale (s)                                                                                                                   |
| $\tau_i$             | Element values of symmetric tridiagonal matrix J in Golub–Welsch algorithm                                                                     |
| $\tau_L$             | Lagrangian micro time scale, or Lagrangian microscale (s)                                                                                      |
| $\tau_{cd}$          | ( $= \rho_d d_p^2 / 18 \mu_c$ ) particle relaxation time for Stokes flow (s)                                                                   |
| $\tau_{gp}$          | Particle relaxation time (s)                                                                                                                   |
| $\sigma'_{k,I}$      | Temporal deviation between the instantaneous stress and the interfacial mean stress variable (Pa)                                              |
| $\theta_c$           | Mean circulation time in stirred tank (s)                                                                                                      |
| $\theta_m$           | Mean mixing time in stirred tank (s)                                                                                                           |
| $\theta$             | Angle (radians) or ( $^\circ$ )                                                                                                                |
| $\theta$             | Angle between the incoming laser beams in the dual beam fringe anemometer LDA                                                                  |
| $\theta$             | Granular temperature ( $\text{m}^2/\text{s}^2$ )                                                                                               |
| $\theta$             | Scattering angle                                                                                                                               |
| $\theta$             | The beam crossing angle in the PDA optical arrangement ( $^\circ$ )                                                                            |
| $\theta$             | The vertical angle between probe axis and the bubble trajectory in FPECPT arrangement (rad)                                                    |
| $\Theta_i$           | Granular temperature for particle type $i$ in multiple particle mixture ( $\text{kg m}^2/\text{s}^2$ )                                         |
| $\gamma$             | Rate of deformation or rate of strain ( $\text{s}^{-1}$ )                                                                                      |
| $\Upsilon$           | Function representing an expression in Boltzmann H-theorem relation                                                                            |
| $\sigma_w$           | Wall shear stress (Pa)                                                                                                                         |
| $\varepsilon$        | Ensemble, consisting of a specific number of realizations $\mu$                                                                                |
| $\varepsilon$        | Event space domain                                                                                                                             |
| $\varepsilon$        | Maximum energy of attraction between a pair of molecules in kinetic theory (kJ)                                                                |
| $\varepsilon$        | Perturbation parameter in Enskog expansion                                                                                                     |
| $\varepsilon$        | Porosity of porous medium (–)                                                                                                                  |
| $\varepsilon$        | Turbulent energy dissipation rate per unit mass ( $\text{m}^2/\text{s}^3$ )                                                                    |
| $\varepsilon_\omega$ | Scalar dissipation rate ( $\text{s}^{-1}$ )                                                                                                    |
| $\varepsilon_b$      | Bed area occupied by bubble zone in bubbling bed (–)                                                                                           |
| $\varepsilon_s$      | Solid phase volume fraction (–)                                                                                                                |
| $\varepsilon_{as}$   | Solids volumetric concentration in annulus (–)                                                                                                 |
| $\varepsilon_{cs}$   | Solids volumetric concentration in core (–)                                                                                                    |
| $\varepsilon_{gp}$   | Dissipation rate of the gas-particle fluctuation covariance ( $\text{m}^2/\text{s}^3$ )                                                        |

|                                   |                                                                                                                                      |
|-----------------------------------|--------------------------------------------------------------------------------------------------------------------------------------|
| $\varepsilon_{ijk}$               | Permutation symbol, or alternating unit tensor (—)                                                                                   |
| $\varepsilon_{mf}$                | Holdup of fluidized bed at minimum fluidization conditions (—)                                                                       |
| $\varepsilon_{ov}$                | Gas holdup or overall void fraction (—)                                                                                              |
| $\varepsilon_{SGS}$               | SGS dissipation rate per unit mass in LES ( $\text{m}^2/\text{s}^3$ )                                                                |
| $\varphi_i$                       | Basis function used in MWR solution approximation function                                                                           |
| $\varphi_n$                       | The horizontal angle between probe sensor $n$ axis and the bubble trajectory in FPECPT arrangement (rad)                             |
| $\lambda$                         | Vector of Lagrange multipliers                                                                                                       |
| $\Omega$                          | Solid angle (steradians, sr)                                                                                                         |
| $\Omega(\psi)$                    | Generalized source term in granular kinetic theory                                                                                   |
| $\Phi(\psi)$                      | Generalized flux term in granular kinetic theory                                                                                     |
| $\psi_{\text{Collisional}}$       | Dense gas collisional transfer flux                                                                                                  |
| $\psi_{\text{Kinetic}}$           | Dense gas kinetic transfer flux                                                                                                      |
| $\hat{\psi}_k$                    | Spatial deviation of the point variable $\psi_k$ from the intrinsic volume average value $\langle \psi_k \rangle_{V_k}$              |
| $\hat{\sigma}_{k,I}$              | Deviation between the local instantaneous stress and the interfacial area averaged stress (Pa)                                       |
| $\hat{\psi}_k$                    | Spatial deviation of the point variable $\psi_k$ from the mass-weighted volume average value $\langle \psi_k \rangle_V^{X_k \rho_k}$ |
| $\tilde{\psi}$                    | MWR solution approximation function                                                                                                  |
| $\Xi$                             | Function representing an expression in Boltzmann H-theorem relation                                                                  |
| $\xi$                             | extent of reaction (mole)                                                                                                            |
| $\xi$                             | Model parameter (—)                                                                                                                  |
| $\xi$                             | Particle diameter                                                                                                                    |
| $\xi$                             | Property coordinate                                                                                                                  |
| $\xi$                             | The diameter of spherical particle measured by PDA (m)                                                                               |
| $\xi_i$                           | Pivotal points in $A_i$                                                                                                              |
| $\xi_{1,2}^{(i)}$                 | Approximate solution of PD algorithm in SQMOM                                                                                        |
| $\xi_{ij}$                        | Ratio of the diameters of a pair of unlike bubbles $d_i/d_j$ (—)                                                                     |
| $\zeta$                           | Independent variable (—)                                                                                                             |
| $\zeta$                           | Model parameter (—)                                                                                                                  |
| $\zeta$                           | Parameter called a surface coordinate or curvilinear coordinate of a point on a surface                                              |
| $d\chi$                           | Differential plane angle                                                                                                             |
| $d\xi_r$                          | Extent of reaction for reaction $r$ (kmol)                                                                                           |
| $w_{1,2}^{(i)}$                   | Approximate solution of PD algorithm in SQMOM                                                                                        |
| $\langle \varepsilon_s \rangle_A$ | Cross sectional averaged solid volumetric concentration (—)                                                                          |
| $k$                               | Thermal conductivity of dilute gas (kW/m K)                                                                                          |
| $\tilde{\sigma}_{ij}^n$           | Numerical stresses in LES (Pa)                                                                                                       |
| $\tilde{\sigma}_{ij}^R$           | Modeled residual stresses in LES (Pa)                                                                                                |

|                                   |                                                                                                          |
|-----------------------------------|----------------------------------------------------------------------------------------------------------|
| $\Omega$                          | Angular momentum tensor (N/m)                                                                            |
| $\sigma$                          | Viscous stress tensor ( $\text{Pa} = \text{N/m}^2$ )                                                     |
| $\sigma^{\text{kin}}$             | Deviatoric kinetic pressure tensor in granular theory ( $\text{N/m}^2$ )                                 |
| $\sigma_{Mm}$                     | Diffusion stress due to phase slip ( $\text{N/m}^2$ )                                                    |
| $\sigma_{Vm}$                     | Drift stress due to the phase slip ( $\text{N/m}^2$ )                                                    |
| $\zeta_I e_I$                     | Fluxes of isotropic second order tensors                                                                 |
| $(-\Delta \underline{H}_{r_A}^*)$ | Heat of reaction for reaction $r$ defined with species $A$ as basis ( $\text{kJ/kmol}$ )                 |
| $\Delta \underline{H}_c^*(T)$     | Molar enthalpy at temperature $T$ associated with species $c$ ( $\text{kJ/kmol}$ )                       |
| $\Delta \underline{H}_{f,c}^*$    | Standard molar heat of formation of species $c$ ( $\text{kJ/kmol}$ )                                     |
| $\alpha$                          | Solution vector of linear system in DQMOM                                                                |
| $\Psi(t)$                         | Variable defined by a volume integral                                                                    |
| $\kappa$                          | Curvature vector ( $\text{m}^{-1}$ )                                                                     |
| $\Omega$                          | Angular velocity or rate of rotation $\Omega = \frac{1}{2} \nabla \times \mathbf{v}$ ( $\text{s}^{-1}$ ) |
| $\omega$                          | Vorticity vector; $\omega = 2\Omega = \nabla \times \mathbf{v}$ ( $\text{s}^{-1}$ )                      |
| $\Phi(\psi)$                      | Net flux denoting the transfer of the property $\psi$ during a set of particle collisions                |
| $\Phi(\mathbf{r}, t)$             | Flux vector in kinetic theory                                                                            |
| $\sigma_d$                        | Deviatoric pressure tensor in kinetic theory ( $\text{Pa}$ )                                             |
| $\varphi_I$                       | Flux of the quantity $\psi_I$ (per unit length of line) through $l_I(t)$                                 |
| $\varsigma_I$                     | Interface flux vector                                                                                    |
| $\xi$                             | Material coordinates                                                                                     |
| $\mathbf{f}_e$                    | FEM vector of nodal values of the solution                                                               |

## Superscripts

|   |                                                                                                                                                       |
|---|-------------------------------------------------------------------------------------------------------------------------------------------------------|
| ' | Prime, denotes a pseudo-mixture quantity associated with the dusty gas model                                                                          |
| ' | Prime, denotes fluctuation quantity in conventional Reynolds (time) averaging                                                                         |
| ' | Prime, denotes sub-grid-scale or residual quantity in LES                                                                                             |
| ' | Prime, primed quantities refer to the final property values after a binary molecular collision in kinetic theory                                      |
| ' | Property of one of the particles colliding or breaking in PBE modeling                                                                                |
| ' | Small correction of a variable in FVM discretization                                                                                                  |
| " | Double prime, fluctuation component of an instantaneous quantity around it's mean weighted value. Used in the time- and ensemble averaging approaches |
| * | Fractional step index, or intermediate value                                                                                                          |

|        |                                                                                                                                               |
|--------|-----------------------------------------------------------------------------------------------------------------------------------------------|
| *      | Previous-iteration value of a variable, or provisional velocity value based on a guessed (or outer iteration) pressure, in FVM discretization |
| *      | Vector with properties after performing a rotation in space or reflection with respect to a given plane, or a combination                     |
| 0      | Maxwellian state property                                                                                                                     |
| 0      | Constant property value                                                                                                                       |
| $\nu$  | Iteration counter index                                                                                                                       |
| new    | Fractional step iteration index indicating latest obtained value                                                                              |
| $\sim$ | Property of a complementary particle in PBE modeling                                                                                          |
| *      | Asterisk denotes ideal gas state properties, or non-dimensional variables                                                                     |
| $c$    | Cloud zone or region                                                                                                                          |
| $c$    | conductive                                                                                                                                    |
| $cr$   | Critical quantity                                                                                                                             |
| $d$    | Inter-diffusive                                                                                                                               |
| $dry$  | Dry conditions                                                                                                                                |
| $n$    | Old value at time $t$ in FVM discretization                                                                                                   |
| $n+1$  | New value at time $t + \Delta t$ in FVM discretization                                                                                        |
| $o$    | Diffusion-thermal                                                                                                                             |
| $r$    | Radiative                                                                                                                                     |
| $s$    | Superficial                                                                                                                                   |
| $V$    | Volume average quantity                                                                                                                       |
| coll   | Collisional                                                                                                                                   |
| dilute | Dilute properties in kinetic theory                                                                                                           |
| flu    | Fluid dynamic                                                                                                                                 |
| fric   | Frictional                                                                                                                                    |
| kin    | Kinematic                                                                                                                                     |
| max    | Maximum                                                                                                                                       |
| min    | Minimum                                                                                                                                       |
| pec    | Peculiar                                                                                                                                      |
| t      | Turbulent                                                                                                                                     |

## Subscripts

|        |                                                                                                                                       |
|--------|---------------------------------------------------------------------------------------------------------------------------------------|
| 0      | Inlet, or initial condition                                                                                                           |
| $\psi$ | Representing a general quantity                                                                                                       |
| BI     | Bubble induced quantity in $k - \epsilon$ turbulence model for bubbly flow [103]: <a href="#">Chap. 8</a> , Lopez de Bertodano (1992) |
| crit   | Critical or threshold value                                                                                                           |
| eff    | Effective, sum of molecular and turbulent contributions                                                                               |

| min    | Minimum value                                                                                                                         |

|       |                                                                                                                     |
|-------|---------------------------------------------------------------------------------------------------------------------|
| SI    | Shear induced quantity in $k - \epsilon$ turbulence model for bubbly flow [103]: Chap. 8, Lopez de Bertodano (1992) |
| surr  | Property of surroundings                                                                                            |
| sur   | Surface                                                                                                             |
| sys   | Property of a simple subsystem                                                                                      |
| sys   | Property of surroundings                                                                                            |
| $A$   | Area                                                                                                                |
| $a$   | Ambient property                                                                                                    |
| $a$   | Annulus                                                                                                             |
| $ad$  | Adiabatic conditions                                                                                                |
| $B$   | Breakage                                                                                                            |
| $B$   | Neighbor at the bottom (in the negative $z$ direction) in FVM discretization                                        |
| $b$   | Grid cell volume face between $P$ and $B$ in FVM discretization                                                     |
| $b$   | Single bubble or bubble zone                                                                                        |
| $C$   | Coalescence                                                                                                         |
| $c$   | Center of mass property                                                                                             |
| $c$   | Cloud zone                                                                                                          |
| $c$   | Core                                                                                                                |
| $c$   | Index to identify a species/component in a binary or multicomponent mixture                                         |
| $cap$ | Capture particle property                                                                                           |
| $cat$ | Catalyst particle property                                                                                          |
| $E$   | Neighbor node on the east side (in the positive $x$ direction) in FVM discretization                                |
| $e$   | Element                                                                                                             |
| $e$   | Emulsion zone                                                                                                       |
| $e$   | Grid cell volume face between $P$ and $E$ in FVM discretization                                                     |
| $e_I$ | Interface average property in ensemble averaging procedure                                                          |
| $I$   | Interface property                                                                                                  |
| $i$   | Index                                                                                                               |
| $L$   | Laboratory frame                                                                                                    |
| $m$   | Medium                                                                                                              |
| $m$   | Mixture property                                                                                                    |
| $N$   | Neighbor node on the north side (in the positive $y$ direction) in FVM discretization                               |
| $n$   | Grid cell volume face between $P$ and $N$ in FVM discretization                                                     |
| $nb$  | General neighbor grid node in FVM discretization                                                                    |
| $ov$  | Overall                                                                                                             |
| $P$   | Central grid node under consideration in FVM discretization                                                         |
| $P$   | Index marking the first grid cell away from the wall                                                                |
| $p$   | Particle                                                                                                            |
| $r$   | Relative                                                                                                            |

|     |                                                                                       |
|-----|---------------------------------------------------------------------------------------|
| $S$ | Neighbor node on the south side (in the negative $y$ direction) in FVM discretization |
| $S$ | Surface                                                                               |
| $s$ | Grid cell volume face between $P$ and $S$ in FVM discretization                       |
| $s$ | Solids phase or particle phase                                                        |
| $s$ | Species in a binary or multicomponent mixture                                         |
| $T$ | Neighbor on the top (in the positive $z$ direction) in FVM discretization             |
| $T$ | Time average quantity                                                                 |
| $t$ | Grid cell volume face between $P$ and $T$ in FVM discretization                       |
| $t$ | Tube                                                                                  |
| $W$ | Neighbor on the west side (in the negative $x$ direction) in FVM discretization       |
| $W$ | Wall                                                                                  |
| $w$ | Grid cell volume face between $P$ and $W$ in FVM discretization                       |
| $x$ | $x$ -coordinate direction in Cartesian system (m)                                     |
| $y$ | $y$ -coordinate direction in Cartesian system (m)                                     |
| $z$ | $z$ -coordinate direction in Cartesian system (m)                                     |
| $j$ | Index                                                                                 |
| $k$ | Index                                                                                 |
| mb  | Minimum bubbling                                                                      |
| mf  | Minimum fluidization                                                                  |
| $n$ | Normal component of a vector                                                          |
| pp  | Primary particles in SQMOM                                                            |
| sp  | Secondary particles in SQMOM                                                          |

## Operators

|                                    |                                                                                                                                                |
|------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------|
| $(\dots)$                          | Component vector                                                                                                                               |
| $:$                                | Multiplication sign, the scalar product (or double dot product) of two tensors                                                                 |
| $[..., ...]$                       | Poisson bracket operator in classical mechanics                                                                                                |
| $[...]$                            | Square matrix                                                                                                                                  |
| $\cdot$                            | Multiplication sign, used for Scalar Product (or Dot Product) of two vectors, Divergence of a Vector Field, and other vector/tensor operations |
| $\ddot{\psi}$                      | Second order partial derivative of quantity $\psi$ with respect to time                                                                        |
| $\delta$                           | Denotes a variation about the motion of the system in Classical Mechanics                                                                      |
| $\delta/\delta x$                  | Generalized discretized spatial derivative                                                                                                     |
| $\dot{\psi}$                       | Partial derivative of quantity $\psi$ with respect to time                                                                                     |
| $\frac{\mathbb{D}()}{\mathbb{D}t}$ | Hypothetical total time derivative operator in phase space                                                                                     |

|                                            |                                                                                                                                 |
|--------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------|
| $\frac{D()}{Dt}$                           | Hypothetical substantial time derivative operator in phase space                                                                |
| $\frac{\partial ()}{\partial \mathbf{c}}$  | Gradient of () with respect to $\mathbf{c}$                                                                                     |
| $\frac{\partial ()}{\partial \mathbf{r}}$  | Gradient of () with respect to $\mathbf{r}$                                                                                     |
| $\frac{\partial ()}{\partial t}$           | Partial time derivative, denoting the partial derivative of the quantity () with respect to $t$ , at constant $x, y, z, (()/s)$ |
| $\frac{D()}{Dt}$                           | Substantial time derivative, material derivative, hydrodynamic derivative, derivative following the motion $(()/s)$             |
| $\frac{d()}{dt}$                           | Total derivative operator                                                                                                       |
| $\frac{d\Gamma}{dt}$                       | Material surface derivative ( $s^{-1}$ )                                                                                        |
| $\langle \dots \rangle$                    | General averaging operator                                                                                                      |
| $\langle \dots \rangle_{A_I}^{\Gamma}$     | Mass flux weighted interfacial area average quantity                                                                            |
| $\langle \dots \rangle_{X_k \rho_k}^{X_k}$ | Mass-weighted average                                                                                                           |
| $\langle \dots \rangle_A$                  | Area averaging operator                                                                                                         |
| $\langle \dots \rangle_e$                  | Ensemble averaging operator                                                                                                     |
| $\langle \dots \rangle_M$                  | Maxwellian averaging operator                                                                                                   |
| $\langle \dots \rangle_V$                  | Volume averaging operator                                                                                                       |
| $\langle \dots \rangle_{A_I}$              | Interface area averaged quantity                                                                                                |
| $\langle \psi_k \rangle_{X_k}^{X_k}$       | $X_k$ -weighted average of $\psi_k$ over the entire time period $T$                                                             |
| $\langle \psi_k \rangle_V^{X_k}$           | Intrinsic volume averaging operator                                                                                             |
| $\langle \psi_k \rangle_{T_k}$             | Time average of $\psi_k$ over the accumulated time interval $T_k$                                                               |
| $\langle \psi_k \rangle_{V_k}$             | Intrinsic volume averaging operator                                                                                             |
| $\mathcal{B}\bullet$                       | Boundary condition operator in WRM                                                                                              |
| $\mathcal{L}$                              | Linear problem operator                                                                                                         |
| $ \dots $                                  | Length of vector, magnitude of vector, or absolute value of scalar variable                                                     |
| $\nabla \cdot$                             | Divergence operator                                                                                                             |
| $\nabla$                                   | Gradient operator, vector differential operator, also known as <i>nabla</i> or <i>del</i> operator                              |
| $\nabla_I$                                 | Interface del or nabla operator                                                                                                 |
| $\nabla_{\mathbf{c}}()$                    | Gradient of () with respect to $\mathbf{c}$                                                                                     |
| $\nabla_{\mathbf{r}}()$                    | Gradient of () with respect to $\mathbf{r}$                                                                                     |
| $\overline{\langle \dots \rangle}^f$       | Number weighted average quantity in external space                                                                              |
| $\overline{\psi}$                          | Overlines, time averaging operator                                                                                              |
| $\  \bullet \ ^2_{Y(t)}$                   | $L^2$ norm used in least squares method outline                                                                                 |
| $\partial$                                 | Partial derivative                                                                                                              |
| $\Pi_i()$                                  | Product of all labeled variables in ()                                                                                          |
| $\times$                                   | Multiplication sign, vector product (or cross product) of two vectors                                                           |
| $\tilde{\phi}$                             | Mesosopic smoothly varying quantity in VOF                                                                                      |
| $\psi$                                     | Tilde, filtering operator                                                                                                       |
| $covar(A, B)$                              | Covariance between two variables, $A$ and $B$                                                                                   |
| $div()$                                    | Divergence of a vector                                                                                                          |

|          |                                |
|----------|--------------------------------|
| $G$      | Filtering function used in LES |
| $grad()$ | Gradient of a scalar           |

## Abbreviations

|              |                                                                               |

# **Part I**

## **Single Phase Fundamentals**

# Chapter 1

## Single Phase Flow

In this chapter the governing equations of change for single-phase reactive mixtures are presented.

An introduction to the basic continuum mechanics notation is given first ensuring that the fundamental principles are interpreted in an appropriate manner. Then, the derivation of the rigorous balance equations for multi-component fluid mixtures by use of the control volume approach is discussed. Alongside a standard set of approximate constitutive equations is listed. Thereafter several derived formulas, frequently also referred to by names like simplified-, macroscopic-, design-, or engineering models, are examined. In the latter context the primary aims are to explain how these formulas can be deduced from the fairly rigorous conservation equations, and to elucidate the inherent assumptions. The governing equations are applied to turbulent flows in the subsequent portion of sections in the chapter.

The theory of single phase materials is not only of principal importance analyzing single phase reactor systems, it also serves as basis for the description of multiphase flows.

### 1.1 Basic Principles of Fluid Mechanics

*Fluid mechanics* is the study of motions of gases and liquids. In the literature the subject is often divided into *compressible* and *incompressible* flows. However, the strict mathematical definitions of these two types of flows are not trivial. There is more to this than one may think, as will be discussed in Sect. 1.2.5.2. Meanwhile, considering physical properties rather than strict mathematics, preliminary characterizations of these two classes of flows will provide important ideas why this subdivision of fluid mechanics is useful.

The majority of chemical engineers have stronger theoretical background in thermodynamics than fluid mechanics, so the vocabulary used in fluid mechanics literature may be a first barrier that one needs to pass. At this point, we thus intend to

remove a possible source of confusion that is common among chemical engineers. From a thermodynamic standpoint, gases and liquids have quite different characteristics. In thermodynamics liquids are often modeled as incompressible fluids. In this context, an incompressible fluid denotes a fluid having density that doesn't change significantly due to pressure variations (i.e.,  $\frac{1}{\rho} \frac{\partial \rho}{\partial p} |_T, \omega_c \approx 0$ ). Having this thermodynamic definition in mind, one may be surprised to learn about an incompressible flow of a compressible fluid in mechanics. However, *incompressible fluids* is a thermodynamical term, whereas *incompressible flow* is a fluid mechanical term. As will be discussed in Sect. 1.2.5.2, the main criterion for incompressible flow is that the flow doesn't induce any significant fluid density changes. A criterion for such effects has been developed in fluid mechanics. That is, the so-called Mach number (i.e., that can be interpreted as a measure of the relative density changes due to flow effects) has to be low. Mathematical analyzes will be given at a later stage after the basic tools, the governing equations, have been presented.

Typical characteristics of compressible flows are given next. Under certain flow conditions density changes due to momentum (flow) effects must be considered in gas dynamics [169]. In practice, such compressible flows may be divided into the following categories:

- Flows where fluid dynamic wave propagation within the fluid are important. These phenomena may be important for a restricted number of chemical reactor systems, as for example certain industrial multi-phase systems operated in bubble column and fluidized bed reactors.
- Steady flow in which the fluid speed is of the same order of magnitude as the speed of sound. This situation hardly exist in chemical reactor systems. However, in an industrial chemical process plant there are many unit operations containing flows belonging to this category.
- Convection driven by body forces, e.g., gravity, acting on fluid subject to thermal expansion. These phenomena are very important in the geophysical sciences, but may be less important in the chemical industry.
- Large-scale convection of gases and liquids in the presence of body forces. A lot of work has been done on this subject in the geophysical sciences, but is not very important in the chemical industry.

Summarizing these results from fluid mechanics, a layman may erroneously conclude that the flows in chemical reactors are incompressible. Notice, however, that the analyzes referred were all performed on non-reactive flow systems. In chemical reactors, on the other hand, we may be dealing with flow situations where the densities of fluids vary both due to pressure and temperature changes, chemical reactions and non-ideal mixing. From a thermodynamic standpoint both compressible and incompressible fluids are considered in reactor modeling. This indicates that a general reactor technology modeling approach should be able to handle compressible flows.

The traditional modeling framework describing reactive flow systems is presented in the following. The basic conservation equations applied in most reactor model

analyses are developed from the concept that the fluid is a *continuum*. This means that a *fluid* is considered to be a matter which exhibits no finer structure [169]. This model makes it possible to treat fluid properties at a point in space and mathematically as continuous functions of space and time. From the continuum viewpoint, fluid mechanics and solid mechanics have much in common and the subject of both these sciences are traditionally called *continuum mechanics*.

The basic assumptions in fluid mechanics are thus that for lengths and time scales much larger than the characteristic molecular lengths and times, the continuum representation provides a quantitative correct description of the fluid dynamic behavior of the system. In general, the differential description is useful for processes where there is a wide separation of scales between the smallest macroscopic scales of interest and the microscopic scales associated with the internal structure of the fluid. The mean free path which is of the order of  $10^{-7}$  m for gases is commonly used as a suitable characteristic dimension (see Sect. 2.10). The continuum model in gas dynamics is thus expected to fail when the model resolution is no longer very much larger than the mean free path [169]. For liquids, a corresponding characteristic molecular dimension is not clearly defined but may be taken to be a distance equal to several intermolecular spacings which are of the order of  $10^{-10}$  m. These dimensions are so small that the continuum model is violated only in extreme cases. For single phase flow systems in reactor technology, we are usually not concerned with such extreme cases and the continuum approach is expected to provide useful information of the reactor performance.

Note, however, that in reactor technology we are very often dealing with dispersed and granular flows. Granular flow is referred to as flow of a powder in a vacuum [58]. Traditionally, the continuum approach have been adopted modeling these flows too. It might sometimes be useful to apply an alternative way of proceeding which is based on the results from elementary *kinetic theory of gases*, where such results enhance our physical insight of reactor performance. If this particulate view of matter is adopted we can, by use of a statistical procedure average over a large number of molecules or particles, derive a set of conservation equations which is analogue to the continuum equations. In fact, the results from these two alternative approaches are virtually identical. The latter method, which is more general in principle, is however much more complex theoretically and has been limited by theoretical difficulties to practically dilute gases. During the last decades several papers have been published, even on multiphase flow, presenting ideas on how to extend the kinetic theory closures to more general flow situations. These ideas are further discussed in later chapters related to multiphase flows. Keeping these basic assumptions in mind, the chemically reacting fluids can quantitatively be described in terms two categories of the governing equations [135]:

1. *Balance equations*, which summarize the experience of the last three centuries on the behavior of all forms of matter. The balance equations express that for any fluid, in any state of motion, the quantities being transported are balanced. Experience have taught us that there are certain physical laws which must be valid irrespective of the type of fluid mixture being considered. These laws express *the*

*balance principles* which impose constraints upon the coexisting field variables describing instantaneous motions of a chemically reacting fluid mixture. The term *conservation equations* usually refers to the equations expressing the classical laws of the separate conservation of total mixture mass, momentum and total energy. Based on the balance principle one can nevertheless formulate appropriate balance equations for other physical quantities which are not necessarily conserved. Such equations are often called *transport equations* to imply that we are dealing with non-conservable quantities. However, the conservation equations can be formulated on a general form similar to the transport equations.

In many practical situations it is common to formulate *transport equations*, which are based purely on the balance principle and not on a physical law, to determine how the pertinent non-conservative quantities vary in time and space. Important examples:

- Transport of individual chemical species mass.  
Note that each chemical *element* is conserved. This means that ordinary chemical reactions involving the elements are merely changing partners, rather than being produced or destructed. Individual chemical species are however not really conserved since they can be generated or consumed in chemical reactions, but one can nevertheless write an appropriate balance equation or transport equation for each chemical species [135].
- Transport of the total entropy of the mixture, based on the second law of thermodynamics.
- Transport of the turbulent kinetic energy.
- Transport of the turbulent dissipation rate.
- Transport of the turbulent Reynolds stresses.
- Transport of other covariances or turbulent moments.
- Transport of probability density functions.

Note that the conservation equations can be distinguished from the transport equations since they do not contain any production or destruction terms. Nevertheless, the conservation equations may contain terms on the RHS expressing a divergence of fluxes related to transport phenomena. The way in which these flux terms are divided into divergence of transport fluxes or source terms is rather involved, but procedures exist based on a number of requirements on the two types of terms which determine this separation uniquely.

The equations expressing these balance laws are, by themselves, insufficient to uniquely define the system, and statements on the material behavior are also required. Such statements are termed constitutive relations or constitutive laws.

2. *Constitutive equations*, which quantitatively describe the physical properties of the fluids. The most important constitutive equations used in this book are the Newton's viscosity law, the Fourier's law of heat conduction, and the Fick's law of mass diffusion. The equation of state and more empirical relations for the physical properties of the fluid mixture also belong to this group of equations.

To be able to formulate these continuum equations we need to apply certain mathematical theorems which are not expressing physical laws, but purely based on geometrical aspects of the fluid motion [11, 13, 105, 135, 169]. These relations are called *kinematic theorems*. The most important example of such a kinematic relation is the so-called *Leibnitz formula* for the derivative of an integral with variable limits. *Leibnitz theorem*, also known as the generalized transport theorem, represents a generalization of the fundamental Leibnitz formula. Note that in some physical sciences this transport theorem is called *the Reynolds transport theorem* to distinguish the generalized theorem from the original formula. A third variation is that a particular version of the generalized Leibnitz theorem is referred to as the Reynolds transport theorem ([181], Sect. 3.4). To avoid any confusion, the various kinematic theorems applied are defined as we proceed deriving the governing equations.

Furthermore, for non-isothermal situations we need to be able to calculate the energy variables in the fluid dynamics balance equations. These energy variables are related to thermodynamics. However, the classical equilibrium thermodynamics deals with relatively permanent states, called equilibrium states, within uniform fields of matter [7, 42, 54, 146]. In this thermodynamics theory any changes in the state variables are assumed to be extremely slow. On the other hand, the fluid motions of interest in fluid dynamics are not necessarily slow. It is generally assumed that the classical thermodynamics relations can be applied locally in fluid dynamics systems assuming instantaneous *local* thermodynamic equilibrium [169]. A more formal statement is that the thermodynamics require that the fluids are close to *local* equilibrium, but may not be in *global* equilibrium. However, all systems are supposed to be relaxing towards a state of *global* thermodynamic equilibrium.

The transport equations derived cannot be solved directly as they contain unknown terms which have to be expressed in terms of the known dependent variables, i.e., parameterized. A relation between observable effects and the internal constitution of matter are described by *constitutive equations or constitutive laws*. It is, however, hardly possible to formulate general expressions for these constitutive laws. The principles of constitutive equations given by Truesdell and Toupin [171] are considered to provide a rational means for obtaining descriptions of classes of materials, without inadvertently neglecting an important dependence. In reactor modeling practice only a limited number of guiding principles (if any) which are considered to be the most fundamental and restrictive ones provided by continuum mechanics have been applied. According to Aris [3] and Malvern [105], the correct work on constitutive equations should consider the principles of consistency, coordinate invariance, isotropy, just setting, dimensional invariance, material indifference and equipresence. In addition, the set of model equations formulated should be well-posed as an initial value problem [131]. These mathematical principles are elaborated in Chap. 5 and Sect. 3.6 discussing multi-fluid models.

By use of the above mentioned framework and mathematical tools, and by reasonable assumptions based on analysis of *experimental data* we are hopefully able to formulate proper models providing reasonable predictions of the chemical reactor performance. In the following sections the basic mathematical and conceptual tools determining the general reactor technology fundamentals are given and discussed.

## 1.2 Equations of Change for Multi-Component Mixtures

In this section the governing equations of change determining the behavior of multi-component mixtures are formulated on the general vector form. These fundamental balance equations can be transformed into any coordinate system by use of rigorous mathematical formulas [3, 11, 13, 17] ensuring that all the transport equations have the same physical meaning irrespective of the particular coordinate system used to locate points in space. The governing balance equations, as defined in the elementary orthogonal coordinate systems (e.g., Cartesian, cylindrical, spherical) commonly used in engineering practice, are tabulated in many textbooks (e.g., [11, 13]) to ease the work of the modelers. Nevertheless, it is still recommended to study this mathematical theory to be able to understand these transformations and, if necessary, transform the generalized equations into the body fitted non-orthogonal curvilinear coordinate system lately being very popular treating complex geometries in computational fluid dynamics (CFD). In general, however, the choice of coordinate system to describe any particular flow problem is determined largely by convenience. There are also various ways that the physical laws (i.e., the laws of conservation of mass, linear—and angular momentum, and energy) can be applied describing the fluid behavior. It is usually distinguished between the *system approach* and the *control volume approach* (e.g., [2, 114, 135, 145, 180, 183, 184]). In this context a *system* is defined as a collection of matter of fixed identity (i.e., a particular collection of atoms or molecules constituting a specified portion of the material), which may move and interact with its surroundings. A *control volume* (CV), on the other hand, is basically a volume in space (a geometric entity, independent of mass). Different types of CVs have been defined over the years, including some through which fluid may flow. In solid mechanics the system approach is generally used to describe the motion of solid bodies because a given particle is easily identified. The control volume approach is normally used in fluid mechanics since the identification of a particular system becomes a tedious task. An issue of fundamental importance is that the physical laws determining the fluid behavior are stated in terms of fluid systems, not control volumes. To formulate the governing laws in a control volume approach we must re-phrase the laws in an appropriate manner. In the integral formulation the Leibnitz or Reynolds transport theorem provides the relationship between the time rate of change of an extensive property for a system and that for a control volume. For differential equations a similar interrelation between the system and control volume approaches is expressed through the substantial—or material derivative operator. Hence it follows that by use of these mathematical tools we may convert a system analysis to a control volume analysis. One particular control volume definition might be confusing at first because it is interchangeable with a system as defined above (e.g., [105, 114, 135]). Such a control volume is called a *material control volume* (a geometric entity, dependent on mass) since it always retains the material originally present within its control surface (CS). The model framework for such an analysis of motion of material control volumes is termed *Lagrangian*. This is the familiar approach of particle and rigid body dynamics. An important alternative

control volume retains stationary enabling a description of the material behavior at a fixed location. This framework is named *Eulerian*.<sup>1</sup> The relationship between the system and control volume approaches can be defined in terms of the material control volume representing a system. The Reynolds theorem, for example, defines the relationship between the material and Eulerian control volume descriptions. To proceed formulating the governing equations, yet some important considerations concerning when or for what flow situations it is favorable to apply the alternative mathematical model frameworks are required. In general there is no single best choice of frame valid for all flow situations, rather several possibilities exist that can lead to the same useful predictions. Therefore, as expected perhaps, for most flow problems this decision is often based on convenience or level of detail sought. Nevertheless, in the context of reactor simulations a brief evaluation considering the complexity and use of the different control volumes might be given. In continuum dynamics the balance principles and conservation laws can be applied to the fluid contained in a control volume of arbitrary size, shape and state of motion. Conceptually, the simplest control volume is perhaps the Lagrangian or material one that moves at every point on its surface with the local fluid velocity, see Fig 1.1b. However, while the balance principles and conservation laws of fluid dynamics are readily stated for material control volumes, they are not so readily used in this form. This is because the use of Lagrangian material control volumes involve complex and computationally expensive mathematics as the Lagrangian control volume moving through space, may both change its volume and deform in shape. In this context, control volumes with *fixed* surfaces through which the fluid flows, offer the important advantage of involving simpler mathematics. Thus, most fluid dynamic reactor models are formulated using fixed (Eulerian) control volumes, see Fig 1.1a. However, the most general type of control volumes is defined by surfaces that are neither fixed nor moving with the local fluid velocity, that is, the CV surfaces move with an arbitrary velocity. These generalized descriptions are commonly referred to as mixed Lagrangian-Eulerian-, generalized Lagrangian- or arbitrary Lagrangian-Eulerian (ALE) methods [36, 37], and were first reported by Hirt et al. [69]. In this book this particular framework is termed *the general Lagrangian* approach, see Fig 1.1c. This approach also involves quite complex mathematics and is thus hardly ever used in chemical reactor analysis.

It is remarked that in the standard literature on fluid dynamics and transport phenomena three different modeling frameworks, which are named in a physical notation rather than in mathematical terms, have been followed formulating the single phase balance equations [91]. These are: (1) The *infinitesimal particle* approach [2, 3, 67, 91, 145]. In this case a differential cubical fluid particle is considered as it moves through space relative to some fixed coordinate system. By applying the balance principle to this Lagrangian control volume the conservation equations for

---

<sup>1</sup> Note that according to Truesdell and Toupin [171] the material coordinates were introduced by Euler in 1762, although they are now widely referred to as the Lagrangian coordinates, while the spatial coordinates, often called Eulerian coordinates, were introduced by Jean le Rond d'Alembert (1717–1783) in 1752. Elaborate discussions of these coordinates are given by Malvern [105] (Sect. 4.3) and Truesdell and Toupin [171] (pp. 326–327).

**Fig. 1.1** **a** Finite Eulerian control volume *fixed* in space with the fluid moving through it. **b** Finite Lagrangian control volume *moving with the fluid* such that the same fluid particles are always in the same control volume (i.e., a material control volume). **c** Finite general Lagrangian control volume *moving with an arbitrarily velocity* not necessarily equal to the fluid velocity. The *solid line* indicate the control volume surface (CS) at time  $t$ , while the *dashed line* indicate the same CS at time  $t + dt$

mass, momentum and energy are obtained. The value of a given property at a fixed position  $\mathbf{r}$  and time  $t$  coincides with the value appropriate to the particle which is at  $\mathbf{r}$  at time  $t$ . The substantial derivative operator establishes a connection between the Lagrangian and Eulerian frameworks. (2) The *infinitesimal control volume* approach [2, 11, 13]. In this method one considers a differential cubical volume element fixed in space, through which a fluid is flowing. By applying the balance principle to this Eulerian control volume the conservation equations for mass, momentum and energy are achieved. (3) The *finite control volume* approach [2, 12, 32, 105, 169]. In this approach a control volume of finite size is considered. This control volume can have any arbitrary shape and is either fixed in space or moves through space relative to some fixed coordinate system. By applying the balance principle to the finite control volume the conservation equations for mass, momentum and energy are written on the integral form. The Leibnitz theorem is used to define the time rate of change. The Gauss's theorem is used to relate the surface and volume integrals, resulting in an equation involving only volume integrals. It is then argued that the conditions must be satisfied for the integrand, since the integration is arbitrary. Needless to say, the three approaches (1)–(3) give rise to identical results, the governing equations. However, it is not always clear which approach is being followed. There is also a subtle difference between the integral and differential forms of the governing flow equations [2].

The integral form of the equations allows for the presence of discontinuities inside the control volume (there is no inherent mathematical reason to assume otherwise). However, the differential form of the governing equations assumes the flow properties are differentiable, hence continuous. This consideration becomes of particular importance when calculating a flow with real discontinuities, such as shock waves and interfaces. In this book the *finite control volume* approach is applied for single phase flows because it coincides with the method adopted formulating the multi-fluid models (e.g., [39, 43, 74, 149, 153, 181]) in the subsequent chapters of this book. To establish the integral form of the basic conservation laws for mass, momentum and energy, the fundamental approach is to start out from a system analysis and then transform the balance equations into a control volume analysis by use of the transport theorem. However, to achieve a more compact presentation of this theory it is customary to start out from a generic Eulerian form of the governing equations. That is, the material control volume analysis is disregarded.

The balance principle applied to an Eulerian CV is thus by definition expressed as a balance of accumulation, net inflow by convection and diffusion and volumetric production. The Eulerian transport equations can be cast in the generalized form:

$$\left\{ \begin{array}{c} \text{Rate of } ( ) \\ \text{accumulation} \\ \text{in CV} \end{array} \right\} = \left\{ \begin{array}{c} \text{Net inflow} \\ \text{rate of } ( ) \\ \text{by convection} \\ \text{across} \\ \text{CV surface} \end{array} \right\} + \left\{ \begin{array}{c} \text{Net inflow} \\ \text{rate of } ( ) \\ \text{by diffusion} \\ \text{across} \\ \text{CV surface} \end{array} \right\} + \left\{ \begin{array}{c} \text{Net source} \\ \text{of } ( ) \\ \text{within CV} \end{array} \right\}$$

where  $( )$  applies to mass, momentum, energy, entropy, etc.

Therefore, as basis we formulate the generalized form of the local instantaneous transport equation for the mixture mass, component mass, momentum, energy and entropy in a fixed control volume (CV) on microscopic scales, as illustrated in Fig. 1.1. This approach thus consider the conservation law of the quantity  $\psi$  within the fixed macroscopic volume  $V$  bounded by the fixed macroscopic surface area  $A$ :

$$\frac{\partial}{\partial t} \int_V (\rho\psi) dv = - \int_A (\rho\mathbf{v}\psi) \cdot \mathbf{n} da - \int_A \mathbf{J} \cdot \mathbf{n} da + \int_V \phi dv \quad (1.1)$$

in which the  $\mathbf{n}$  is the outward directed normal unit vector to the surface of the control volume,  $\mathbf{v}$  is the fluid velocity,  $\rho$  is the mixture density,  $\psi$  is the conserved quantity,  $\mathbf{J}$  is the diffusive flux and  $\phi$  is the source term.

The transient term in (1.1) can be manipulated as the order in which the partial time derivation and the integration is performed can be reversed. The convective and diffusive transport terms in (1.1) can be rewritten as a volume integral using Gauss' theorem (App A). Equation (1.1) can then be assembled in a single volume integral:

**Table 1.1** The definitions of  $\psi$ ,  $\mathbf{J}$  and  $\phi$  for the different balance equations

| Balance principle | $\psi$                | $\mathbf{J}$                               | $\phi$                                                  |
|-------------------|-----------------------|--------------------------------------------|---------------------------------------------------------|
| Total mass        | 1                     | 0                                          | 0                                                       |
| Component mass    | $\omega_c$            | $\mathbf{j}_c$                             | $R_c$                                                   |
| Momentum          | $\mathbf{v}$          | $\mathbf{T}$                               | $\sum_{c=1}^N \rho_c \mathbf{g}_c$                      |
| Energy            | $e + \frac{1}{2} v^2$ | $\mathbf{T} \cdot \mathbf{v} + \mathbf{q}$ | $\sum_{c=1}^N \rho_c (\mathbf{g}_c \cdot \mathbf{v}_c)$ |

$e$  the internal energy of the multicomponent system,  $\mathbf{g}_c$  the external forces per unit mass of component  $c$ ,  $\mathbf{j}_c$  is the molecular (diffusive) flux of component  $c$ ,  $N$  the total number of species,  $\mathbf{q}$  the multi-component energy flux vector,  $q$  the number of independent reactions,  $R_c$  the rate of generation of component  $c$  by chemical reaction ( $R_c = \sum_{r=1}^q R_{r,c}$  where  $R_{r,c} = R'_{r,c} M_{w_c}$  (kg/m<sup>3</sup> s) and  $R'_{r,c}$  (mol/m<sup>3</sup> s)),  $\mathbf{T}$  the total stress tensor (i.e.,  $\mathbf{T} = p\mathbf{e} + \boldsymbol{\sigma}$ ),  $\omega_c$  the mass fraction of component  $c$ ,  $\boldsymbol{\sigma}$  the viscous stress tensor

$$\int_V \left( \frac{\partial(\rho\psi)}{\partial t} + \nabla \cdot (\rho\mathbf{v}\psi) + \nabla \cdot \mathbf{J} - \phi \right) dv = 0 \quad (1.2)$$

Equation (1.2) must be satisfied for any macroscopic volume  $V$ , thus the expressions inside the volume integral must be equal to zero.

A generic local instantaneous equation for a general conserved quantity  $\psi$ , where  $\mathbf{J}$  represents the diffusive fluxes and  $\phi$  the sources of  $\psi$ , can be expressed as:

$$\frac{\partial(\rho\psi)}{\partial t} + \nabla \cdot (\rho\mathbf{v}\psi) + \nabla \cdot \mathbf{J} - \phi = 0 \quad (1.3)$$

The values for  $\psi$ ,  $\mathbf{J}$  and  $\phi$  for the different balances are listed in Table 1.1 (e.g., [11, 13, 32, 91]).

Note that the momentum and energy equations for mixtures and pure fluids differ in their last terms (e.g., [11–13, 170]), where  $\rho\mathbf{g}$  has been replaced by  $\sum_{c=1}^N \rho_c \mathbf{g}_c$  in the momentum equation and  $\rho(\mathbf{g} \cdot \mathbf{v})$  has been replaced by  $\sum_{c=1}^N \rho_c (\mathbf{g}_c \cdot \mathbf{v}_c)$  in the energy equation, respectively. In the mixture equations account are taken of the fact that each chemical species present may be acted on by a different external force per unit mass  $\mathbf{g}_c$ .

The complete set of governing equations for single phase flow is summarized in App C and written out in the most commonly occurring orthogonal coordinates (i.e., the Cartesian, the cylindrical and spherical coordinates).

However, for the less experienced readers such a list of equations may not provide sufficient knowledge of the physical phenomena involved. Hence for that reason in the following sub-sections the governing equations are derived again from scratch utilizing the advantages of the different descriptions to improve the elementary understanding of the physical phenomena and the basic modeling principles.

At this point a few mathematical prerequisites are required before the derivation of the equations of change can be discussed. First, the three kinds of time derivatives involved in this task are defined. Secondly, the transport theorem is introduced. Let  $\psi = \psi(t, \mathbf{r})$  be a general scalar, vector or tensor function. By the *partial time derivative*,  $\partial\psi/\partial t$ , we mean the partial of  $\psi$  with respect to  $t$ , holding the independent space coordinate variables constant:  $\partial\psi/\partial t = \partial\psi/\partial t|_{\mathbf{r}}$ . In Cartesian coordinates<sup>2</sup> the *total time derivative* of  $\psi$  is defined by:

$$\frac{d\psi}{dt} = \frac{\partial\psi}{\partial t}\bigg|_{x,y,z} + \frac{\partial\psi}{\partial x} \frac{dx}{dt}\bigg|_{y,z,t} + \frac{\partial\psi}{\partial y} \frac{dy}{dt}\bigg|_{x,z,t} + \frac{\partial\psi}{\partial z} \frac{dz}{dt}\bigg|_{x,y,t} \quad (1.4)$$

in which  $dx/dt$ ,  $dy/dt$  and  $dz/dt$  are the components of the arbitrary velocity of a given particle as seen by an observer in a framework not necessary moving along with the fluid. The vector form is:

$$\frac{d\psi}{dt} = \frac{\partial\psi}{\partial t} + \mathbf{v}_S \cdot \nabla\psi \quad (1.5)$$

where  $\nabla$  is the gradient operator and  $\mathbf{v}_S$  denotes the arbitrary velocity.

In Cartesian coordinates the *substantial time derivative*,  $D/Dt$ , is given by:

$$\frac{D\psi}{Dt} = \frac{\partial\psi}{\partial t} + v_x \frac{\partial\psi}{\partial x} + v_y \frac{\partial\psi}{\partial y} + v_z \frac{\partial\psi}{\partial z} \quad (1.6)$$

in which  $v_x$ ,  $v_y$  and  $v_z$  are the components of the velocity of a given particle as seen by an observer in a framework moving along with the fluid. The substantial time derivative is a special kind of total time derivative and is sometimes more logically called the total derivative following the motion. In (1.6) the last three terms on the right hand side are called the convective derivative, since they vanish if the velocity is zero or if  $\psi$  has no spatial change. The first term on the right hand side is called the local derivative. The vector form is given by:

$$\frac{D\psi}{Dt} = \frac{\partial\psi}{\partial t} + \mathbf{v} \cdot \nabla\psi \quad (1.7)$$

where  $\nabla$  is the gradient operator.

To establish the relationship between the system and control volume representations we need to evaluate the rate of change of integrals of scalar and vector functions over a moving material volume occupied by fluid. Consider thus a material volume  $V(t)$  bounded by a smooth closed surface  $A(t)$  whose points at time  $t$  move with the material velocity  $\mathbf{v} = \mathbf{v}(\mathbf{r}, t)$  where  $\mathbf{r} \in A$ . The material time derivative of the integral of a scalar function  $f(\mathbf{r}, t)$  over the time-varying material volume  $V(t)$  is given by the transport theorem:

---

<sup>2</sup> In the Cartesian coordinate system the independent space coordinates are  $x$ ,  $y$  and  $z$ .

$$\frac{D}{Dt} \int_{V(t)} f(\mathbf{r}, t) dv = \int_V \frac{\partial f(\mathbf{r}, t)}{\partial t} dv + \int_A f(\mathbf{r}, t) (\mathbf{v} \cdot \mathbf{n}) da \quad (1.8)$$

The volume integral on the RHS is defined over a control volume  $V$  fixed in space, which coincides with the moving material volume  $V(t)$  at the considered instant,  $t$ , in time. Similarly, the fixed control surface  $A$  coincides at time  $t$  with the closed surface  $A(t)$  bounding the material volume  $V(t)$ . In the surface integral,  $\mathbf{n}$  denotes the unit outward normal to the surface  $A(t)$  at time  $t$ , and  $\mathbf{v}$  is the material velocity of points of the boundary  $A(t)$ . The first term on the RHS of (1.8) is the partial time derivative of the volume integral. The boundary integral represents the flux of the scalar quantity  $f$  across the fixed boundary of the control volume  $V$ .

Noting that by use of the Gauss theorem (App A) yields:

$$\int_A f(\mathbf{r}, t) (\mathbf{v} \cdot \mathbf{n}) da = \int_V \nabla \cdot (f\mathbf{v}) dV \quad (1.9)$$

the familiar form of the transport theorem can be obtained:

$$\frac{D}{Dt} \int_{V(t)} f(\mathbf{r}, t) dv = \int_V \left[ \frac{\partial f(\mathbf{r}, t)}{\partial t} + \nabla \cdot (f\mathbf{v}) \right] dv \quad (1.10)$$

The transient term on the RHS might be manipulated as the order in which the partial time derivation and the integration is performed can be reversed.

Similar forms of the transport theorem hold for the material derivative of the volume integral for vector and tensor quantities.

### 1.2.1 Conservation of Mass

The continuity equation for a mixture formulated in terms of the mass averaged mixture velocity has the same form as the continuity equation for single-component systems.

#### 1.2.1.1 System Analysis

The fundamental conservation of mass law for a multi-component system can be formulated employing the material Lagrangian framework (e.g., [11, 13, 91, 170]). The mixture mass  $M$  in a macroscopic material control volume  $V(t)$ , is given by:

$$M = \int_{V(t)} \rho dv \quad (1.11)$$

The *mass conservation principle* can then be formulated for the system considering the material control volume  $V(t)$  which is moving in space and bounded by a closed material surface  $A(t)$ :

$$\frac{DM}{Dt} = \frac{D}{Dt} \int_{V(t)} \rho dv = 0 \quad (1.12)$$

The *transport theorem* (1.10) enables the time rate of change of the material volume integral (1.12) to be transformed into the Eulerian formulation:

$$\frac{D}{Dt} \int_{V(t)} \rho dv = \int_V \left[ \frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) \right] dv = 0 \quad (1.13)$$

Equation (1.13) must be satisfied for any macroscopic volume  $V$ , thus the expressions inside the volume integral must be equal to zero. This result is termed the *equation of continuity* for a mixture, and is given by:

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = 0 \quad (1.14)$$

The fact that the control volume was fixed in space leads by definition to the specific differential form which is called the *conservative or flux form*.

### 1.2.1.2 Finite Eulerian Control Volume Analysis

The mixture mass  $M$  in a macroscopic Eulerian control volume  $V$ , at time  $t$  is given by:

$$M = \int_V \rho dv \quad (1.15)$$

In the Eulerian formulation the mass  $M$  can only be changed by convection across the CV surface considering non-nuclear-active materials. The conservation equation of mixture mass can thus be expressed like<sup>3</sup>:

$$\frac{\partial M}{\partial t} = \left[ \frac{\partial M}{\partial t} \right]_{\text{Convection}} \quad (1.16)$$

using a fractional time step notation for convenience.

---

<sup>3</sup> The partial time derivation can be performed before the integration since the integration limits are fixed and no longer depend on the independent variable,  $t$ .

The convective term is by definition given by:

$$\left[ \frac{\partial M}{\partial t} \right]_{\text{Convection}} = - \int_A (\rho \mathbf{v}) \cdot \mathbf{n} \, da \quad (1.17)$$

where  $\mathbf{n}$  is the outward directed normal unit vector to the surface of the fixed control volume.

The convective transport term in (1.17) can be transformed into a volume integral using Gauss' theorem (App A). The continuity equation (1.16), can then be expressed as:

$$\int_V \left[ \frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) \right] dv = 0 \quad (1.18)$$

Equation (1.18) must be satisfied for any macroscopic volume  $V$ , thus the expressions inside the volume integral must be equal to zero. The resulting differential equation coincides with (1.14), as expected.

### 1.2.1.3 Infinitesimal Eulerian Control Volume Analysis

We end this subsection deriving the convective mass flux terms over an infinitesimal Eulerian control volume element, intending to provide improved understanding of the physics and mathematical concepts involved. Note that even though we consider convective mass fluxes only at this point, the mathematical flux concepts are general. That is, all convective and diffusive fluxes can be derived in a similar manner.

As we adopt a Cartesian coordinate system, the velocity and density are functions of  $(x, y, z)$  space and time  $t$ . In this  $(x, y, z)$  space we have placed an infinitesimally control volume of sides  $dx$ ,  $dy$  and  $dz$  fixed in space, with the fluid moving through it as illustrated in Fig 1.2. Consider the left and right faces of the element which are perpendicular to the  $x$  axis. The area of these faces is  $dy \, dz$ . The mass flow through the left face is  $(\rho v_x) dy dz$ . Since the velocity and density are functions of spatial location, the value of the mass flux across the right face will be different from that across the left face. The difference in mass flux between the two faces is  $[\partial(\rho v_x)/\partial x] dx$ . Thus, the mass flow across the right face can be expressed as  $(\rho v_x + [\partial(\rho v_x)/\partial x] dx) dy dz$ . In a similar manner, the mass flow through both the bottom and top faces, which are perpendicular to the  $y$  axis, is  $(\rho v_y) dx dz$  and  $(\rho v_y + [\partial(\rho v_y)/\partial y] dy) dx dz$ , respectively. The mass flow through both the front and back faces, which are perpendicular to the  $z$  axis,  $(\rho v_z) dx dy$  and  $(\rho v_z + [\partial(\rho v_z)/\partial z] dz) dx dy$ , respectively. Note that  $v_x$ ,  $v_y$ , and  $v_z$  are positive, by convention, in the positive  $x$ ,  $y$ , and  $z$  directions, respectively. Hence, the arrows in Fig 1.2 show the contributions to the inflow and outflow of mass through the sides of the fixed element.

**Fig. 1.2** A physical model of an infinitesimal Eulerian control volume fixed in space indicating the convective mass fluxes through the various faces of the volume element, used for derivation of the continuity equation

*Net inflow in x direction:*

$$(\rho v_x)dydz - [\rho v_x + \frac{\partial(\rho v_x)}{\partial x}dx]dydz = -\frac{\partial(\rho v_x)}{\partial x}dxdydz \quad (1.19)$$

*Net inflow in y direction:*

$$(\rho v_y)dxdz - [\rho v_y + \frac{\partial(\rho v_y)}{\partial y}dy]dxdz = -\frac{\partial(\rho v_y)}{\partial y}dxdydz \quad (1.20)$$

*Net inflow in z direction:*

$$(\rho v_z)dxdy - [\rho v_z + \frac{\partial(\rho v_z)}{\partial z}dz]dxdy = -\frac{\partial(\rho v_z)}{\partial z}dxdydz \quad (1.21)$$

Hence, the net mass flow into the element is given by:

$$\text{Net mass inflow} = -[\frac{\partial(\rho v_x)}{\partial x} + \frac{\partial(\rho v_y)}{\partial y} + \frac{\partial(\rho v_z)}{\partial z}]dxdydz \quad (1.22)$$

The mixture mass of fluid in the infinitesimally small element is  $\rho (dx dy dz)$ , and the time rate of increase or accumulation of mass inside the element is given by:

$$\text{Time rate of mass increase} = \frac{\partial \rho}{\partial t}dxdydz \quad (1.23)$$

The physical principle that mass is conserved, when applied to the fixed element in Fig 1.2, can be expressed in words as follows: *the net mass flow into the element*

must equal the time rate of increase or accumulation of mass inside the element. This statement can mathematically be expressed as:

$$\frac{\partial \rho}{\partial t} dx dy dz = - \left[ \frac{\partial(\rho v_x)}{\partial x} + \frac{\partial(\rho v_y)}{\partial y} + \frac{\partial(\rho v_z)}{\partial z} \right] dx dy dz \quad (1.24)$$

or

$$\frac{\partial \rho}{\partial t} = - \left[ \frac{\partial(\rho v_x)}{\partial x} + \frac{\partial(\rho v_y)}{\partial y} + \frac{\partial(\rho v_z)}{\partial z} \right] \quad (1.25)$$

In (1.25), the terms inside the brackets can be reformulated by use of vector and tensor notations. By comparing the terms inside the brackets with the mathematical definitions of the *nabla* or *del* operator, the vector product between this nabla operator and the mass flux vector we recognize that these terms can be written as  $\nabla \cdot (\rho \mathbf{v})$ . The mass balance equation, (1.25), written in Cartesian coordinates can thus be rewritten in the general vector form as:

$$\frac{\partial \rho}{\partial t} = - \nabla \cdot (\rho \mathbf{v}) \quad (1.26)$$

We recall that the resulting equation is identical to the vector equation (1.14) formulated earlier based on a more direct mathematical approach.

### 1.2.2 Transport of Species Mass

The concentration of the various species in a multi-component mixture may be expressed in numerous ways. In this book the equations are formulated in terms of mass fluxes, thus mass concentrations are used. However, the equations could as well be formulated in terms of molar fluxes, and molar concentrations as usually applied in basic textbooks in Chemical Engineering (e.g., [11, 13, 170]). The mass concentration,  $\rho_c$ , is the mass of species  $c$  per unit of volume of solution. The species  $c$  mass density relates to the familiar molar concentration by the simple formula:  $C_c = \rho_c / M_{w_c}$ .  $M_{w_c}$  is the molecular weight of species  $c$ . The mass fraction,  $\omega_c = \rho_c / \rho$ , is the mass concentration of species  $c$  divided by the mixture mass density of the solution. The corresponding mole fraction,  $x_c = C_c / C$ , is the molar concentration of species  $c$  divided by the total molar concentration of the solution. The individual chemical species in a mixture moves at different velocities. The  $\mathbf{v}_c$  denotes the velocity of the species  $c$  with respect to stationary coordinate axes. Thus, for a mixture of  $N$  species, the local mass-average velocity  $\mathbf{v}$  is defined as:

$$\mathbf{v} = \frac{\sum_{c=1}^N \rho_c \mathbf{v}_c}{\sum_{c=1}^N \rho_c} = \frac{\sum_{c=1}^N \rho_c \mathbf{v}_c}{\rho} = \sum_{c=1}^N \omega_c \mathbf{v}_c \quad (1.27)$$

where  $\rho = \sum_{c=1}^N \rho_c$  is the mixture density.

In flow systems, one is frequently interested in the velocity of a given species with respect to  $\mathbf{v}$  rather than with respect to stationary coordinates. This leads to the definition of the diffusion velocities:

$$\mathbf{v}_{c,d} = \mathbf{v}_c - \mathbf{v} \quad (1.28)$$

These diffusion velocities indicate the motion of component  $c$  relative to the local motion of the mixture stream.

The mass flux of species  $c$  is a vector quantity denoting the mass of species  $c$  that passes through a unit area per unit time. The mass flux relative to stationary coordinates is defined by:

$$\mathbf{m}_c = \rho_c \mathbf{v}_c \quad (1.29)$$

where  $\rho_c$  is the mass concentration or density of species  $c$ .

The *relative* mass flux (concentration diffusion) is defined as:

$$\mathbf{j}_c^o = \rho_c (\mathbf{v}_c - \mathbf{v}) = \rho_c \mathbf{v}_{c,d} \quad (1.30)$$

The *convective* mass flux is thus defined by:

$$\rho_c \mathbf{v} = \mathbf{m}_c - \mathbf{j}_c^o \quad (1.31)$$

For binary mixtures the diffusive mass flux  $\mathbf{j}_c$  of species  $c$  is normally approximated by *Fick's first law*:

$$\mathbf{j}_c^o = -\rho D_c \nabla \omega_c \quad (1.32)$$

where the mass flux of species  $c$  is in the direction of decreasing concentration (which accounts for the minus sign). The quantity  $D_c$  is called the mass diffusion coefficient or diffusivity and has generally dimensions (length)<sup>2</sup>/time.

The rigorous kinetic theory, described in Sect. 2.9.5, shows that the net species *relative* mass flux in a multi-component mixture  $\mathbf{j}_c$  will consist of three contributions associated with the mechanical driving forces and an additional contribution associated with the thermal driving force:

$$\mathbf{j}_c = \mathbf{j}_c^o + \mathbf{j}_c^p + \mathbf{j}_c^g + \mathbf{j}_c^T \quad (1.33)$$

as explained by Hirschfelder et al. [68] and Bird et al. [11, 13].

The  $\mathbf{j}_c^o$  term denotes the *ordinary concentration diffusion* (i.e., multi-component mass diffusion). In general, the concentration diffusion contribution to the mass flux depends on the concentration gradients of all the substances present. However, in a few reactor systems, containing a solvent and one or only a few solutes having

relatively low concentrations, the binary form of Fick's law might be considered a sufficient approximation of the diffusive fluxes. Nevertheless, for most reactive systems of interest there are situations where a multi-component closure (e.g., a Stefan-Maxwell equation formulated in terms of mass average velocities) should be considered [167]. The *pressure diffusion* term  $\mathbf{j}_c^p$  accounts for the fact that there may be a net movement of the  $c$ 'th species in a mixture if there is a pressure gradient imposed on the system. The pressure diffusion effect is usually very small in chemical reactor systems as the local pressure gradients are much smaller than the concentration gradients. The pressure-diffusion proportionality coefficient is apparently much smaller than the mass diffusion coefficient. The *forced diffusion* term  $\mathbf{j}_c^g$  accounts for the fact that there may be a net movement of the  $c$ -th species in a mixture if there is an external force which is different for the individual species (e.g., electric field on an ionic system). This diffusion effect is seldom important in chemical reactor systems as only the gravity field is considered in most cases. The *thermal-diffusion* term  $\mathbf{j}_c^T$  describes the tendency for species to diffuse under the influence of a temperature gradient. The thermal-diffusion effect (or Soret effect) is usually neglected in chemical reactor systems because the thermal-diffusion coefficient is typically much smaller than the mass diffusion coefficient. In reactor modeling only the ordinary concentration diffusion term is generally considered, thus  $\mathbf{j}_c \approx \mathbf{j}_c^p$ . The rigorous kinetic theory model derivation for multi-component mixtures is outlined in Chap. 2. Meanwhile, the Fick's law for binary systems is used.

### 1.2.2.1 System Analysis

For an individual species  $c$  in a multi-component mixture the *species mass balance principle* postulates that the time rate of change of the mass of a system of species  $c$  is equal to the rate at which the mass of  $c$  is produced by homogeneous chemical reactions.

The species  $c$  mass in a macroscopic material control volume  $V_c(t)$  is given by:

$$M_c = \int_{V_c(t)} \rho_c dv \quad (1.34)$$

Let  $V_c(t)$  denote the material volume occupied by species  $c$  (see Fig 1.1b), and  $R_c$  denote the rate of production of species  $c$  per unit volume by homogeneous chemical reactions. The species mass balance can thus be expressed as:

$$\frac{DM_c}{Dt} = \frac{D}{Dt} \int_{V_c(t)} \rho_c dv = \int_{V_c(t)} R_c dv \quad (1.35)$$

To transform the system balance into an Eulerian control volume balance a particular form of the transport theorem applicable to single-phase systems of species  $c$  is

required [150]. Let  $f$  be any scalar, vector or tensor field. The transport theorem for species  $c$  can be expressed as:

$$\frac{D}{Dt} \int_{V_c(t)} f(\mathbf{r}, t) dv = \int_{V_c} \left[ \frac{\partial f(\mathbf{r}, t)}{\partial t} + \nabla \cdot (f \mathbf{v}_c) \right] dv \quad (1.36)$$

The transport theorem (1.36) enables the time rate of change in the species mass balance (1.35) to be transformed into the Eulerian formulation. Hence,

$$\int_{V_c} \left[ \frac{\partial \rho_c}{\partial t} + \nabla \cdot (\rho_c \mathbf{v}_c) - R_c \right] dv = 0 \quad (1.37)$$

Equation (1.37) must be satisfied for any macroscopic volume  $V_c$ , thus at each point the differential mass balance for species  $c$  yields:

$$\frac{\partial \rho_c}{\partial t} + \nabla \cdot (\rho_c \mathbf{v}_c) = R_c \quad (1.38)$$

The species  $c$  total mass flux can be divided into the sum of convective and diffusive fluxes in accordance with (1.30). The result is:

$$\frac{\partial \rho_c}{\partial t} + \nabla \cdot (\rho_c \mathbf{v}) + \nabla \cdot \mathbf{j}_c = R_c \quad (1.39)$$

This equation is the Eulerian species  $c$  mass balance equation.

### 1.2.2.2 Finite Eulerian Control Volume Analysis

The species  $c$  mass in a fixed macroscopic volume  $V_c$ , is given by:

$$M_c = \int_{V_c} \rho_c dv \quad (1.40)$$

The Eulerian (see Fig 1.1a) transport equation for the species  $c$  mass can be defined by:

$$\frac{\partial M_c}{\partial t} = \left[ \frac{\partial M_c}{\partial t} \right]_{\text{Convection}} + \left[ \frac{\partial M_c}{\partial t} \right]_{\text{Relative mass fluxes}} + \left[ \frac{\partial M_c}{\partial t} \right]_{\text{Reactions}} \quad (1.41)$$

The equation states that for non-nuclear-active mixtures the species  $c$  mass  $M_c$  can only be changed by convection and relative mass fluxes across the CV surface, and due to chemical reactions per unit volume.

The *convective term* can then be formulated as a surface integral, and converted to a volume integral by use of Gauss' theorem (App A):

$$\left[\frac{\partial M_c}{\partial t}\right]_{\text{Convection}} = - \int_{A_c} (\rho_c \mathbf{v}) \cdot \mathbf{n} \, da = - \int_{V_c} \nabla \cdot (\rho_c \mathbf{v}) \, dv \quad (1.42)$$

The *relative mass flux term* denotes the net rate of component  $c$  mass input per unit volume by concentration diffusion, pressure diffusion, forced diffusion and thermal diffusion can then be formulated as a surface integral, and converted to a volume integral by use of Gauss' theorem (App A):

$$\left[\frac{\partial M_c}{\partial t}\right]_{\text{Relative mass diffusion}} = - \int_{A_c} \mathbf{j}_c \cdot \mathbf{n} \, da = - \int_{V_c} \nabla \cdot \mathbf{j}_c \, dv \quad (1.43)$$

The *reaction rate term*, denoting the net rate of species  $c$  mass input per unit volume by chemical reactions is given by:

$$\left[\frac{\partial M_c}{\partial t}\right]_{\text{Reactions}} = \int_{V_c} R_c \, dv \quad (1.44)$$

The general form of the Eulerian transport equation for species  $c$  mass, can then be formulated as:

$$\begin{aligned} \frac{\partial M_c}{\partial t} &= \left[\frac{\partial M_c}{\partial t}\right]_{\text{Convection}} + \left[\frac{\partial M_c}{\partial t}\right]_{\text{Relative mass fluxes}} + \left[\frac{\partial M_c}{\partial t}\right]_{\text{Reactions}} \\ &= - \int_{V_c} \nabla \cdot (\rho_c \mathbf{v}) \, dv - \int_{V_c} \nabla \cdot \mathbf{j}_c \, dv + \int_{V_c} R_c \, dv \end{aligned} \quad (1.45)$$

or with a little reformulation:

$$\int_{V_c} \left[ \frac{\partial \rho_c}{\partial t} + \nabla \cdot (\rho_c \mathbf{v}) + \nabla \cdot \mathbf{j}_c - R_c \right] \, dv = 0 \quad (1.46)$$

Equation (1.46) must be satisfied for any macroscopic volume  $V_c$ , thus the expression inside the volume integral must be equal to zero. The resulting differential species mass balance coincides with (1.39).

Introducing the well known *Einstein summation notation* (e.g., described by [155]), the Cartesian form of the equation can be formulated

$$\frac{\partial \rho_c}{\partial t} + \frac{\partial (\rho_c v_i)}{\partial x_i} + \frac{\partial j_{c,i}}{\partial x_i} = R_c \quad (1.47)$$

where we have used the rigorous mathematical definitions of the Cartesian operators (e.g., [11]). The *divergence of a vector* is defined as:

$$\text{div}(\mathbf{j}_c) = \nabla \cdot \mathbf{j}_c = \sum_{i=1}^3 \frac{\partial j_{c,i}}{\partial x_i} = \frac{\partial j_{c,i}}{\partial x_i} = \frac{\partial j_{c,x}}{\partial x} + \frac{\partial j_{c,y}}{\partial y} + \frac{\partial j_{c,z}}{\partial z} \quad (1.48)$$

Similarly, the *gradient of a scalar* is defined as:

$$\text{grad}(\rho) = \nabla \rho = \sum_{i=1}^3 \frac{\partial \rho}{\partial x_i} \mathbf{e}_i = \frac{\partial \rho}{\partial x_i} \mathbf{e}_i = \frac{\partial \rho}{\partial x} \mathbf{e}_x + \frac{\partial \rho}{\partial y} \mathbf{e}_y + \frac{\partial \rho}{\partial z} \mathbf{e}_z \quad (1.49)$$

From these definitions we see that  $\text{grad}()$  is a vector while  $\text{div}()$  is a scalar quantity.

The sum of the transport equations for all the  $N$  species in the mixture equals the *continuity* equation:

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = 0 \quad (1.50)$$

where by definition the sum of the relative or diffusive mass fluxes vanishes. Thus,

$$\sum_{c=1}^N \mathbf{j}_c = 0 \quad (1.51)$$

and, due to the mass conservation law, the sum of the reaction rate terms is by definition zero:

$$\sum_{c=1}^N R_c = 0 \quad (1.52)$$

Again, the fundamental principles are confirmed since (1.50) equals (1.14).

### 1.2.2.3 The Molar Analog to the Species Mass Balance

The foregoing species mass balance development could equally well have been made in terms of molar units.

If  $r_A$  is the molar rate of production of A per unit volume, then the molar analog of (1.39) is:

$$\frac{\partial c_A}{\partial t} + \nabla \cdot (c_A \mathbf{v}^*) = -\nabla \cdot \mathbf{J}_A^* + r_A \quad (1.53)$$

in which  $c_A$  is the molar concentration of species A,  $\mathbf{v}^*$  is the molar average velocity, and  $\mathbf{J}_A^*$  is the molar diffusive flux relative to the molar average velocity.

Similarly, for species B, the species mole balance yields:

$$\frac{\partial c_B}{\partial t} + \nabla \cdot (c_B \mathbf{v}^*) = -\nabla \cdot \mathbf{J}_B^* + r_B \quad (1.54)$$

Adding these two equations gives the molar continuity equation:

$$\frac{\partial c}{\partial t} + \nabla \cdot (c \mathbf{v}^*) = r_A + r_B \quad (1.55)$$

in which  $\mathbf{J}_A^* + \mathbf{J}_B^* = 0$ , but  $r_A + r_B \neq 0$  as the total number of moles  $c$  is not necessarily a conservative property.

The molar average velocity is defined as:

$$\mathbf{v}^* = \frac{\sum_{i=1}^N c_i \mathbf{v}_i}{\sum_{i=1}^N c_i} = \frac{\sum_{i=1}^N c_i \mathbf{v}_i}{c} = \sum_{i=1}^N x_i \mathbf{v}_i \quad (1.56)$$

The mass average velocity (1.27) and the molar average velocity (1.56) are related by [13]:

$$\mathbf{v} - \mathbf{v}^* = \sum_{c=1}^N \omega_c (\mathbf{v}_c - \mathbf{v}^*) = \sum_{c=1}^N \omega_c \mathbf{v}_{d,c}^* \quad (1.57)$$

or

$$\mathbf{v}^* - \mathbf{v} = \sum_{c=1}^N x_c (\mathbf{v}_c - \mathbf{v}) = \sum_{c=1}^N x_c \mathbf{v}_{d,c} \quad (1.58)$$

The mole- and mass fractions are related by:

$$x_c = \frac{\omega_c / M_{w_c}}{\sum_{i=1}^N \omega_i / M_{w_i}} \quad \text{and} \quad \omega_c = \frac{x_c M_{w_c}}{\sum_{i=1}^N x_i M_{w_i}} \quad (1.59)$$

The mixture molar weight can thus be computed as:

$$M_w = \sum_{i=1}^N x_i M_{w_i} = \left[ \sum_{i=1}^N \omega_i / M_{w_i} \right]^{-1} \quad (1.60)$$

### 1.2.3 Conservation of Momentum

The equation of motion is examined in this section.

#### 1.2.3.1 System Analysis

The momentum associated with a material control volume  $V(t)$  is defined by:

$$\mathbf{P} = \int_{V(t)} \rho \mathbf{v} dv \quad (1.61)$$

The basis for any derivation of the momentum equation is the relation commonly known as *Newton's second law of motion* which in the material Lagrangian form (see Fig 1.1b) expresses a proportionality between the applied forces and the resulting acceleration of a fluid particle with momentum density,  $\mathbf{P}$  (e.g., [91]):

$$\frac{D\mathbf{P}}{Dt} = \frac{D}{Dt} \int_{V(t)} (\rho \mathbf{v}) dv = \mathbf{f} \quad (1.62)$$

where  $\mathbf{f}$  is the net force acting on the fluid in the control volume.

Again, the system balance can be transformed into an Eulerian control volume balance by use of the transport theorem (1.10). Hence,

$$\frac{D}{Dt} \int_{V(t)} (\rho \mathbf{v}) dv = \int_{V(t)} \left[ \frac{\partial(\rho \mathbf{v})}{\partial t} + \nabla \cdot (\rho \mathbf{v} \mathbf{v}) \right] dv = \int_{V(t)} \mathbf{F} dv \quad (1.63)$$

where  $\mathbf{F}$  is the net force per unit volume acting on the fluid within the control volume.

That is,

$$\mathbf{f} = \int_{V(t)} \mathbf{F} dv \quad (1.64)$$

Preliminarily, we keep the force undefined as our main purpose in this paragraph is to show the connection between the two formulations. The physical forces will be considered shortly.

The relation (1.63) must be satisfied for any macroscopic volume  $V(t)$ , so at each point the differential momentum balance yields:

$$\frac{\partial(\rho \mathbf{v})}{\partial t} + \nabla \cdot (\rho \mathbf{v} \mathbf{v}) = \mathbf{F} \quad (1.65)$$

This is the Eulerian control volume form of the momentum conservation equation.

### 1.2.3.2 Finite Eulerian Control Volume Analysis

The mixture momentum associated with an Eulerian control volume  $V$ , at time  $t$ , is given by:

$$\mathbf{P} = \int_V (\rho \mathbf{v}) dv \quad (1.66)$$

Hence, the Eulerian (see Fig 1.1a) momentum balance equation is written considering a fixed control volume  $V$ :

$$\begin{aligned} \frac{\partial \mathbf{P}}{\partial t} &= \left[ \frac{\partial \mathbf{P}}{\partial t} \right]_{\text{Convection}} + \mathbf{f}_{\text{Forces}} \\ &= \left[ \frac{\partial \mathbf{P}}{\partial t} \right]_{\text{Convection}} + \mathbf{f}_{\text{Body Forces}} + \mathbf{f}_{\text{Surface Forces}} \end{aligned} \quad (1.67)$$

The equation states that the momentum density  $\rho \mathbf{v}$  can only be changed by convection across the CV surface and by the applied forces per unit volume on the fluid particle. The force term consists of two groups of forces. *The body forces* are due to external fields such as gravity or an applied electro-magnetic potential and act on the entire volume of the fluid element. *The surface forces* are applied by external stresses on the surfaces of the volume element.

*The convective term* can then be formulated as a surface integral (analogous to the mass flux formulation, Fig 1.2), and converted to a volume integral by use of Gauss' theorem (App A):

$$\left[ \frac{\partial \mathbf{P}}{\partial t} \right]_{\text{Convection}} = - \int_A (\rho \mathbf{v} \mathbf{v}) \cdot \mathbf{n} da = - \int_V \nabla \cdot (\rho \mathbf{v} \mathbf{v}) dv \quad (1.68)$$

The last term is somewhat complicated containing a *dyadic product*,  $\mathbf{v} \mathbf{v}$ . To be able to reformulate this expression into Cartesian coordinates we have to apply rigorous mathematical algorithms.

Using the algorithm given by Bird et al. [11, 13], the component form is given by:

$$\begin{aligned} \nabla \cdot (\rho \mathbf{v} \mathbf{v}) &= \sum_{i=1}^3 \mathbf{e}_i \frac{\partial}{\partial x_i} \cdot \sum_{j=1}^3 \sum_{k=1}^3 \mathbf{e}_j \mathbf{e}_k (\rho v_j v_k) = \sum_{i=1}^3 \sum_{j=1}^3 \sum_{k=1}^3 (\mathbf{e}_i \cdot \mathbf{e}_j) \mathbf{e}_k \frac{\partial}{\partial x_i} (\rho v_j v_k) \\ &= \sum_{i=1}^3 \sum_{j=1}^3 \sum_{k=1}^3 \delta_{ij} \mathbf{e}_k \frac{\partial}{\partial x_i} (\rho v_j v_k) = \sum_{k=1}^3 \mathbf{e}_k \sum_{i=1}^3 \frac{\partial}{\partial x_i} (\rho v_i v_k) \end{aligned} \quad (1.69)$$

hence the  $k$ th component of  $\nabla \cdot (\rho \mathbf{v} \mathbf{v})$  is  $[\nabla \cdot (\rho \mathbf{v} \mathbf{v})]_k = \sum_{i=1}^3 \frac{\partial}{\partial x_i} (\rho v_i v_k)$  where  $\mathbf{e}_k$  is the unit vector in the  $k$  direction.

The  $\delta_{ij}$  is the *Kronecker delta* defined as:

$$\delta_{ij} = \begin{cases} 1 & \text{if } i = j, \text{ and} \\ 0 & \text{if } i \neq j. \end{cases} \quad (1.70)$$

From the geometrical definition of the vector scalar- or dot product between the unit vectors, we can write:

$$(\mathbf{e}_i \cdot \mathbf{e}_j) = \delta_{ij} \quad (1.71)$$

The *body force terms* on unit volume basis are usually formulated in terms of the body forces per unit mass (e.g., [11, 170]):

$$\mathbf{f}_{\text{Body Forces}} = \left[ \frac{\partial \mathbf{P}}{\partial t} \right]_{\text{Body Forces}} = \int_V \sum_{c=1}^N \rho_c \mathbf{g}_c dv \quad (1.72)$$

where  $\mathbf{g}_c$  is the total sum of body forces per unit mass. In this term account is taken of the fact that each chemical species present may be acted on by different body forces per unit mass. Considering the gravitational body force only,  $\mathbf{g}_c$ , becomes the vector acceleration of gravity which is the same for all species.

The *surface force terms* per unit volume basis can be formulated as a surface integral in terms of the total stress tensor  $\mathbf{T}$ , and then converted to a volume integral by use of Gauss' theorem (App A):

$$\mathbf{f}_{\text{Surface Forces}} = \left[ \frac{\partial \mathbf{P}}{\partial t} \right]_{\text{Surface Forces}} = - \int_A \mathbf{T} \cdot \mathbf{n} da = - \int_V \nabla \cdot \mathbf{T} dv \quad (1.73)$$

Stresses are the forces tending to produce deformation in a body, measured as a force per unit area. The total stress tensor,  $\mathbf{T}$ , is thus interpreted physically as the surface forces per surface unit acting through the infinitesimal surface on the surrounding fluid with normal unit vector  $\mathbf{n}$  directed out of the CV. This means that the total stress tensor by definition acts on the surrounding fluid. The counteracting force on the fluid element (CV) is therefore expressed in terms of the total stress tensor by introducing a minus sign in (1.73). The physical interpretation of tensors are not always obvious. We will therefore pay some attention to the definition of such a quantity in the hope of improving our understanding. From basic mathematics (e.g., [3]) we recall that a Cartesian vector, as the velocity  $\mathbf{v}$ , in three dimensions is a quantity with three components,  $v_x$ ,  $v_y$  and  $v_z$  can collectively be written as:

$$\mathbf{v} = \sum_{i=1}^3 v_i \mathbf{e}_i \quad (1.74)$$

The vector  $\mathbf{v}$  is regarded as an entity, just as the physical quantity it represents is an entity. Similarly, a second order Cartesian tensor, as the stress tensor, is defined as an entity having nine components:

$$\mathbf{T} = \sum_{i=1}^3 \mathbf{T}_i \mathbf{e}_i = \sum_{i=1}^3 \sum_{j=1}^3 T_{ij} \mathbf{e}_i \mathbf{e}_j \quad (1.75)$$

Note that scalars and vectors can be looked upon as tensors of zero and first order, respectively.

To proceed formulating the momentum equation we need a relation defining the total stress tensor in terms of the known dependent variables, *a constitutive relationship*. In contrast to solids, a fluid tends to deform when subjected to a shear stress. Proper constitutive laws have therefore traditionally been obtained by establishing *the stress-strain relationships* (e.g., [11–13, 91, 105, 183]), relating the total stress tensor  $\mathbf{T}$  to the rate of deformation (sometimes called rate of strain, i.e., giving the name of this relation) of a fluid element. However, the resistance to deformation is a property of the fluid. For some fluids, *Newtonian fluids*, the viscosity is independent both of time and the rate of deformation. For *non-Newtonian fluids*, on the other hand the viscosity may be a function of the prehistory of the flow (i.e., a function both of time and the rate of deformation).

The total stress tensor (i.e., force due to the stresses per surface unit, sometimes called ‘traction’) has commonly been divided into two components; *the hydrostatic pressure*,  $p\mathbf{e}$ , and *the viscous stress*,  $\boldsymbol{\sigma}$ , tensors [11]:

$$\mathbf{T} = p\mathbf{e} + \boldsymbol{\sigma} \quad (1.76)$$

The first term on the right hand side denotes the pressure and is well known from thermodynamics. Pressure is a type of stress that can act on a fluid at rest. For an infinitesimally small fluid element, being in a state of local equilibrium, pressure acts equally in all directions. Characteristics such as pressure that are the same in all directions are said to be *isotropic*. Note, however, that this assumption is rigorously only justified for systems consisting of spherical molecules or at very low densities. For other systems, the pressure tensor may contain an anti-symmetric part [32]. Pressure is a scalar quantity since it is not dependent on direction, and we need just one number to describe it at any point in space and time. The second term on the right hand side denotes the viscous stresses, which exist when there are shearing motions in the fluid. The result of this stress is a deformation of the fluid. When one portion of a fluid moves, the intermolecular forces due to internal friction tend to drag adjacent fluid molecules in the same direction. The strength of these intermolecular forces depend on the nature of the fluid, and they determine the internal energy dissipation rate in

the fluid relaxing the system towards a state of global thermodynamic equilibrium. Based on physical analysis, for example considering a conceptual cube, it has been found that these viscous forces can act in any of the three Cartesian directions on any of the three faces (as indicated in Fig 1.3). This is one of the mathematical characteristics of a tensor, thus the viscous stress is a tensor with nine components. From a microscopic point of view one can say that the pressure tensor results from the short-range interactions between the molecules of the system, whereas the viscous term contain long-range interactions in the system [32].

A lot of confusion is related to the fact that several similar, but not equal, definitions of the total stress tensor have been observed in the literature. The different definitions deviate due to the introduction of pre factors of  $-1$  and/or  $\frac{1}{2}$ . In this book the definition of Bird et al. [11, 13] is used. There are three reasons why the adopted convention is preferred. Firstly, this convention is commonly used in chemical engineering. Secondly, in heat conduction described by Fourier's law it is customary to define the heat flux to be positive in the direction of decreasing temperature, when the heat is moving in the positive space directions. Similarly, in species mass diffusion described by Fick's law the mass flux is defined as positive in the direction of decreasing concentration, when the mass is moving in the positive space directions. Therefore in a shear flow it seems natural to define the total stress tensor so that it is positive in the direction of decreasing velocity. Thus, the laws for all three transport phenomena are formulated with the same sign convention. Thirdly, when the total stress tensor is divided into two parts, a pressure contribution and a viscous contribution, both parts have the same sign. In this way, the sign convention used here is in accordance with the sign convention normally applied in thermodynamics. That is, compression is positive in both terms. This generalized form of the so-called *deformation law* have been used for most fluids, whereas the formulation of the  $\sigma$  term contains different expressions accounting for the various properties of the fluids. Since the Newtonian formulation is the simplest, and this law is satisfied by all gases and most common fluids [183] this formulation has been implemented into the majority of the existing Computational Fluid Dynamic (CFD) program codes. When the momentum equation appears without a specific stress law (not even divided into pressure and viscous parts), it is known as *Cauchy's equation* (e.g., [3] and [105], p. 214). The constitutive equation for a Newtonian fluid in vector form is formulated by use of sophisticated tensor analysis (e.g., [2, 11, 91, 94, 183]). The following expression for the viscous stress tensor is applied:

$$\sigma = -\mu[\nabla \mathbf{v} + (\nabla \mathbf{v})^T] + \left(\frac{2}{3}\mu - \mu_B\right)(\nabla \cdot \mathbf{v})\mathbf{e} \quad (1.77)$$

where  $\mu_B$  is known as the bulk viscosity, dilatational viscosity or second viscosity. The bulk viscosity is identically zero (shown by kinetic theory) for low density mono atomic gases and is probably not too important in dense gases and liquids (e.g., [11]). The bulk viscosity is usually negligible in combustion processes [91]. Therefore, the parameter is set to zero for most reactor models too.

The quantity:

$$\gamma = \nabla \mathbf{v} + (\nabla \mathbf{v})^T \quad (1.78)$$

is defined as *the rate of deformation (or rate of strain)*. Note, in some sciences it is common practice to define this variable deviating from this definition by a pre factor of  $\frac{1}{2}$ .

The component form of the dyadic product,  $\nabla \mathbf{v}$ , is given by:

$$\nabla \mathbf{v} = \sum_{i=1}^3 \sum_{j=1}^3 \frac{\partial}{\partial x_i} v_j \mathbf{e}_i \mathbf{e}_j \quad (1.79)$$

The surface force term is then given by:

$$\begin{aligned} \mathbf{f}_{\text{Surface Forces}} &= \left[ \frac{\partial \mathbf{P}}{\partial t} \right]_{\text{Surface Forces}} = - \int_V \nabla \cdot \mathbf{T} \, dv \\ &= - \int_V \nabla \cdot (p \mathbf{e}) \, dv - \int_V \nabla \cdot \boldsymbol{\sigma} \, dv \\ &= - \int_V \nabla p \, dv - \int_V \nabla \cdot \boldsymbol{\sigma} \, dv \\ &= - \int_V \nabla p \, dv + \int_V \nabla \cdot (\mu [\nabla \mathbf{v} + (\nabla \mathbf{v})^T]) \, dv \\ &\quad + \int_V \nabla \cdot \left[ (\mu_B - \frac{2}{3} \mu) (\nabla \cdot \mathbf{v}) \right] \, dv \end{aligned} \quad (1.80)$$

Applying the tensor algorithm given by [11, 13], the component form is given by:

$$\begin{aligned} \nabla \cdot \mathbf{T} &= \sum_{i=1}^3 \mathbf{e}_i \frac{\partial}{\partial x_i} \cdot \sum_{j=1}^3 \sum_{k=1}^3 \mathbf{e}_j \mathbf{e}_k T_{jk} = \sum_{i=1}^3 \sum_{j=1}^3 \sum_{k=1}^3 (\mathbf{e}_i \cdot \mathbf{e}_j) \mathbf{e}_k \frac{\partial}{\partial x_i} T_{jk} \\ &= \sum_{i=1}^3 \sum_{j=1}^3 \sum_{k=1}^3 \delta_{ij} \mathbf{e}_k \frac{\partial}{\partial x_i} T_{jk} = \sum_{k=1}^3 \mathbf{e}_k \sum_{i=1}^3 \frac{\partial}{\partial x_i} T_{ik} \end{aligned} \quad (1.81)$$

hence the  $j$ th component of  $\nabla \cdot \mathbf{T}$  is  $[\nabla \cdot \mathbf{T}]_j = \sum_{i=1}^3 \frac{\partial T_{ij}}{\partial x_i}$ . Note that by convenience we simply changed the index denoting the direction of the stress from  $k$  to  $j$  in the mathematical operation above.

The total stress tensor written in Cartesian tensor notation is formulated:

$$T_{ij} = p\delta_{ij} - \mu\left(\frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i}\right) - \left(\mu_B - \frac{2}{3}\mu\right)\frac{\partial v_k}{\partial x_k}\delta_{ij} \quad (1.82)$$

where  $T_{ij}$  is the total stress acting in the positive  $j$ th direction on a face normal to the  $i$  axis.

The total stress tensor is a symmetric tensor (i.e.,  $T_{ij} = T_{ji}$ ), and in Cartesian coordinates it can thus be written:

$$T_{ij} = \begin{pmatrix} T_{xx} & T_{yx} & T_{zx} \\ T_{xy} & T_{yy} & T_{zy} \\ T_{xz} & T_{yz} & T_{zz} \end{pmatrix} = \begin{pmatrix} T_{xx} & T_{xy} & T_{xz} \\ T_{yx} & T_{yy} & T_{yz} \\ T_{zx} & T_{zy} & T_{zz} \end{pmatrix} \quad (1.83)$$

where the rows in the array correspond to the applied force (per surface unit) in each coordinate direction. The surface forces acting in the  $x$ -direction on the faces of the Cartesian fluid element, CV, are sketched Fig. 1.3.

As before, the convention used here is that  $T_{ij}$  denotes the total stress in the  $j$  direction exerted on a plane perpendicular to the  $i$  axis. Recall that the shear stresses are related to the time rate of change of the shearing deformation of the fluid element, whereas the normal stresses are related to the time rate of change of volume of the fluid element. As a result, both shear and normal stresses depend on velocity gradients in the flow. In most viscous flows, normal stresses are much smaller than shear stresses and usually neglected. The normal stresses may however become important when the normal velocity gradients are very large.

The surface forces which act directly on the surface of the fluid element are, as mentioned earlier, due to two sources only. The pressure distribution acting on the surface, imposed by the outside fluid surrounding the fluid element, and the viscous shear and normal stresses distribution acting on the surface imposed by outside fluid tugging or pushing on the surface by means of friction [2]. Before we proceed explaining the physical mechanism of the surface stresses, attention is put on the sign convention adopted regarding the direction of the stresses on the control volume surface. Contrary to the more common sign conventions applied for the surface stresses in standard literature on fluid mechanics (e.g., [2], pp. 60–66; [183], pp. 65–72; [184], pp. 225–230), the sign convention used here for the total stress tensor follow the approach introduced by [11, 13]. Therefore, a pre factor of  $-1$  have been implemented for the total stress tensor acting on the fluid element, in contrast to the standard convention that positive stresses act on the fluid element surfaces. By substitution of the given closures, the general form of the Eulerian conservation equation for the momentum density,  $\rho\mathbf{v}$ , can be formulated as:

$$\begin{aligned} \frac{\partial \mathbf{P}}{\partial t} &= \left[\frac{\partial \mathbf{P}}{\partial t}\right]_{\text{Convection}} + \left[\frac{\partial \mathbf{P}}{\partial t}\right]_{\text{Body Forces}} + \left[\frac{\partial \mathbf{P}}{\partial t}\right]_{\text{Surface Forces}} \\ &= - \int_V \nabla \cdot (\rho \mathbf{v} \mathbf{v}) dv + \int_V \sum_{c=1}^N \rho_c \mathbf{g}_c dv - \int_V \nabla p dv - \int_V \nabla \cdot \boldsymbol{\sigma} dv \end{aligned} \quad (1.84)$$

**Fig. 1.3** A sketch of a Cartesian fixed control volume showing the surface forces acting on a moving fluid element. This figure is based on the illustrations of the surface forces given in the textbooks on fluid mechanics by [2], pp. 60–66; [183], pp. 65–72; [184], pp. 225–230. However, contrary to the usual sign conventions applied in these books, the sign convention used in this book for the total stress tensor follows the approach given by Bird et al. [11, 13]. Therefore, a pre factor of  $-1$  have been introduced for the forces in the figure. Only the surface forces in the  $x$ -direction are shown

or with a little rearranging of the terms:

$$\int_V \left[ \frac{\partial(\rho \mathbf{v})}{\partial t} + \nabla \cdot (\rho \mathbf{v} \mathbf{v}) + \nabla p + \nabla \cdot \boldsymbol{\sigma} + \sum_{c=1}^N \rho_c \mathbf{g}_c \right] dv = 0 \quad (1.85)$$

Equation (1.85) must be satisfied for any macroscopic volume  $V$ , thus the expression inside the volume integral must be equal to zero. The result is known as the *momentum equation*:

$$\frac{\partial(\rho \mathbf{v})}{\partial t} + \nabla \cdot (\rho \mathbf{v} \mathbf{v}) = -\nabla p - \nabla \cdot \boldsymbol{\sigma} + \sum_{c=1}^N \rho_c \mathbf{g}_c \quad (1.86)$$

This relation coincides with (1.65) provided that the formulas for the forces are substituted into the latter one.

The physical meaning of the terms in the momentum equation (1.86) is inferred from the above modeling analysis. *The first term on the LHS* denotes the rate of accumulation of momentum within the control volume per unit volume; *the second term on the LHS* denotes the net rate of momentum increase by convection per unit volume; *the first term on the RHS* denotes the pressure force acting on the control volume per unit volume; *the second term on the RHS* denotes the viscous force acting on the control volume per unit volume; and *the third term on the RHS* denotes the external body forces acting on the control volume per unit volume.

### 1.2.3.3 Infinitesimal Eulerian Control Volume Stress Analysis

For someone the physical meaning of the surface stresses might be intuitive and best explained formulating a stress balance over an infinitesimal Eulerian control volume. Considering the surface forces in the  $x$ -direction exerted on the fluid element as sketched in Fig. 1.3, the physical mechanisms of the various stresses are described in the following. At this point it may be informative to split the total stress tensor into two contributions, the viscous normal stresses and the pressure (note, only the net surface forces expressed in terms of the total stress tensor is indicated in Fig. 1.3). The pressure is imposed by the outside fluid surrounding the fluid element, and is thus always defined positive acting on the fluid element. Considering the face *adhe*, which is perpendicular to the  $x$  axis, both the pressure and the viscous normal stresses act in the  $x$ -direction. The negative total stress tensor contains a negative pressure component that acts in the negative direction of the axis (to the left). The pressure negative force,  $-pdydz$ , acts in the direction out of the fluid element. Considering the face *bcgf* the negative total stress tensor contains a negative pressure component that acts in the positive direction of the axis (to the right). The negative pressure force,  $-[p + (\partial p/\partial x)dx]dydz$ , acts in the direction out of the fluid element. The viscous stresses are defined in agreement with the convention that negative viscous stresses act in the direction of decreasing velocity ([2], pp. 60–66), and that an increase in all three components of velocity,  $v_x$ ,  $v_y$ , and  $v_z$ , occur in the positive directions of the axes. The direction of the viscous stresses acting on the *adhe* face can then be determined in the following way. When  $v_x$  increases in the positive  $x$ -direction,  $v_x$  is lower just in front of the face than on the face itself. This causes a retarding or dragging action on the fluid element, which acts in the negative  $x$ -direction (to the left). The negative total stress tensor contains a negative viscous stress component that acts in the negative  $x$ -direction,  $-\sigma_{xx}dydz$ . Considering the viscous stresses acting on the *bcgf* face,  $v_x$  still increases in the positive  $x$ -direction.  $v_x$  will now be higher just outside the face than on the face itself. This causes a tugging action (i.e., the fluid outside the CV moves outwards with a velocity higher than the CV surface velocity and the intermolecular forces due to internal friction in the fluid tend to drag adjacent fluid molecules out of the fluid element in the same direction) on the fluid element, which tries to pull the fluid element in the positive  $x$ -direction (to the right). The negative total

stress tensor contains a negative viscous stress component that acts in the positive  $x$ -direction,  $-\left[\sigma_{xx} + (\partial\sigma_{xx}/\partial x)dx\right]dydz$ . According to the conventions mentioned above,  $v_x$  increases in the positive  $y$  direction. Therefore, concentrating on face  $efgh$ ,  $v_x$  is higher just above the face than on the face itself. This causes a tugging action on the fluid element, which tries to pull the fluid element in the positive  $x$ -direction (to the right). The negative total stress tensor contains a negative viscous stress component that acts in the positive  $x$ -direction. Face  $efgh$  is a distance  $dy$  above face  $abcd$ . The shear force in the  $x$ -direction on a face  $efgh$  is:  $-\left[\sigma_{yx} + (\partial\sigma_{yx}/\partial y)dy\right]dxdz$ . In turn, concentrating on face  $abcd$ ,  $v_x$  is lower just beneath the face than on the face itself. This causes a retarding or dragging action on the fluid element, which acts in the negative  $x$ -direction (to the left). On the face  $abcd$  the only force in the  $x$ -direction is that due to tangential (or shear) stresses  $-\sigma_{yx}dxdz$ . The directions of all the other stresses can be justified in a similar way.

With the above physical interpretation in mind, considering the front faces of a cubic CV, the surface force components due to the surface stresses are [2, 183]:

$$\begin{aligned} f_{\text{Front Surface Force},x} &= -T_{xx}dydz - T_{yx}dxdz - T_{zx}dxdy \\ f_{\text{Front Surface Force},y} &= -T_{xy}dydz - T_{yy}dxdz - T_{zy}dxdy \\ f_{\text{Front Surface Force},z} &= -T_{xz}dydz - T_{yz}dxdz - T_{zz}dxdy \end{aligned} \quad (1.87)$$

For an element in equilibrium, these forces would be balanced by equal and opposite forces on the back faces of the element. If the element is accelerating, however, the front- and back- face stresses are different by differential amounts:

$$\begin{aligned} f_{\text{Back Surface Force},x+dx} &= -\left[T_{xx} + \frac{\partial T_{xx}}{\partial x}dx\right]dydz - \left[T_{yx} + \frac{\partial T_{yx}}{\partial y}dy\right]dxdz - \left[T_{zx} + \frac{\partial T_{zx}}{\partial z}dz\right]dxdy \\ f_{\text{Back Surface Force},y+dy} &= -\left[T_{xy} + \frac{\partial T_{xy}}{\partial x}dx\right]dydz - \left[T_{yy} + \frac{\partial T_{yy}}{\partial y}dy\right]dxdz - \left[T_{zy} + \frac{\partial T_{zy}}{\partial z}dz\right]dxdy \\ f_{\text{Back Surface Force},z+dz} &= -\left[T_{xz} + \frac{\partial T_{xz}}{\partial x}dx\right]dydz - \left[T_{yz} + \frac{\partial T_{yz}}{\partial y}dy\right]dxdz - \left[T_{zz} + \frac{\partial T_{zz}}{\partial z}dz\right]dxdy \end{aligned} \quad (1.88)$$

A net surface force on the element can now be obtained using the relations derived for the forces acting on the front and back faces. That is, the leftward force on the left face is balanced by the rightward force on the right face, leaving only the net rightward force on the right face.

Similar force balances can be formulated on the other four faces and for the other two axes directions, so that the net force on the control volume in each direction is due to three derivative terms:

$$\begin{aligned}
f_{\text{Surface Force},x} &= -f_{\text{Front Surface Force},x} + f_{\text{Back Surface Force},x+dx} \\
&= -\left(\frac{\partial T_{xx}}{\partial x} dx\right) dy dz - \left(\frac{\partial T_{yx}}{\partial y} dy\right) dx dz - \left(\frac{\partial T_{zx}}{\partial z} dz\right) dx dy \\
f_{\text{Surface Force},y} &= -f_{\text{Front Surface Force},y} + f_{\text{Back Surface Force},y+dy} \\
&= -\left(\frac{\partial T_{xy}}{\partial x} dx\right) dy dz - \left(\frac{\partial T_{yy}}{\partial y} dy\right) dx dz - \left(\frac{\partial T_{zy}}{\partial z} dz\right) dx dy \\
f_{\text{Surface Force},z} &= -f_{\text{Front Surface Force},z} + f_{\text{Back Surface Force},z+dz} \\
&= -\left(\frac{\partial T_{xz}}{\partial x} dx\right) dy dz - \left(\frac{\partial T_{yz}}{\partial y} dy\right) dx dz - \left(\frac{\partial T_{zz}}{\partial z} dz\right) dx dy
\end{aligned}$$

or, on a unit volume basis, dividing by  $dx dy dz$ , yields:

$$\begin{aligned}
F_{\text{Surface Force},x} &= -\frac{\partial T_{xx}}{\partial x} - \frac{\partial T_{yx}}{\partial y} - \frac{\partial T_{zx}}{\partial z} \\
F_{\text{Surface Force},y} &= -\frac{\partial T_{xy}}{\partial x} - \frac{\partial T_{yy}}{\partial y} - \frac{\partial T_{zy}}{\partial z} \\
F_{\text{Surface Force},z} &= -\frac{\partial T_{xz}}{\partial x} - \frac{\partial T_{yz}}{\partial y} - \frac{\partial T_{zz}}{\partial z}
\end{aligned} \tag{1.89}$$

which we note is equivalent to taking the divergence of the vector  $\mathbf{T}_k$ , the  $k$  component of the tensor  $\mathbf{T}$ .

Hence, the net surface force yields [11]:

$$\begin{aligned}
\mathbf{F}_{\text{Surface Force},k} &= -\nabla \cdot \mathbf{T}_k = -\sum_{i=1}^3 \mathbf{e}_i \frac{\partial}{\partial x_i} \cdot \sum_{j=1}^3 T_{jk} \mathbf{e}_j = -\sum_{i=1}^3 \sum_{j=1}^3 (\mathbf{e}_i \cdot \mathbf{e}_j) \frac{\partial}{\partial x_i} T_{jk} \\
&= -\sum_{i=1}^3 \sum_{j=1}^3 \delta_{ij} \frac{\partial T_{jk}}{\partial x_i} = -\sum_{i=1}^3 \frac{\partial T_{ik}}{\partial x_i}
\end{aligned} \tag{1.90}$$

which is one of the total stress tensor components expressed in terms of the upper row of the total stress tensor. Note that  $\mathbf{T}_k$  denotes the tensor component  $k$  (i.e., a vector) which in Cartesian coordinates may be  $x$ ,  $y$  or  $z$ . To avoid any misunderstanding in formulating of the components of the vectors and tensors we have applied the index  $k$  denoting the direction of the stresses, instead of  $j$ . The vector form of the momentum equation, adopted in (1.73), can now be obtained by comparing (1.90) and (1.81).

The components of the total stress tensor for Newtonian fluids in Cartesian coordinates  $(x, y, z)$  are defined as (e.g., [11, 13]):

$$T_{xx} = p + \sigma_{xx} = p - \mu \left[ 2 \frac{\partial v_x}{\partial x} - \frac{2}{3} (\nabla \cdot \mathbf{v}) \right] \tag{1.91}$$

$$T_{yy} = p + \sigma_{yy} = p - \mu \left[ 2 \frac{\partial v_y}{\partial y} - \frac{2}{3} (\nabla \cdot \mathbf{v}) \right] \quad (1.92)$$

$$T_{zz} = p + \sigma_{zz} = p - \mu \left[ 2 \frac{\partial v_z}{\partial z} - \frac{2}{3} (\nabla \cdot \mathbf{v}) \right] \quad (1.93)$$

$$T_{xy} = \sigma_{xy} = T_{yx} = \sigma_{yx} = -\mu \left[ \frac{\partial v_x}{\partial y} + \frac{\partial v_y}{\partial x} \right] \quad (1.94)$$

$$T_{yz} = \sigma_{yz} = T_{zy} = \sigma_{zy} = -\mu \left[ \frac{\partial v_y}{\partial z} + \frac{\partial v_z}{\partial y} \right] \quad (1.95)$$

$$T_{zx} = \sigma_{zx} = T_{xz} = \sigma_{xz} = -\mu \left[ \frac{\partial v_z}{\partial x} + \frac{\partial v_x}{\partial z} \right] \quad (1.96)$$

$$(\nabla \cdot \mathbf{v}) = \frac{\partial v_x}{\partial x} + \frac{\partial v_y}{\partial y} + \frac{\partial v_z}{\partial z} \quad (1.97)$$

### 1.2.4 Conservation of Total Energy

The balance principle, that is well known from the previous discussion, underlie any fundamental formulation of the total energy balance or conservation equation. Starting out from fluid dynamic theory the resulting partial differential equation contains unknown terms that need further consideration. We need a sound procedure for the formulation of closure laws. Introductory it is noted that the constitutive relations we are assessing have traditionally been investigated by researchers in thermodynamics rather than fluid mechanics. This has the unfortunate consequence that the descriptions of these constitutive relations, as found in most textbooks on chemical reaction engineering, are vague as the conceptual vocabulary and nomenclature adopted in thermodynamics are not necessarily identical with the corresponding ones (i.e., if a true analogue exists at all) in fluid mechanics and visa versa. In addition, the fact that many of the thermodynamic relations adopted are developed under system restrictions very different from those under which chemical reaction engineering systems are operated investigating the rate of change of certain measurable physical quantities (e.g., species densities, temperature, pressure, mixture density, etc.), naturally makes a novice suspicious. The understanding is apparently improved as we grasp that thermodynamics is a very broad field of science that can be split into several disciplines. However, at this point in our presentation it is obvious that we need a common language for the researchers working on the edge between the two fields of sciences (i.e., thermodynamics and fluid dynamics) to avoid any ambiguity. Therefore, to

make sure that non-experts can follow the principal discussion in this paragraph, we define some basic thermodynamic concepts before we proceed describing the energy balance closures.

The word *thermodynamics*, which comes from Greek, means the power of heat [146]. The terms heat and energy are thus central to thermodynamics. Thermodynamics is a branch of science that deals with the properties of matter as related to change of temperature, where matter is anything that occupies space (including vacuum). The *state* of the system is defined by the set of values of all its primitive properties.<sup>4</sup> The succession of states through which a system passes during a change of state is called a *path*. Thermodynamics is based on a number of laws or postulates that enable the state of matter, which is affected by a vast quantity of properties, to be expressed in terms of a small number of properties. A property is defined as a quantity whose change in a process depends on the *end states* (i.e., equilibrium states) only, or alternatively, whose change in a cycle is always zero. The concept of equilibrium is fundamental to thermodynamics. *Classical thermodynamics* solely deals with states of *equilibrium*,<sup>5</sup> whereas in the context of chemical reaction engineering we are concerned with *non-equilibrium* situations in which momentum, heat and mass are being transferred (i.e., irreversible processes<sup>6</sup>). Thermodynamics for non-equilibrium processes is referred to as *irreversible thermodynamics*. The scientific field of irreversible thermodynamics was established during the early 1900s.<sup>7</sup>

---

<sup>4</sup> In thermodynamics one distinguishes between primitive properties and derived properties. A primitive property is a characteristic quantity of the system which can be determined by a test, i.e., a measurement ([146], p. 7). The outcome of the measurement is the value of the property.

<sup>5</sup> A thermodynamic system is in equilibrium when there is no change of intensive variables within the system. An equilibrium state is a state that cannot be changed without interactions with the environment. This definition includes that of mechanical equilibrium, but is a more general one. A state of thermodynamic equilibrium is a state of simultaneous chemical-, thermal-, and mechanical equilibrium. In other words, thermodynamic equilibrium is the state of the simultaneous vanishing of all fluxes ([32], p. 267). A thermodynamic system is thus in equilibrium when the intensive (macroscopic) variables that specify the state of the system are uniform and do not change with time. This is a state at rest (static system) as the inertia terms vanish in the momentum equation at mechanical equilibrium. The mechanical equilibrium state is the condition in which the acceleration, the total derivative of the velocity vector, vanishes ([32], p. 43).

<sup>6</sup> In a reversible, cyclic process both the system and the surroundings are returned exactly to their original conditions [186]. A reversible process is thus a process during which the system is never away from equilibrium. In a reversible process there are no irreversible dissipation of energy to heat as no driving forces exists. It turns out that any reversible process is a hypothetical process, as one has failed to invent a perpetual motion machine. On the other hand, an irreversible process is one in which, even when the system is cycled and thus returned to its original state, the surroundings is changed in a permanent way. Using a real process to do work requires that some of the energy is degraded. Velocity, temperature, and concentration gradients are always associated with losses of work, since energy is irreversibly transferred to internal energy through dissipation. An irreversible process involves the natural movement of a system from a non-equilibrium state to an equilibrium state without intervention, thus it is a spontaneous process. Basically thermodynamics can tell us the direction in which a process will occur, but can say nothing about the speed (rate) of the process.

<sup>7</sup> Onsager might be counted as the founder of the field with his papers from in 1931 entitled *Reciprocal relations in irreversible processes*, *Phys Rev*, vol. 37, pp. 405–426; *Phys Rev*, vol. 38, pp. 2265–2279.

There are three major reasons why irreversible thermodynamics is important for non-equilibrium systems. In the first place special attention is paid to the validity of the classical thermodynamic relations outside equilibrium (i.e., simple systems). In the second place the theory gives a description of the coupled transport processes (i.e., the Onsager reciprocal relations). In the third place the theory quantifies the entropy that is produced during transport. Irreversible thermodynamics can also be used to assess the second law efficiency of how valuable energy resources are exploited. The thermodynamics of irreversible processes should be set up from the scratch as a continuum theory, treating the state parameters of the theory as field variables [32]. This is also the way in which classical fluid mechanic theory is formulated. Therefore, in the computational fluid dynamics literature, the transport phenomena and the extensions of the classical thermodynamic relations are both interpreted as closures of the fluid dynamic theory. The validity of the thermodynamic relations for fluid dynamic systems has been approached from the viewpoint of the kinetic theory of gases [13]. However, any firm distinction between irreversible thermodynamics and fluid mechanics is difficult to define, as irreversible thermodynamics seems to overlap with transport phenomena and kinetics in many ways. For the purpose of thermodynamic analysis one usually focus on a finite amount of matter (including vacuum), which is separated from its *surroundings*, and is called a *system* (e.g., [42, 54, 146]). In order to define a system one must specify its boundaries and describe the contents within the boundaries. Anything outside the boundary of the system is called the surroundings or the environment. A *closed* system is one in which *no* mass crosses the system boundaries. The amount of mass within the closed system is then constant, ignoring the effects of relativity and nuclear activity. An *open* system is one in which mass crosses the system boundaries. The system may gain or lose mass or simply have some mass passing through it. The selection of a suitable system for the application of the basic laws is quite flexible and is, in many cases, a complex problem. Any analysis utilizing a fundamental law must follow the designation of a specific system, and the difficulty of solution varies greatly depending on the choice made. It has been mentioned that the mobility of a fluid makes the identification of a particular system cumbersome. Thus, in fluid mechanics we normally transform the fundamental physical laws into a control volume formulation instead (i.e., in which the system may change from instant to instant), and in this way the analysis of fluid flow is greatly simplified. In particular, the non-material control-volume approaches circumvent the difficulty of system identification. Nevertheless, it might seem obvious that the fluid mechanical *control volume* has connexions to the thermodynamical *system* definitions. In general, it is convenient to imagine that an open system in thermodynamics coincides with an Eulerian control volume in fluid mechanics. In a similar manner a closed system coincides with a material Lagrangian control volume. The concept in thermodynamics that describes what is happening to a system, is a *process*. When a change of states takes place in a system, the system is said to undergo a process. A process is completely specified by the end states, the path and the interactions that take place at the boundary. Another important aspect of thermodynamics is the relationship between energy, heat and work. Energy describes a property that has a distinct value for each state, thus being a state function. Work

and heat on the other hand are interactions and not properties. Hence, it is impossible to assign a value for work or heat to any state. Work and heat depend on the details of the process connecting to states. They can, therefore, be measured during a change of state only. The interactions called heat and work differ from one another. Work is an interaction which passes the test for equivalence of change in the level of a weight. Heat, on the other hand, does not. Heat is an interaction that may take place between two systems, each being in equilibrium but not in mutual equilibrium. The ability to have an interaction between systems in equilibrium is the main feature that distinguishes heat and work. Thermodynamics also makes use of experimental facts. By experimental fact we mean an experiment that may be repeated many times, always yielding the same result. Generalizations and extensions of experimental facts are known as laws or axioms. A law is formulated on the basis of all the experimental facts available without a single fact to contradict it. Of course, if we were to find even a single experimental fact that contradicts the law then we would have to modify the law or dispense with it altogether. Two such thermodynamic laws of especial importance, the first and second laws of thermodynamics, determine the main basis of modern thermodynamics. In the succeeding paragraphs we will thus convert the pertinent laws of thermodynamics from the system approach to the control volume approach (for further details, see e.g., [114], Chap. 4 and [180], Chap. 6).

To proceed supplementary knowledge of certain fundamental aspects of classical thermodynamics is required, revealing that the first law of thermodynamics leads to the law of conservation of total energy. This field of thermodynamics was developed largely through the efforts of J. W. Gibbs during the late 1800s.<sup>8</sup> In two famous papers Gibbs was working with the mathematical transformations of energy and entropy in fluids. These transformations are subject to several constraints owing to the nature of state functions ([42], p. 173). In these studies one considers systems with no internal temperature gradients, rigid impermeable walls, and no external fields. These restrictions are said to comprise what is referred to as *simple* systems. For such simple systems the energy balance terms accounting for heat and work can be transformed from extensive properties (i.e., properties that depend on the size of the system) and expressed in terms of intensive properties (i.e., properties that do not depend on the size of the system) like density, temperature, and specific entropy. The set of thermodynamic variables used to specify the state of a fluid is referred to as state variables. As all engineering processes involve transition from one state (i.e., set of primitive property values) to another, one has to relate the state functions to each other mathematically to determine the changes in the state variables. It has been recognized that any transition calculation procedure is independent of path as long as it simply relates state properties.

The energy balance relates work, heat, and flow to the internal energy, kinetic energy, and potential energy of the closed system:

$$dE_{\text{total}} = d(E_i + E_k + E_p) = \delta Q + \delta W \quad (1.98)$$

---

<sup>8</sup> Gibbs is counted as the founder of the field with his papers entitled ‘On the equilibrium of heterogeneous substances’, *Trans. Conn. Acad.*, vol. III, pp. 108–248, 1876; pp. 343–524, 1878.

where  $E_i$ ,  $E_k$  and  $E_p$  are the intensive internal, kinetic and potential energies of the center of mass of the system. It is seen that classical thermodynamics takes no account of the atomic structure of matter, but considers matter as a continuum. In (1.98) the symbol  $d$  indicates a differential element of a state function,<sup>9</sup> and the symbol  $\delta$  indicates a differential element of some quantity which is not a state function.

Eliminating all surface forces except those that cause expansion or contraction, because a simple system has no gradients or shaft work (i.e., the work of a turbine or a pump) and neglecting  $E_k$  and  $E_p$  changes by taking the system's center of mass as the frame of reference, the energy balance takes a specific simple form. The energy balance yields

$$dE_i = \delta Q + \delta W \quad (1.99)$$

This relation is recognized from introductory subjects on thermodynamics. Recall that in equilibrium thermodynamics a local formulation is generally not needed, since the intensive state variables are independent of the space coordinates. This fundamental formulation of the total energy balance is known as *the first law of thermodynamics* for a closed system, which expresses the fundamental physical principle that the total energy of the system,  $E_{\text{total}}$ , is conserved (a postulate).

Until this point we have limited our thermodynamic description to simple (closed) systems. We now extend our analysis considering an *open* system. In this case the material control volume framework might not be a convenient choice for the fluid dynamic model formulation because of the computational effort required to localize the control volume surface. The Eulerian control volume description is often a better choice for this purpose.

#### 1.2.4.1 System Analysis

The total energy associated with a material control volume  $V(t)$  is defined by:

$$E_{\text{total}} = \int_{V(t)} \rho \left( e + \frac{1}{2} v^2 + \Phi \right) dv \quad (1.100)$$

where  $e$  is *the internal energy* per unit mass. From a microscopic point of view  $e$  represents the energy of thermal agitation as well as the energy due to the short-range molecular interactions.  $\Phi$  is *the potential energy* per unit mass, and  $\frac{1}{2} v^2$  is the *kinetic energy* per unit mass.

---

<sup>9</sup> From a thermodynamic point of view  $E_{\text{total}}$  is a state function, thus the integration of  $dE_{\text{total}}$  between two thermodynamic states gives a value which is independent of the thermodynamic path taken by the system between the two states. The situation is different when  $\delta Q$  and  $\delta W$  are integrated. The heat and work effects, which involve energy transfer, depend on the path taken between the two states, as a result of which the integrals of  $\delta Q$  and  $\delta W$  cannot be evaluated without knowledge of the path [54].

Note that in the derivation of the kinetic energy term we have used the scalar product of a vector with itself which is just the square of the magnitude of the vector:

$$(\mathbf{v} \cdot \mathbf{v}) = |\mathbf{v}|^2 = v^2 \quad (1.101)$$

In the material *Lagrangian* framework the total energy balance also known as the first law of thermodynamics yields<sup>10</sup>:

$$\frac{DE_{\text{total}}}{Dt} = \dot{Q} + \dot{W} \quad (1.102)$$

where  $\dot{Q}$  and  $\dot{W}$  are energy transfer functions (i.e., not energy functions).

In the moving system, it is assumed that the heat transfer to the element,  $\delta\dot{Q}$ , is determined by the various forms of conduction and radiation across the CV surface.  $\delta\dot{W}$  denotes the work done on the fluid element due to surface forces. The potential energy term,  $\Phi$ , may be reformulated and treated as a term denoting the work done on the fluid element due to body forces. We will return to the derivation of the closure laws shortly. Again, the system balance can be transformed into an Eulerian control volume balance by use of the transport theorem (1.10). In short, the result can be expressed as:

$$\begin{aligned} \int_V \left[ \frac{\partial(\rho(e + \frac{1}{2}v^2 + \Phi))}{\partial t} + \nabla \cdot (\rho\mathbf{v}(e + \frac{1}{2}v^2 + \Phi)) + \nabla \cdot \mathbf{q} + \nabla \cdot (p\mathbf{v}) \right. \\ \left. + \nabla \cdot (\boldsymbol{\sigma} \cdot \mathbf{v}) + \nabla \cdot \sum_{c=1}^N \rho_c \mathbf{v}_{c,d} \Phi_c \right] dv = 0 \end{aligned} \quad (1.103)$$

The energy balance must be satisfied for any macroscopic control volume  $V$ , so at each point the differential Eulerian energy balance can be written as:

$$\begin{aligned} \frac{\partial(\rho(e + \frac{1}{2}v^2 + \Phi))}{\partial t} + \nabla \cdot (\rho\mathbf{v}(e + \frac{1}{2}v^2 + \Phi)) = -\nabla \cdot \mathbf{q} - \nabla \cdot (p\mathbf{v}) - \nabla \cdot (\boldsymbol{\sigma} \cdot \mathbf{v}) \\ - \nabla \cdot \sum_{c=1}^N \rho_c \mathbf{v}_{c,d} \Phi_c \end{aligned} \quad (1.104)$$

This result is known as the *total energy equation*.

To solve the given energy equation the net energy flux  $\mathbf{q}$  has to be replaced by an appropriate multi-component heat flux closure. For single-component fluids the energy flux closure contains the familiar heat conduction- and the energy radiation fluxes. The rigorous kinetic theory of dilute gases shows that for multi-component

---

<sup>10</sup> For a simple thermodynamic system the change in total energy,  $dE_{\text{total}}$ , is given by the differential of  $E_{\text{total}}$ , whereas for a fluid dynamic CV  $\frac{DE_{\text{total}}}{Dt}$  denotes the *substantial derivative* operator applied on the total energy variable.

mixtures there are, in addition to the heat conduction- and thermal radiation fluxes, two additional contributions associated with the inter-diffusion of the different species in the mixture and a diffusion-thermo effect. For dilute multi-component gas mixtures Hirschfelder et al. [68] and Bird et al. [11, 13] proposed the following rigorous closure:

$$\mathbf{q} = \mathbf{q}^c + \mathbf{q}^d + \mathbf{q}^o + \mathbf{q}^r \quad (1.105)$$

It is well established in thermodynamics that heat flow is the result of temperature variations, i.e., a temperature gradient. This can be expressed as a proportionality between heat flux and temperature gradient, i.e., *Fourier's law*:

$$\mathbf{q}^c = -k \nabla T \quad (1.106)$$

where the  $\mathbf{q}^c$  is the *conductive heat flux* vector denoting the rate of heat flow per unit area. The flux of heat is in the direction of decreasing temperature (which accounts for the minus sign). The quantity  $k$  is a transport coefficient, i.e., the thermal conductivity, which in general has dimensions of heat per time per length per degree.

The energy flux contribution resulting from the *inter-diffusion* of the various species is denoted by  $\mathbf{q}^d$ . This energy flux is defined by:

$$\mathbf{q}^d = \sum_{c=1}^N \check{h}_c \rho_c \mathbf{v}_{c,d} = \sum_{c=1}^N \frac{\bar{h}_c}{M_{w_c}} \mathbf{j}_c \quad (1.107)$$

where  $\bar{h}_c$  is the partial molar enthalpy of species  $c$ .

A similar heat contribution is included implicitly within the  $e$  and  $h$  variables, thus occurring explicitly in the temperature equation. However, the energy or heat flux contributions from these inter-diffusion processes are in general believed to be small and omitted in most applications (e.g., [11], p. 566; [91], p. 198; [149], p. 816).

The *diffusion-thermal effect* or the *Dufour energy flux*  $\mathbf{q}^x$  describes the tendency of a temperature gradient under the influence of mass diffusion of chemical species. Onsager's reciprocal relations for the thermodynamics of irreversible processes imply that if temperature gives rise to diffusion velocities (the *thermal-diffusion effect* or *Soret effect*), concentration gradients must produce a heat flux. This reciprocal effect, known as the Dufour effect, provides an additional contribution to the heat flux [91]. For dilute gas mixtures we may employ the linearity postulate in irreversible thermodynamics to obtain the transport fluxes for heat and mass. The fundamental theory is examined in Chap. 2 and we simply refer to the expressions (2.348) and (2.349). Moreover, a particular form of the generalized Maxwell-Stefan equations, i.e., deduced from (2.392) in Chap. 2, is given by:

$$\mathbf{d}_r = \sum_{\substack{k=1 \\ k \neq r}}^q \frac{x_r x_k}{\bar{D}_{rk}} \left( \frac{D_k^T}{\rho_k} - \frac{D_r^T}{\rho_r} \right) \nabla \ln T + \sum_{\substack{k=1 \\ k \neq r}}^q \frac{x_r x_k}{\bar{D}_{rk}} \left( \frac{\mathbf{j}_k}{\rho_k} - \frac{\mathbf{j}_r}{\rho_r} \right), \quad r = 1, 2, 3, \dots, q \quad (1.108)$$

When the expression for  $\mathbf{d}_r$  in (1.108) is substituted into (2.348), we get:

$$\begin{aligned} \mathbf{q} - \sum_{r=1}^q \mathbf{j}_r \check{h}_r &= -\frac{1}{T} \alpha_{00} \nabla T - \sum_{r=1}^q \left( \frac{cRTD_r^T}{\rho_r} \right) \mathbf{d}_r \\ &= - \left[ \alpha_{00} + \sum_{r=1}^q \sum_{\substack{k=1 \\ k \neq r}}^q \left( \frac{cRTD_r^T}{\rho_r} \right) \frac{x_r x_k}{\tilde{D}_{rk}} \left( \frac{D_k^T}{\rho_k} - \frac{D_r^T}{\rho_r} \right) \right] \nabla \ln T \quad (1.109) \\ &\quad - \sum_{r=1}^q \sum_{\substack{k=1 \\ k \neq r}}^q \left( \frac{cRTD_r^T}{\rho_r} \right) \frac{x_r x_k}{\tilde{D}_{rk}} \left( \frac{\mathbf{j}_k}{\rho_k} - \frac{\mathbf{j}_r}{\rho_r} \right) \end{aligned}$$

It is already mentioned that the thermal conductivity of a mixture is defined to be the coefficient of proportionality between the heat flux and the temperature gradient when there are no mass fluxes in the system. Hence it follows that the quantity in brackets is the thermal conductivity  $k$  times the temperature  $T$ . The closure equation for the net heat flux thus yields:

$$\mathbf{q} = -k \nabla T + \sum_{r=1}^q \mathbf{j}_r \check{h}_r - \sum_{r=1}^q \sum_{\substack{k=1 \\ k \neq r}}^q \left( \frac{cRTD_r^T}{\rho_r} \right) \frac{x_r x_k}{\tilde{D}_{rk}} \left( \frac{\mathbf{j}_k}{\rho_k} - \frac{\mathbf{j}_r}{\rho_r} \right) \quad (1.110)$$

By comparison, we see that the Dufour term is given by:

$$\mathbf{q}^x = - \sum_{r=1}^q \sum_{\substack{k=1 \\ k \neq r}}^q \left( \frac{cRTD_r^T}{\rho_r} \right) \frac{x_r x_k}{\tilde{D}_{rk}} \left( \frac{\mathbf{j}_k}{\rho_k} - \frac{\mathbf{j}_r}{\rho_r} \right) \quad (1.111)$$

The Dufour term is usually small and can generally be neglected in reactor analysis.

The radiative heat-flux  $\mathbf{q}^r$  is generally treated separately from the other heat flux contributions because these physical phenomena are quite different in nature and involve unacquainted mathematics. Besides, the radiative contributions in the bulk of the fluid are limited because this flux is merely a surface phenomenon. Nevertheless, the radiative losses from solid surfaces are often significant in combustion and in particular chemical reactor processes. A brief introduction to the theory of thermal radiation is presented in Sect. 5.2.6. In summary, the heat transport by conduction is generally important in reaction engineering applications. The thermal radiation flux is important in particular cases. The multi-component mixture specific contributions to the total energy flux are usually negligible.

### 1.2.4.2 Finite Eulerian Control Volume Analysis

The conventional *Eulerian* form of the conservation equation for total energy can be formulated<sup>11</sup>:

$$\frac{\partial E_{\text{total}}}{\partial t} = \left[ \frac{\partial E_{\text{total}}}{\partial t} \right]_{\text{Convection}} + \left[ \frac{\partial E_{\text{total}}}{\partial t} \right]_{\text{Heat}} + \left[ \frac{\partial E_{\text{total}}}{\partial t} \right]_{\text{Work}} \quad (1.112)$$

*The convective term*, denoting the net rate of total energy input per unit volume by convection can then be formulated as a surface integral, and converted to a volume integral by use of Gauss' theorem (App A):

$$\left[ \frac{\partial E_{\text{total}}}{\partial t} \right]_{\text{Convection}} = - \int_A (\rho(e + \frac{1}{2}v^2 + \Phi)\mathbf{v}) \cdot \mathbf{n} da = - \int_V \nabla \cdot (\rho(e + \frac{1}{2}v^2 + \Phi)\mathbf{v}) dv \quad (1.113)$$

*The heat term*, denoting the net rate of total energy input per unit volume by conduction and radiation can then be formulated as a surface integral, and converted to a volume integral by use of Gauss' theorem (App A):

$$\left[ \frac{\partial E_{\text{total}}}{\partial t} \right]_{\text{Heat}} = - \int_A (\mathbf{q} \cdot \mathbf{n}) da = - \int_V (\nabla \cdot \mathbf{q}) dv \quad (1.114)$$

*The work term*, for a multi-component mixture is commonly divided into two types, *mechanical work* and *potential work* (e.g., [32]):

$$\left[ \frac{\partial E_{\text{total}}}{\partial t} \right]_{\text{Work}} = \left[ \frac{\partial E_{\text{total}}}{\partial t} \right]_{\text{Mechanical Work}} + \left[ \frac{\partial E_{\text{total}}}{\partial t} \right]_{\text{Potential Work}} \quad (1.115)$$

*The mechanical work term*, denoting the net rate of work done on the fluid per unit volume by surface stress forces can be formulated as a surface integral, and converted to a volume integral by use of Gauss' theorem (App A):

$$\begin{aligned} \left[ \frac{\partial E_{\text{total}}}{\partial t} \right]_{\text{Mechanical Work}} &= - \int_A [(\mathbf{T} \cdot \mathbf{v}) \cdot \mathbf{n}] da = - \int_V \nabla \cdot (\mathbf{T} \cdot \mathbf{v}) dv \\ &= - \int_V \nabla \cdot (p\mathbf{v}) dv - \int_V \nabla \cdot (\boldsymbol{\sigma} \cdot \mathbf{v}) dv \end{aligned} \quad (1.116)$$

*The potential work term*, denotes the rate at which work is done on each of the individual species  $c$  in the fluid per unit volume by *the individual species body forces*,  $\mathbf{g}_c$ , due to the diffusion of the various components in external fields such

<sup>11</sup> Alternative presentations of the derivation of the first law of thermodynamics for open systems in the Eulerian CV framework on global scales are given by [42, 47, 54].

as an applied electro-magnetic potential. The term can be formulated as a surface integral, and as before converted to a volume integral by use of Gauss' theorem (App A):

$$\left[\frac{\partial E_{\text{total}}}{\partial t}\right]_{\text{Potential Work}} = - \int_A \left[ \left( \sum_{c=1}^N \rho_c \mathbf{v}_{c,d} \Phi_c \right) \cdot \mathbf{n} \right] da = - \int_V \nabla \cdot \left( \sum_{c=1}^N \rho_c \mathbf{v}_{c,d} \Phi_c \right) dv \quad (1.117)$$

Note that the expected contribution due to the gravity field vanishes because each species present is acted on by the same external force per unit mass,  $\mathbf{g}$ .

The general form of the Eulerian conservation equation for total energy,  $E_{\text{total}}$ , can then be formulated

$$\begin{aligned} \frac{\partial E_{\text{total}}}{\partial t} &= \left[\frac{\partial E_{\text{total}}}{\partial t}\right]_{\text{Convection}} + \left[\frac{\partial E_{\text{total}}}{\partial t}\right]_{\text{Heat}} + \left[\frac{\partial E_{\text{total}}}{\partial t}\right]_{\text{Work}} \\ &= - \int_V \nabla \cdot \left( \rho \left( e + \frac{1}{2} v^2 + \Phi \right) \mathbf{v} \right) dv - \int_V (\nabla \cdot \mathbf{q}) dv \\ &\quad - \int_V \nabla \cdot (p \mathbf{v}) dv - \int_V \nabla \cdot (\boldsymbol{\sigma} \cdot \mathbf{v}) dv - \int_V \nabla \cdot \left( \sum_{c=1}^N \rho_c \mathbf{v}_{c,d} \Phi_c \right) dv \quad (1.118) \end{aligned}$$

or with a little rearranging (1.103) is obtained. Again, (1.103) must be satisfied for any macroscopic volume  $V$ , thus (1.104) is re-produced as expected.

The final form of this equation, often used in the literature, is obtained by introducing a transformation of the potential energy term,  $\Phi$ . In general, a force field is called *conservative* if it is the gradient of a scalar function.

Considering that the body forces  $\mathbf{g}_c$  are expressible in terms of the gradient of a scalar function (i.e.,  $\mathbf{g}_c = -\nabla \Phi_c$ ), then by use of the species continuity equation (1.39), we get:

$$\begin{aligned} &\frac{\partial(\rho \Phi)}{\partial t} + \nabla \cdot (\rho \mathbf{v} \Phi) + \nabla \cdot \sum_{c=1}^N \rho_c \mathbf{v}_{c,d} \Phi_c \\ &= \frac{\partial}{\partial t} \left( \sum_{c=1}^N \rho_c \Phi_c \right) + \nabla \cdot \left( \sum_{c=1}^N \rho_c \mathbf{v}_c \Phi_c \right) \\ &= \sum_{c=1}^N \rho_c \left[ \frac{\partial \Phi_c}{\partial t} + \mathbf{v}_c \cdot \nabla \Phi_c \right] + \sum_{c=1}^N \Phi_c \left[ \frac{\partial \rho_c}{\partial t} + \nabla \cdot (\rho_c \mathbf{v}_c) \right] \\ &= \sum_{c=1}^N \rho_c \left[ \frac{\partial \Phi_c}{\partial t} - \mathbf{v}_c \cdot \mathbf{g}_c \right] + \sum_{c=1}^N \Phi_c \sum_{r=1}^q \nu_{c,r} R_r \quad (1.119) \end{aligned}$$

The last term vanishes if the potential energy is conserved in a chemical reaction (i.e.,  $\sum_{c=1}^N \Phi_c \nu_{c,r} = 0$ ;  $r = 1, 2, \dots, q$ ) [32]. This is the case if the property of the particles, which is responsible for the interaction with a field of force, is itself conserved. Examples for this case are the mass in a gravitational field and the charge in an electrical field.

For conservative forces, which can be derived from a potential  $\Phi$  being independent of time, the terms reduce to

$$\frac{\partial(\rho\Phi)}{\partial t} + \nabla \cdot (\rho \mathbf{v} \Phi) + \nabla \cdot \sum_{c=1}^N \rho_c \mathbf{v}_{c,d} \Phi_c = \sum_{c=1}^N \rho_c [-\mathbf{v}_c \cdot \mathbf{g}_c] = - \sum_{c=1}^N \rho_c (\mathbf{v}_c \cdot \mathbf{g}_c) \quad (1.120)$$

The term,  $-\sum_{c=1}^N \rho_c (\mathbf{v}_c \cdot \mathbf{g}_c)$ , reduces to the term applied for one component fluids,  $-\rho(\mathbf{v} \cdot \mathbf{g})$ , when  $\mathbf{g}_c$  is the same for all species. The interested reader is referred to de Groot and Mazur [32] for further discussion of these terms.

Adopting this simplified formulation (i.e., (1.120)), the total energy equation, (1.104), may be transformed to the equation of internal- and kinetic [or mechanical] energy:

$$\frac{\partial(\rho(e + \frac{1}{2}v^2))}{\partial t} = -\nabla \cdot (\rho \mathbf{v}(e + \frac{1}{2}v^2)) - \nabla \cdot \mathbf{q} + \sum_{c=1}^N \rho_c (\mathbf{v}_c \cdot \mathbf{g}_c) - \nabla \cdot (p\mathbf{v}) - \nabla \cdot (\boldsymbol{\sigma} \cdot \mathbf{v}) \quad (1.121)$$

The physical meaning of the terms in this equation can be inferred from the above modeling analysis. *The term on the LHS* denotes the rate of accumulation of internal and kinetic energy within the control volume per unit volume; *the first term on the RHS* denotes the net rate of of internal and kinetic energy increase by convection per unit volume; *the second term on the RHS* denotes the net rate of heat addition due to heat conduction, inter-diffusion effects, Dufour effects and radiation per unit volume; *the third term on the RHS* denotes the rate of work done on the fluid within the control volume by external body forces per unit volume; *the fourth term on the RHS* denotes the rate of work done on the fluid within the control volume by the pressure forces per unit volume; and *the fifth term on the RHS* denotes the rate of work done on the fluid within the control volume by the viscous forces per unit volume.

In convectional chemical reactor modeling the kinetic and potential energy terms are assumed to be negligible in comparison with the internal energy term (e.g., [47]). Therefore, only the thermal energy equation is applied in reactor models. Furthermore, the experimental studies on reaction kinetics provide empirical data and correlations which chemical engineers intend to utilize as far as possible. For numerical studies on chemical reactor performance, the heat generation due to chemical reactions should then be expressed by an explicit term in the energy equation. For real fluids this can be obtained by reformulating the equation in terms of temperature or a suitable enthalpy quantity. In the past the latter approach has seldom been used in reactor technology. Furthermore, there are two possible ways to formulate the ther-

mal energy equation in terms of temperature. One approach is to relate the internal energy,  $e$ , to temperature by use of a constitutive relation from thermodynamics including the definition of *the specific heat capacity measured at constant volume*,  $C_V$ . In the second approach we reformulate the energy equation in terms of enthalpy,  $h$ , and thereafter relate the enthalpy to temperature by use of another constitutive relation from thermodynamics including the definition of *the specific heat capacity measured at constant pressure*,  $C_P$  (e.g., [7]). The second approach has conventionally been used in reactor technology. The heat of reaction can then be calculated from the standard heats of formation tabulated for many chemical compounds. To proceed in our model derivation, the equation for internal energy,  $e$ , is obtained by subtracting the mechanical energy equation from the total energy equation. The first step in this mathematical exercise, is to formulate the equation for mechanical energy.

### 1.2.4.3 Transport of Kinetic Energy

It is possible to derive the kinetic [mechanical] energy equation by forming the scalar product of the local velocity,  $\mathbf{v}$ , with the equation of motion (1.86). The result is:

$$\mathbf{v} \cdot \frac{\partial(\rho \mathbf{v})}{\partial t} = -\mathbf{v} \cdot \nabla \cdot (\rho \mathbf{v} \mathbf{v}) - \mathbf{v} \cdot \nabla \cdot \mathbf{T} + \mathbf{v} \cdot \sum_{c=1}^N \rho_c \mathbf{g}_c \quad (1.122)$$

or reformulated by use of some vector and tensor algebra:

$$\begin{aligned} \frac{\partial}{\partial t}(\rho \mathbf{v} \cdot \mathbf{v}) - \rho \mathbf{v} \cdot \frac{\partial \mathbf{v}}{\partial t} &= -\nabla \cdot [\rho \mathbf{v}(\mathbf{v} \cdot \mathbf{v})] + \rho \mathbf{v} \mathbf{v} : \nabla \mathbf{v} - \mathbf{v} \cdot \nabla \cdot \mathbf{T} + \mathbf{v} \cdot \sum_{c=1}^N \rho_c \mathbf{g}_c \\ &= -\nabla \cdot [\rho \mathbf{v}(\mathbf{v} \cdot \mathbf{v})] + \rho \mathbf{v} \cdot [(\mathbf{v} \cdot \nabla) \mathbf{v}] - \mathbf{v} \cdot \nabla \cdot \mathbf{T} \\ &\quad + \mathbf{v} \cdot \sum_{c=1}^N \rho_c \mathbf{g}_c \end{aligned} \quad (1.123)$$

In this equation manipulation, we have used following vector and tensor relations for the time derivative term:

$$\frac{\partial}{\partial t}(\rho \mathbf{v} \cdot \mathbf{v}) = \mathbf{v} \cdot \frac{\partial(\rho \mathbf{v})}{\partial t} + \rho \mathbf{v} \cdot \frac{\partial \mathbf{v}}{\partial t} \quad (1.124)$$

The vector and tensor differential operators that have been applied to the symmetrical dyad product  $\rho \mathbf{v} \mathbf{v}$  can be defined (e.g., [12], p. 574):

$$(\rho \mathbf{v} \mathbf{v} : \nabla \mathbf{v}) = \nabla \cdot [\rho \mathbf{v} \mathbf{v} \cdot \mathbf{v}] - \mathbf{v} \cdot [\nabla \cdot (\rho \mathbf{v} \mathbf{v})] \quad (1.125)$$

The scalar product or double dot product of the two tensors occurring in this relation can be reformulated in accordance with ([12], p. 569):

$$(\mathbf{ab} : \mathbf{cd}) = (\mathbf{a} \cdot \mathbf{d})(\mathbf{c} \cdot \mathbf{b})$$

by setting  $\mathbf{a} = \rho \mathbf{v}$ ,  $\mathbf{b} = \mathbf{v}$ ,  $\mathbf{c} = \nabla$ ,  $\mathbf{d} = \mathbf{v}$  we obtain:

$$\rho \mathbf{v} \mathbf{v} : \nabla \mathbf{v} = \rho \mathbf{v} \cdot [(\mathbf{v} \cdot \nabla) \mathbf{v}] \quad (1.126)$$

In the derivation we will also use the scalar product of a vector with itself which we recall is just the square of the magnitude of the vector:

$$(\mathbf{v} \cdot \mathbf{v}) = |\mathbf{v}|^2 = v^2 \quad (1.127)$$

The scalar product of two vectors  $\mathbf{u}$  and  $\mathbf{w}$  is a scalar quantity defined by (e.g., [11, 12]):

$$(\mathbf{u} \cdot \mathbf{w}) = uw \cos \Phi_{u,w} \quad (1.128)$$

in which  $\Phi_{u,w}$  is the angle between the vectors  $\mathbf{u}$  and  $\mathbf{w}$ . The scalar product is thus the magnitude of  $\mathbf{w}$  multiplied by the projection of  $\mathbf{u}$  on  $\mathbf{w}$ , or vice versa.

By inserting all these relations into (1.123), we can write:

$$\frac{\partial}{\partial t}(\rho v^2) - \rho \mathbf{v} \cdot \left[ \frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v} \cdot \nabla) \mathbf{v} \right] = -\nabla \cdot [\rho v^2 \mathbf{v}] - \mathbf{v} \cdot \nabla \cdot \mathbf{T} + \mathbf{v} \cdot \sum_{c=1}^N \rho_c \mathbf{g}_c \quad (1.129)$$

The equation of motion (1.86) will now, with a little reformulation of the terms, be reintroduced into the kinetic energy equation:

$$\mathbf{v} \left[ \frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) \right] + \rho \left[ \frac{\partial \mathbf{v}}{\partial t} + \mathbf{v} \cdot \nabla \mathbf{v} \right] = -\nabla \cdot \mathbf{T} + \sum_{c=1}^N \rho_c \mathbf{g}_c$$

After forming the scalar product of the local velocity with the latter equation which yields:

$$\rho \mathbf{v} \cdot \left[ \frac{\partial \mathbf{v}}{\partial t} + \mathbf{v} \cdot \nabla \mathbf{v} \right] = -\mathbf{v} \cdot \nabla \cdot \mathbf{T} + \mathbf{v} \cdot \sum_{c=1}^N \rho_c \mathbf{g}_c - v^2 \left[ \frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) \right] \quad (1.130)$$

The final form of the kinetic energy equation is obtained:

$$\frac{\partial}{\partial t}(\rho v^2) = -\nabla \cdot [\rho v^2 \mathbf{v}] - 2\mathbf{v} \cdot \nabla \cdot \mathbf{T} + 2\mathbf{v} \cdot \sum_{c=1}^N \rho_c \mathbf{g}_c - v^2 \left[ \frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) \right]$$

A minor modification is obtained multiplying the above equation by  $1/2$ :

$$\frac{\partial}{\partial t}(\rho \frac{1}{2} v^2) = -\nabla \cdot (\rho \frac{1}{2} v^2 \mathbf{v}) - \mathbf{v} \cdot \nabla \cdot \mathbf{T} + \mathbf{v} \cdot \sum_{c=1}^N \rho_c \mathbf{g}_c - \frac{1}{2} v^2 \left[ \frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) \right] \quad (1.131)$$

Moreover, by use of the continuity equation we obtain the form of the equation of change for kinetic energy which is usually given in the literature (e.g., [32]):

$$\frac{\partial}{\partial t}(\rho \frac{1}{2} v^2) = -\nabla \cdot (\rho \frac{1}{2} v^2 \mathbf{v}) - \mathbf{v} \cdot \nabla \cdot \mathbf{T} + \mathbf{v} \cdot \sum_{c=1}^N \rho_c \mathbf{g}_c \quad (1.132)$$

For convenience in subsequent discussions, we rewrite this equation in accordance with [11] splitting up the total stress tensor into two pressure and two viscous contributions:

$$\begin{aligned} \frac{\partial}{\partial t}(\rho \frac{1}{2} v^2) = & -\nabla \cdot (\rho \frac{1}{2} v^2 \mathbf{v}) - \nabla \cdot p \mathbf{v} + p(\nabla \cdot \mathbf{v}) \\ & - (\nabla \cdot [\boldsymbol{\sigma} \cdot \mathbf{v}]) + (\boldsymbol{\sigma} : \nabla \mathbf{v}) + \mathbf{v} \cdot \sum_{c=1}^N \rho_c \mathbf{g}_c \end{aligned} \quad (1.133)$$

At this point in the model derivation the physical meaning of some of these terms is not clear, but will be appreciated shortly after the internal energy equation has been investigated. Meanwhile, we proceed predicting the physical interpretations that are not obvious. *The term on the LHS* denotes the rate of accumulation of the kinetic energy within the control volume per unit volume; *the first term on the RHS* denotes the net rate of increase of kinetic energy by convection per unit volume; *the second term on the RHS* denotes the rate of work done by the pressure of the surroundings on the fluid within control volume; *the third term on the RHS* denotes the rate of *reversible* conversion of the kinetic energy to internal energy. As will be shown shortly, this term occurs with opposite sign in the equation for the internal energy; *the fourth term on the RHS* denotes the rate of work done by viscous forces on the fluid within the control volume; *the fifth term on the RHS* denotes the rate of *irreversible* conversion of kinetic energy to internal energy.<sup>12</sup> As will be shown shortly, this term occurs with opposite sign in the internal energy equation; *the sixth*

---

<sup>12</sup> The *viscous dissipation* term  $(-\boldsymbol{\sigma} : \nabla \mathbf{v})$  is always positive for Newtonian fluids, because it can be written as a sum of quadratic terms [11]:

$$(-\boldsymbol{\sigma} : \nabla \mathbf{v}) = \mu \Phi_{\text{viscous}} = \frac{1}{2} \mu \sum_i \sum_j \left[ \left( \frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i} \right) - \frac{2}{3} (\nabla \cdot \mathbf{v}) \delta_{ij} \right]^2 \quad (1.134)$$

in which  $i$  and  $j$  take on the values 1, 2, 3, the Cartesian coordinates  $x_i$  become  $x, y, z$  and the velocity components  $v_i$  become  $v_x, v_y, v_z$ .

The viscous dissipation function  $\Phi_{\text{viscous}}$ , i.e., which we have defined by  $\mu \Phi_{\text{viscous}} = (-\boldsymbol{\sigma} : \nabla \mathbf{v})$ , represents the rate at which the shear and deviatoric normal stresses do work on the fluid in the

*term on the RHS* denotes the rate of work done by external body forces on the fluid within the control volume.

Because of the terms  $(\boldsymbol{\sigma} : \nabla \mathbf{v})$  and  $p(\nabla \cdot \mathbf{v})$ , the fluid may be heated (or cooled) internally. Hence, *an isothermal flow system* (i.e., for a system operating in an adiabatic mode having no external heat fluxes through the boundaries,  $\int_{V, \text{Global}} \nabla \cdot \mathbf{q} dv = 0$ ) is a system in which the heat generated (or absorbed) through these terms does not cause appreciable temperature change.

#### 1.2.4.4 Transport of Internal Energy

Now we are in the position of being able to subtract the mechanical energy equation (1.133) from the total energy equation (1.121). The result is *the equation of internal [or thermal] energy*:

$$\frac{\partial(\rho e)}{\partial t} = -\nabla \cdot (\rho \mathbf{v} e) - \nabla \cdot \mathbf{q} - p(\nabla \cdot \mathbf{v}) - (\boldsymbol{\sigma} : \nabla \mathbf{v}) + \sum_{c=1}^N (\mathbf{j}_c \cdot \mathbf{g}_c) \quad (1.135)$$

The short-hand double dot product notation resembles (1.2.4.3) and is defined by:

$$\boldsymbol{\sigma} : \nabla \mathbf{v} = \nabla \cdot (\boldsymbol{\sigma} \cdot \mathbf{v}) - \mathbf{v} \cdot \nabla \cdot \boldsymbol{\sigma} \quad (1.136)$$

The physical meaning of the terms in the internal energy equation can be inferred from the modeling analysis above. *The term on the LHS* denotes the rate of accumulation of the internal energy within the control volume per unit volume; *the first term on the RHS* denotes the net rate of increase of internal energy by convection per unit volume; *the second term on the RHS* denotes rate of increase of internal energy by the heat flow (e.g., conduction, inter-diffusion effects, Dufour effects and radiation) per unit volume; *the third term on the RHS* denotes the *reversible* rate of increase of internal energy by compression per unit volume; *the fourth term on the RHS* denotes the *irreversible* rate of increase of internal energy by viscous dissipation per unit volume; *the fifth term on the RHS* denotes the rate of work done by the external body forces on the fluid mixture within the control volume. This term is due to species mass diffusion as the various chemical species present may be acted

---

(Footnote 12 continued)

CV.  $\Phi_{\text{viscous}}$  may also be viewed as the rate at which the internal energy of the fluid is increased due to viscous dissipation. In accordance with irreversible thermodynamic theory this means that in all flow systems there is a degradation of mechanical to thermal energy since no real processes are reversible.

The  $(-\boldsymbol{\sigma} : \nabla \mathbf{v})$  term can cause considerable temperature rises in viscous high-speed flow systems. In chemical reactor systems, however, this term is usually very small and is generally neglected.

It is noted that an alternative definition of the dissipation function in which the viscosity parameter is included is quite common [180, 183, 184]. In this case the dissipation function coincides with the dissipation term.

on by different external forces per unit mass  $\mathbf{g}_c$ . This term will thus vanish for one component systems and if the external force on all species is equal.

Comparing the mechanical energy equation (1.133) and thermal energy equation (1.135), we note that the terms  $(\boldsymbol{\sigma} : \nabla \mathbf{v})$  and  $p(\nabla \cdot \mathbf{v})$  occur in both equations. Since both terms have different signs in the two equations, they are apparently describing the inter-conversion of mechanical and thermal energy. The term  $p(\nabla \cdot \mathbf{v})$  is positive for those cases in which the fluid mixture is expanding, but negative in other situations where the fluid mixture is contracting. This term thus represents the *reversible* interchange processes. The term  $(\boldsymbol{\sigma} : \nabla \mathbf{v})$ , represents the *irreversible* degradation of mechanical energy to heat. The absolute value of energy is not a convenient quantity for our calculations (i.e., in practice this quantity is not possible to determine for all systems of interest), thus it is common in the study of thermodynamics to speak of energy changes relative to a appropriately chosen reference condition or a base state. Since we are focusing on the continuum scale changes in kinetic energy, potential energy, and energies of reaction, a convenient reference state chosen for determining the derived properties of any substance is *the standard state of formation* where the *elements* of the substance are in their most stable form at 25°C and 1 bar. At this reference state the standard enthalpy of formation for the elements is conveniently taken as zero. The standard enthalpy of formation of a substance is defined as the enthalpy of that substance compared to the enthalpies of the elements from which it is formed. In a general context (e.g., [73], p. 15), the rate of change of internal energy for ideal mixtures within a control volume may consist of five components; a sensible or thermal component which accounts for the translational, rotational, and/or vibrational motion of the atoms/molecules comprising the matter; a latent component which relates to intermolecular forces influencing phase change between solid, liquid, and vapor states; a chemical component which accounts for energy stored in chemical bounds between atoms; and a nuclear component which accounts for binding forces in the nucleus. In this chapter we will not consider any phase change or nuclear processes, only the thermal- and chemical components are considered.

#### 1.2.4.5 The Equation of Internal Energy in Terms of Enthalpy

For many engineering applications it is convenient to reformulate the equation of internal energy in terms of enthalpy or fluid temperature and heat capacity. To be able to transform the internal energy equation into a suitable form we need to apply some important thermodynamic relations which are discussed step by step in the following paragraphs. The first step is to formulate the equation of internal energy in terms of enthalpy.<sup>13</sup> The enthalpy function is defined by (e.g., [89, 91]):

$$h = e + \frac{p}{\rho} \quad (1.137)$$

---

<sup>13</sup> Enthalpy is a mathematical property defined for convenience in solving flow problems ([42], p. 48). Enthalpy is termed a convenience property because we have specifically defined it to be useful in problems where irreversible heat flow and pressure are manipulated ([42], p. 175).

Introducing this relation into the thermal energy equation (1.135), we obtain *the enthalpy equation*:

$$\frac{\partial(\rho h)}{\partial t} = -\nabla \cdot (\rho \mathbf{v} h) - \nabla \cdot \mathbf{q} + \frac{Dp}{Dt} - (\boldsymbol{\sigma} : \nabla \mathbf{v}) + \sum_{c=1}^N (\mathbf{j}_c \cdot \mathbf{g}_c) \quad (1.138)$$

The physical meaning of the terms in the enthalpy equation can be identified from the above modeling analysis. *The term on the LHS* denotes the rate of accumulation of enthalpy within the control volume per unit volume; *the first term on the RHS* denotes the net rate of increase of enthalpy by convection per unit volume; *the second term on the RHS*, that is already known from the foregoing discussion, denotes the rate of increase of enthalpy by the heat flow (e.g., conduction, inter-diffusion effects, Dufour effects and radiation) per unit volume; *the third term on the RHS* denotes the rate of work done by the pressure, which is induced by the surrounding fluid motion, acting on the mixture within the control volume per unit volume; the last two terms are already known from the foregoing discussion, nevertheless *the fourth term on the RHS* denotes the *irreversible* rate of increase of enthalpy by viscous dissipation per unit volume; *the fifth term on the RHS* denotes the rate of work done by external body forces acting on the mixture within control volume.

At this point we reiterate that the *specific enthalpy* of the mixture as defined in (1.137), also include *non-ideal mixing contributions* that should be calculated from a constitutive relation. Two basic thermodynamic parameterizations may be formulated for the specific enthalpy. First, for real gases (i.e., for pure components or mixtures) and in principle also for liquids the specific enthalpy can be expressed in terms of enthalpies of ideal gases and residual functions (i.e.,  $h = h^* - h^{\text{residual}}$ , where the asterisk is used for ideal gas state, see e.g., [92], p. 115). The enthalpies for ideal gases are only functions of temperature and composition and can be found from the standard heats of formation or alternatively from standard heat capacities tabulated for many chemical compounds. The residual function can be found from a suitable equation of state (EOS). In reactor modeling we often assume that the gases are in an ideal gas state. For ideal gases the residual function is zero and the ideal gas law is valid. For liquids, on the other hand, the residual function becomes very large and often no suitable EOS is available. Most EOS formulations which are fitted to experimental data can in principle be applied for liquids too, but in many cases there are no experimental data available. Second, for real liquid mixtures the specific enthalpy can be expressed in terms of enthalpies of pure real fluids and excess enthalpies (i.e.,  $h = h^{\text{ideal mixture}} - h^{\text{excess}}$ , see e.g., [139], p. 400). The enthalpies for an ideal mixture is given by the mole number averaged pure component values (i.e., in some cases reformulated and given as the mass averaged component values). The excess enthalpy can be found from models for activity coefficients. The excess enthalpies (or heat of mixing) are negligible for many liquid systems. In reactor modeling we often assume that the liquid phases are ideal mixtures. Further details on these relations are given in many textbooks on thermodynamics (e.g., [126]) and will not be repeated here. However, before we continue our derivation of the

basic energy equation, the improved descriptions of the thermodynamic variables that can be embedded in single—and multiphase reactor models with limited costs are pointed out. For low pressures (a few atmospheres and lower) we can apply the ideal gas model for gases and ideal mixture models for liquids. This formulation is very common in reactor technology. In some cases at higher pressures, the pressure effect on the gas phase is important. A suitable model for these systems is to use an EOS for the gas phase, and an ideal mixture model for liquids. However, in most situations at low pressures the liquid phase is more non-ideal than the gas phases. Then we will rather apply the ideal gas law for the gas phase, and excess properties for liquid mixtures. For polar mixtures at low to moderate pressures we may apply a suitable EOS for gas phases, and excess properties for liquid mixtures. All common models for excess properties are independent of pressure, and cannot be used at higher pressures. The pressure effect on the ideal (model part of the) mixture can be taken into account by the well known Poynting factor. At very high pressures we may apply proper EOS formulations for both gas and liquid mixtures, as the EOS formulations in principle are valid for all pressures. For non-volatile electrolytes, we have to apply a suitable EOS for gas phases and excess properties for liquid mixtures. For such liquid systems a separate term is often added in the basic model to account for the effects of ions. For very dilute solutions the Debye-Hückel law may hold. For many electrolyte systems we can apply the ideal gas law for the gas phase, as the accuracy reflected by the liquid phase models is low.

#### 1.2.4.6 Internal Energy Equation in Terms of Temperature

The enthalpy is an extensive thermodynamic property (i.e., a property that depends on the size or amount of the system). For an open system which can exchange mass with its surroundings we can write [13, 89]:

$$\hat{H}(T, p, M_1, M_2, M_3, \dots, M_N) = \sum_{c=1}^N M_c \left( \frac{\partial \hat{H}}{\partial M_c} \right)_{T, p, M'} = \sum_{c=1}^N M_c \check{H}_c \quad (1.139)$$

or

$$MH(T, p, \omega_1, \omega_2, \omega_3, \dots, \omega_{N-1}) = \sum_{c=1}^N M \omega_c \check{H}_c \quad (1.140)$$

in which the  $M_c$  are the masses of the various species,  $M$  is the total mass in the system given by the sum of the masses of all the species determining the system,  $M = \sum_{c=1}^N M_c$ , and the  $\omega_c = M_c/M$  are the corresponding mass fractions. Both  $\hat{H}$  and  $H$  are understood to be functions of  $T, p$ , as well as composition. The subscript  $M'$  stands for  $M_1, M_2, \dots, M_{c-1}, M_{c+1}, \dots, M_N$ , and the subscript  $M$  stands for  $M_1, M_2, M_3, \dots, M_N$ .

The introduction of the mass fraction variable in (1.140) induces a constraint on the system:

$$\sum_{c=1}^N \omega_c = 1 \quad (1.141)$$

In this section we just keep this relation in mind and present a survey of the rather complicated mathematical derivation involved. A more rigorous model derivation is given in App B.

The complete differential of  $\hat{H}(T, p, M_1, M_2, M_3, \dots, M_N)$  can then be expressed<sup>14</sup>:

$$d\hat{H} = \left(\frac{\partial \hat{H}}{\partial T}\right)_{p,M} dT + \left(\frac{\partial \hat{H}}{\partial p}\right)_{T,M} dp + \sum_{c=1}^N \check{H}_c dM_c \quad (1.142)$$

By use of the thermodynamic relations  $\hat{H} = MH$  and  $M_c = \omega_c M$ , we get:

$$HdM + MdH = M\left[\left(\frac{\partial H}{\partial T}\right)_{p,\omega} dT + \left(\frac{\partial H}{\partial p}\right)_{T,\omega} dp\right] + \sum_{c=1}^N [\check{H}_c \omega_c dM + \check{H}_c M d\omega_c] \quad (1.143)$$

By the substitution of  $HdM = \sum_{c=1}^N \omega_c \check{H}_c dM$  from (1.140), the above relation can be rewritten as:

$$dH = \left(\frac{\partial H}{\partial T}\right)_{p,\omega} dT + \left(\frac{\partial H}{\partial p}\right)_{T,\omega} dp + \sum_{c=1}^N \check{H}_c d\omega_c \quad (1.144)$$

The first term on the right hand side of (1.144) can be recognized as the definition of the *specific heat at constant pressure*:

$$\left(\frac{\partial H}{\partial T}\right)_{p,\omega} = C_p \quad (1.145)$$

To formulate a proper relation for the second term we have to adopt another form of the Gibbs equation (i.e., an alternative form of (1.144)) and some of the Maxwell relations (e.g., [89]). Since  $H$  is a state variable, different pathways can be applied calculating the variation of this variable. Equivalent to expressing the state variable  $H$  in terms of  $T$ ,  $p$  and composition we can express  $H$  in terms of  $S$ ,  $p$  and composition:

$$dH = \left(\frac{\partial H}{\partial p}\right)_{S,\omega} dp + \left(\frac{\partial H}{\partial S}\right)_{p,\omega} dS + \sum_{c=1}^N \check{H}_c d\omega_c \quad (1.146)$$

By use of suitable Maxwell relations, this relation can be reformulated:

---

<sup>14</sup> Changes in one thermodynamic state variable can be related to changes in other state variables. The set of state functions that determines the simplest relationship between these functions is termed a *natural function*.

$$dH = \left(\frac{1}{\rho}\right)dp + TdS + \sum_{c=1}^N \check{H}_c d\omega_c \quad (1.147)$$

thus

$$\left(\frac{\partial H}{\partial p}\right)_{T,\omega} = \frac{1}{\rho} + T\left(\frac{\partial S}{\partial p}\right)_{T,\omega} \quad (1.148)$$

The second term on the right hand side of the equation is not easy to measure. By use of another of Maxwell's relations this term can be formulated in terms of density and temperature:

$$\left(\frac{\partial H}{\partial p}\right)_{T,\omega} = \frac{1}{\rho} - T\left(\frac{\partial(\frac{1}{\rho})}{\partial T}\right)_{p,\omega} \quad (1.149)$$

Introducing these relations into the first formulation (1.144) we obtain:

$$dH = C_p dT + \left(\frac{1}{\rho} - T\left(\frac{\partial(\frac{1}{\rho})}{\partial T}\right)_{p,\omega}\right) dp + \sum_{c=1}^N \check{H}_c d\omega_c \quad (1.150)$$

In fluid dynamics the corresponding relation is conventionally written as a time rate of change, invoking the local instantaneous thermodynamic equilibrium assumption (further discussed in Sect. 2.4.2). In this way fluid dynamics is closely linked to classical equilibrium thermodynamics which is concerned with very slow changes between equilibrium states. Basically it is assumed that the thermodynamic properties of matter are uniform in space and independent of time, and it might be anticipated that fluid dynamics must (except for fluid statics) be concerned with rather fast changes, and nonequilibrium states. However, the molecular time scales are generally considered so short that any change at the molecular scales can be completed in what still seems to be a very short time in a continuum mechanical point of view, and thus locally effective thermodynamic equilibrium can be maintained all the time. For fluid dynamic systems the discussion may thus still be given within the framework of thermodynamics because although globally these systems are far from equilibrium, they are locally, over small but still macroscopic volume elements, in a state near thermodynamic equilibrium. In the fluid dynamic literature [64, 120] it is often argued in terms of kinetic theory concepts that local thermodynamic equilibrium prevails if the characteristic distance for property variation,  $L = c/|\nabla c|$  (where  $c$  is any thermodynamic variable), is much larger than the mean free path of the fluid molecules. This condition can be expressed as  $l/L \ll 1$ , where  $l$  is the mean free path. Similar arguments can be applied in time if the characteristic time is much larger than the characteristic molecular collision time scale. For dilute gas flow, the applicability of the continuum hypothesis (further discussed in Sect. 2.10) and the local thermodynamic equilibrium are thus expressed in terms of the Knudsen number,  $Kn$  (see

Sect. 2.10.5 for further details). For  $\text{Kn} < 0.01$  the medium can be considered as a continuum and the fluid dynamic transport equations are valid. In the case of liquids, the break-down of the continuum hypothesis manifests in anomalous diffusion mechanisms [64]. Moreover, *the local equilibrium assumption implies that the thermodynamic formulas derived from classical equilibrium thermodynamics may be applied locally for nonequilibrium systems* [13, 88, 89]. When this is done, we have established a fluid dynamic continuum theory in which all intensive thermodynamic variables like  $T, p$  become functions of position  $\mathbf{r}$  and time  $t$ ; thus  $T(t, \mathbf{r}), p(t, \mathbf{r})$  [88, 89]. The extensive variables like  $S, H$  are replaced by mass specific variables that also become functions of position  $\mathbf{r}$  and time  $t$ ; thus  $s(t, \mathbf{r}), h(t, \mathbf{r})$ .

Based on the above analysis it follows that the relation (1.150) can be transformed into the Lagrangian framework considering the enthalpy property on the form  $h(t, \mathbf{r})$  simply by replacing the differential operators by the substantial derivative operators[13]:

$$\frac{Dh}{Dt} = C_p \frac{DT}{Dt} + \left( \frac{1}{\rho} - T \left( \frac{\partial(\frac{1}{\rho})}{\partial T} \right)_{p, \omega} \right) \frac{Dp}{Dt} + \sum_{c=1}^N \check{h}_c \frac{D\omega_c}{Dt} \quad (1.151)$$

Substituting the equation of thermal energy (1.138) and the species mass transport equation (1.39) into the above equation results in the temperature equation<sup>15</sup>:

$$\begin{aligned} \rho C_p \frac{DT}{Dt} = & -\nabla \cdot \mathbf{q} - \frac{T}{\rho} \left( \frac{\partial \rho}{\partial T} \right)_{p, \omega} \frac{Dp}{Dt} - (\boldsymbol{\sigma} : \nabla \mathbf{v}) + \sum_{c=1}^N (\mathbf{j}_c \cdot \mathbf{g}_c) \\ & + \sum_{c=1}^N \check{h}_c \nabla \cdot \mathbf{j}_c + \sum_{c=1}^N (-\check{h}_c) R_c \end{aligned} \quad (1.152)$$

The last term in (1.152), denoting *the heat of reaction*, is seldom used in this form. The term denoting the rate of transformation can be given by:

$$R_c = \sum_{r=1}^q \nu_{c,r} M_{w_c} r_r \quad (1.153)$$

where  $r_r$  denotes the chemical reaction rate of reaction  $r$  per unit volume.

Considering the general homogeneous reaction:

<sup>15</sup> Recall that the relation,  $\sum_{c=1}^N \omega_c = 1$ , states that the weight fractions are linearly dependent. A rigorous model derivation, as given in App B, may be needed to verify the given result. There are two alternative paths available, either to formulate the complete differentiation of the enthalpy function in terms of  $N - 1$  species or in terms of  $N$  species and the constraint that  $\sum_{c=1}^N \omega_c = 1$  (e.g., [104], pp. 66–70).

Moreover, we suppose that initially there are  $n_{A0}$  moles of  $A$ ,  $n_{B0}$  moles of  $B$ , etc. The rate of change of moles on one chemical species is related to that of any other by the stoichiometry of the reaction. Thus,

$$\frac{1}{a} \frac{dn_A}{dt} = \frac{1}{b} \frac{dn_B}{dt} = \frac{1}{c} \frac{dn_C}{dt} = \frac{1}{d} \frac{dn_D}{dt} \quad (1.154)$$

The reaction rate  $r_c$  is defined by:

$$r_c = \nu_c r = \frac{dn_c}{dt} \frac{1}{V}$$

where  $\nu_c$  is the stoichiometric coefficient of species  $c$ . If  $c$  refers to a reactant,  $\nu_c$  is negative, and for a product  $\nu_c$  is positive.

This relation shows that the rate divided by the stoichiometric coefficient is independent of the choice of reactant or product. The ratio between the reaction rate and the stoichiometric coefficient of anyone of the species can be expressed:

$$r = \frac{r_c}{\nu_c} = \frac{1}{\nu_c} \frac{dn_c}{dt} \frac{1}{V} = \frac{d\xi_r}{dt} \frac{1}{V} = \rho \frac{d\xi_r}{dt} \frac{1}{M} \quad (1.155)$$

where  $d\xi_r$  is the *extent of reaction* for reaction  $r$ . The reaction rate quantity  $r$  is proportional with the extent of reaction and represents a useful way of maintaining consistency in reporting rate values, since  $r$  must be the same for all chemical species participating in the reaction (see [152], p. 38).

Introducing the  $r_r$  variable (i.e., characterizing the reaction rate of any reaction  $r$ ), the term in the temperature equation (1.152) denoting the heat of reaction can be reformulated:

$$-\sum_{c=1}^N \check{h}_c R_c = -\sum_{c=1}^N \check{h}_c \sum_{r=1}^q \nu_{c,r} M_{w_c} r_r = -\sum_{r=1}^q r_r \sum_{c=1}^N \check{h}_c M_{w_c} \nu_{c,r} = -\sum_{r=1}^q r_r \sum_{c=1}^N \bar{h}_c \nu_{c,r} \quad (1.156)$$

where  $M_{w_c} \check{h}_c$  is equal to the partial molar enthalpy of component  $c$ . That is, using the relation  $m_c = M_{w_c} n_c$ ,  $\check{h}_c = (\frac{\partial \hat{h}}{\partial m_c})_{T,p,m'} = \frac{1}{M_{w_c}} (\frac{\partial \hat{h}}{\partial n_c})_{T,p,n'} = \frac{1}{M_{w_c}} \bar{h}_c$  (see App B).  $n_c$  is the number of moles of component  $c$  in the mixture, and  $\bar{h}_c$  is the partial molar enthalpy of component  $c$  in the mixture.

In Chemical Engineering it has become common practice to reformulate this term introducing the *heat of reaction* quantity. The heat of reaction is always given per mole of the species which is the basis of calculation (e.g., species  $c_{\text{ref}}$ ):

$$-\sum_{c=1}^N \bar{h}_c \nu_{c,r} = -\nu_{c_{\text{ref}},r} \sum_{c=1}^N \bar{h}_c \frac{\nu_{c,r}}{\nu_{c_{\text{ref}},r}} = \nu_{c_{\text{ref}},r} (-\Delta \bar{H}_{r,c_{\text{ref}}}) \quad (1.157)$$

thus

$$-\sum_{c=1}^N \check{h}_c R_c = -\sum_{r=1}^q r_r \sum_{c=1}^N \bar{h}_c \nu_{c,r} = \sum_{r=1}^q r_{r,c_{\text{ref}}} (-\Delta \bar{H}_{r,c_{\text{ref}}}) \quad (1.158)$$

The thermal energy equation in terms of temperature thus yields:

$$\begin{aligned} \rho C_p \frac{DT}{Dt} = & -\nabla \cdot \mathbf{q} - \frac{T}{\rho} \left( \frac{\partial \rho}{\partial T} \right)_{p,\omega} \frac{Dp}{Dt} - (\boldsymbol{\sigma} : \nabla \mathbf{v}) \\ & + \sum_{c=1}^N (\mathbf{j}_c \cdot \mathbf{g}_c) + \sum_{c=1}^N \bar{h}_c \nabla \cdot \left( \frac{\mathbf{J}_c}{M_{w_c}} \right) + \sum_{r=1}^q r_{r,c_{\text{ref}}} (-\Delta \bar{H}_{r,c_{\text{ref}}}) \end{aligned} \quad (1.159)$$

Note that at this point the enthalpy equation is no longer formulated on conservative form.

It is important to identify the physical meaning of the terms in the temperature equation. *The term on the LHS* denotes the rate of gain of heat content per unit volume; *the first term on the RHS* denotes the rate of energy input by the heat flow (e.g., conduction and radiation) per unit volume; *the second term on the RHS* denotes the rate of work done by pressure of surroundings on the control volume per unit volume due to fluid motion; *the third term on the RHS* denotes the irreversible rate of internal energy increase per unit volume by viscous dissipation; *the fourth term on the RHS* denotes the rate of work done by body forces on the control volume; *the fifth term on the RHS* denotes an energy flux caused by inter-diffusion processes per unit volume<sup>16</sup>; *the sixth term on the RHS* denotes the thermal energy release by homogeneous chemical reactions per unit volume.

In the discussion above the specific enthalpies were expressed in the general form:

$$n\bar{h} = \sum_{c=1}^N n_c \bar{h}_c \quad (1.160)$$

where  $\bar{h}(t, \mathbf{r})$  is the *specific molar enthalpy* of the real mixture, and the *partial molar enthalpy* of component  $c$  in a real mixture is  $\bar{h}_c(t, \mathbf{r})$ . This formulation follows directly from the definition of the partial specific enthalpies. The partial specific enthalpies have to be derived from a differentiation of the specific enthalpies with respect to the mole number.

For an ideal mixture on the other hand, the calculations simplify considerably (e.g., [139], p. 397):

$$n\bar{h} = n\bar{h}^* = \sum_{c=1}^N n_c \bar{h}_c = \sum_{c=1}^N n_c \bar{h}_c^* \quad (1.161)$$

<sup>16</sup> This term can be reformulated by use of the vector differential operators for differentiation of products into the difference between two terms (e.g., [11], p. 567; [91], p. 198; [135], p. 225):  $\sum_{c=1}^N \bar{h}_c \nabla \cdot \mathbf{j}_c = \sum_{c=1}^N \nabla \cdot (\bar{h}_c \mathbf{j}_c) - \sum_{c=1}^N \mathbf{j}_c \cdot \nabla \bar{h}_c$ . The first part of this term constitutes an additional component to  $\mathbf{q}$  in binary and multicomponent systems, as mentioned earlier.

thus

$$\begin{aligned}\bar{h}_c &= \left( \frac{\partial \hat{h}}{\partial n_c} \right)_{T,p,n'} = \left( \frac{\partial (n\bar{h})}{\partial n_c} \right)_{T,p,n'} = \left( \frac{\partial (n\bar{h}^*)}{\partial n_c} \right)_{T,p,n'} \\ &= \left( \frac{\partial}{\partial n_c} \sum_{c=1}^N n_c \bar{h}_c^* \right)_{T,p,n'} = \bar{h}_c^*\end{aligned}\quad (1.162)$$

where  $\bar{h}_c(t, \mathbf{r})$  denotes the *partial molar enthalpy* quantity of component  $c$  in a mixture, whereas the  $\bar{h}_c^*(t, \mathbf{r})$ -quantity is the *molar enthalpy* of component  $c$  in an ideal mixture. We thus notice from the above derivation that for an ideal mixture yields  $\bar{h}_c(t, \mathbf{r}) = \bar{h}_c^*(t, \mathbf{r})$ . Moreover, the subscript  $n'$  stands for  $n_1, \dots, n_{c-1}, n_{c+1}, \dots, n_N$ , and the subscript  $n$  stands for  $n_1, n_2, n_3, \dots, n_N$ .

To illustrate the manipulation needed to get the above equation into the form used in practice, following the approach given by Fogler [47] and Hayes [65] (p. 259 and p. 273), we shall use the generalized reaction with species  $A$  as basis:

The corresponding heat of reaction is defined as:

$$\Delta \underline{H}_{rA}^* = \frac{c}{a} \bar{h}_C^* + \frac{d}{a} \bar{h}_D^* - \frac{b}{a} \bar{h}_B^* - \bar{h}_A^* \quad (1.163)$$

where species  $A$  is chosen as basis and the heat of reaction quantity has units joules per mole of  $A$  reacted.

The heat of reaction quantity is related to the last term in the temperature equation (1.152) in the following manner:

$$\sum_{c=1}^N (-\check{h}_c) R_c = r_A (-\Delta \underline{H}_{rA}^*) \quad (1.164)$$

For an ideal gas the enthalpy is independent of  $p$  at a given  $T$  (as can be verified by use of (1.149)). The heat of reaction at a particular temperature and pressure is thus expressed in terms of the enthalpy of formation at the reference temperature plus the change in enthalpy that results when the temperature is changed from the reference temperature to another temperature:

$$\Delta \underline{H}_c^*(T) = \Delta \underline{H}_{f,c}^*(T_{\text{ref}}) + \int_{T_{\text{ref}}}^T \Delta \underline{C}_{p,c}^*(T) dT \quad (1.165)$$

where  $\Delta \underline{H}_{f,c}^*(T_{\text{ref}})$  is the *molar heat of formation* of species  $c$ .

A possible alternative to the conventional reactor modeling approach which consist in solving the temperature equation (1.152), is to use the enthalpy equation (1.138) in combination with the enthalpy-temperature relation (1.150) making the standard assumption that the thermodynamic formulas derived from classical equilibrium thermodynamics may be applied locally for nonequilibrium systems. Hence, it follows that the two model formulations (1.150) and (1.151) are formally equivalent. The application of the enthalpy equation has the advantage of enabling the solution of an equation on the flux form, whereas the temperature equation is formulated on the advective form. Moreover, it is claimed that the enthalpy quantity is often representing a well behaved smooth function whereas the temperature variable might have steeper gradients. However, the enthalpy approach has the drawback that the enthalpy variable has to be converted into temperature at each discretization point and for every time step in the solution process, if the temperature field is to be analyzed. Furthermore, in many situations the boundary conditions used are expressed in terms of temperature. Besides, the transformation formulas for non-ideal reactive flow systems can be rather complex.

### 1.2.4.7 Transport of Entropy

From the formal macroscopic statement of *the second law of thermodynamics*, as developed from classical thermodynamics arguments, it is difficult to assign a physical significance to entropy. Ultimately, you must reassure yourself that entropy is defined mathematically, and like enthalpy, can be used to solve problems even though our physical connexion with the property is occasionally less than satisfying.

Historically, the concept of entropy as a state function was first introduced on macroscopic scales as a means of tracking transformations of heat into work in the context of heat engine design<sup>17</sup> [54]. On microscopic scales entropy has been interpreted as a measure of the molecular disorder of the system. Its value is related to the number of microscopic states available at a particular macroscopic state. From this point of view it is possible to appreciate the manner in which generation of disorder results in lost work (e.g., [42], Chap. 3). The natural progression of real processes is from order to disorder, from lower entropy to higher entropy. Entropy is thus closely associated with probability. Nature spontaneously proceeds toward the states that have the highest probabilities of existing. We can conclude that the driving force for a spontaneous process is an increase in the entropy of the universe. In irreversible thermodynamics entropy was introduced and discussed as a result of a need for quantification of the degree of irreversibility of a process. The theory thus explain the way in which the generation of disorder reflected by entropy change results in conversion of potentially useful work energy into practically useless thermal energy. In this discipline of thermodynamics the continuum balance equation for entropy plays a central role [32]. This equation expresses the fact that the entropy

---

<sup>17</sup> A heat engine is a device which converts heat into work.

of a volume element changes with time for two reasons. First it changes because entropy flows into the control volume, second because there is an entropy source due to irreversible phenomena inside the control volume. The entropy source is always a non-negative quantity, since entropy can only be created, never destroyed. For reversible transformation the entropy source vanishes. To reduce the lost work in industrial process plants, the minimization of entropy production rates in process equipment is suggested as a strategy for future process design and optimization [82]. The method is based on the hypothesis that *the state of operation that has a minimum total entropy production is characterized by equipartition of the local entropy production*. In this context we need to quantify the entropy sources of the various irreversible unit operations that occur in the industrial system.

In fluid dynamics there is no specific use of the transport equation for entropy other than being a physical condition indicating whether a constitutive relation proposed has a sound physical basis or not (nevertheless, this may be a constraint of great importance in many situations). In this connexion we usually think of *the second law of thermodynamics* as providing an inequality, expressing the observation that irreversible phenomena lead to entropy production. However, even though the application of the entropy equation in chemical reaction engineering is limited today, the understanding and physical interpretations of terms in the equation may be important in future process design and optimization.<sup>18</sup> I view of the above evaluation, the formulation of the transport equation for entropy is outlined in the following paragraphs. By combining the total energy balance with simple thermodynamic relations between state variables, a transport equation that must be satisfied by the entropy density field  $\rho s$  is obtained. At this point, the simplest way to formulate this equation is to reformulate the thermal energy equation written in terms of internal energy (1.135) or enthalpy (1.138) by use of the following thermodynamic relations (e.g., [7, 32, 135]):

$$TdS = dE + pd\left(\frac{1}{\rho}\right) - \sum_{c=1}^N \mu_c d\omega_c \quad (1.166)$$

where  $S = S(E, \rho, \omega_c)$  or

$$TdS = dH - \left(\frac{1}{\rho}\right)dp - \sum_{c=1}^N \mu_c d\omega_c \quad (1.167)$$

---

<sup>18</sup> Kjelstrup and Bedeaux [82] speculate that the need for more accurate modeling tools to enable process designs that waste less work will increase the use of irreversible thermodynamics in the future. It may then no longer be sufficient to optimize the first law efficiency solely. The second law may have to be taken into account as well. Under future UN environmental protection conventions and protocols the process industry may be forced to report on their annual entropy production. As a political tool, economical benefits could also be given to those industries that limit or reduce their entropy production.

where  $S = S(H, p, \omega_c)$ ,  $p$  is the equilibrium pressure, the functions  $\mu_c$  is the specific chemical potential of component  $c$ .

The specific chemical potentials refer to one unit of mass of the component concerned, and is defined by:

$$\mu_c = \left( \frac{\partial(\rho e)}{\partial M_c} \right)_{S, V, M'} \quad \text{for } (c = 1, 2, 3, \dots, N) \quad (1.168)$$

It is then assumed that, although the total system is not in equilibrium, there exists within small mass elements a state of local equilibrium, for which the local entropy is the same function of  $E$ ,  $\rho$  and  $\omega_c$  (or  $H$ ,  $p$  and  $\omega_c$ ) as in real equilibrium for a fluid parcel. In particular we assume that the above formulas remains valid written as a time rate of change for a mass element.

The continuum mechanical analogues of the fundamental thermodynamic relations are written as:

$$T \frac{Ds}{Dt} = \frac{De}{Dt} + p \frac{D(\frac{1}{\rho})}{Dt} - \sum_{c=1}^N \mu_c \frac{D\omega_c}{Dt} \quad (1.169)$$

After introducing the enthalpy quantity (1.137), we get:

$$T \frac{Ds}{Dt} = \frac{Dh}{Dt} - \frac{1}{\rho} \frac{Dp}{Dt} - \sum_{c=1}^N \mu_c \frac{D\omega_c}{Dt} \quad (1.170)$$

Note that the hypothesis of local equilibrium can only be justified by virtue of the validity of the conclusions derived from it.

Invoking these expressions and the transport equation for the species mass balance into the corresponding formulations of the thermal energy equation results in an explicit transport equation for the entropy density:

$$\begin{aligned} \rho \frac{Ds}{Dt} = & -\frac{1}{T} \nabla \cdot \mathbf{q} - \frac{1}{T} (\boldsymbol{\sigma} : \nabla \mathbf{v}) + \frac{1}{T} \sum_{c=1}^N (\mathbf{j}_c \cdot \mathbf{g}_c) + \frac{1}{T} \sum_{c=1}^N \mu_c \omega_c \left( \frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) \right) \\ & + \frac{1}{T} \sum_{c=1}^N \mu_c \nabla \cdot \mathbf{j}_c - \frac{1}{T} \sum_{c=1}^N \mu_c R_c \end{aligned} \quad (1.171)$$

By use of the continuity equation the fourth term on the right hand side vanishes. The term is retained in the equation for convenience of the multi-phase analysis discussed in Sect. 3.3. The last term in the equation above can be reformulated in terms of the chemical affinities as follows:

$$-\frac{1}{T} \sum_{c=1}^N \mu_c R_c = -\frac{1}{T} \sum_{c=1}^N \mu_c \sum_{r=1}^q \nu_{c,r} r_r M_{w_c} = -\frac{1}{T} \sum_{r=1}^q r_r \sum_{c=1}^N \nu_{c,r} M_{w_c} \mu_c = \frac{1}{T} \sum_{r=1}^q r_r A_r \quad (1.172)$$

The chemical affinities of the reactions  $r$  ( $= 1, \dots, q$ ) are defined by:

$$A_r = - \sum_{c=1}^N \nu_{c,r} M_{w_c} \mu_c, \quad (r = 1, \dots, q) \quad (1.173)$$

Thus, in irreversible thermodynamics the affinities act as the driving forces of the reactions [89].

We can then reformulate the entropy equation into the general form of a transport equation, which yields:

$$\begin{aligned} \rho \frac{Ds}{Dt} = & -\nabla \cdot \left( \frac{\mathbf{q} - \sum_{c=1}^N \mu_c \mathbf{j}_c}{T} \right) - \frac{1}{T^2} (\mathbf{q} \cdot \nabla T) + \frac{1}{T} \sum_{c=1}^N \mu_c \omega_c \left( \frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) \right) \\ & - \frac{1}{T} \sum_{c=1}^N \mathbf{j}_c \cdot \left( T \nabla \left( \frac{\mu_c}{T} \right) - \mathbf{g}_c \right) - \frac{1}{T} (\boldsymbol{\sigma} : \nabla \mathbf{v}) + \frac{1}{T} \sum_{r=1}^q A_r r_r \end{aligned} \quad (1.174)$$

The entropy flux,  $\mathbf{J}_s$ , and the entropy production,  $\Phi_{\text{total}}$ , are given by:

$$\mathbf{J}_s = \frac{\mathbf{q} - \sum_{c=1}^N \mu_c \mathbf{j}_c}{T} \quad (1.175)$$

$$\begin{aligned} \Phi_{\text{total}} = & -\frac{1}{T^2} (\mathbf{q} \cdot \nabla T) + \frac{1}{T} \sum_{c=1}^N \mu_c \omega_c \left( \frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) \right) - \frac{1}{T} \sum_{c=1}^N \mathbf{j}_c \cdot \left( T \nabla \left( \frac{\mu_c}{T} \right) - \mathbf{g}_c \right) \\ & - \frac{1}{T} (\boldsymbol{\sigma} : \nabla \mathbf{v}) + \frac{1}{T} \sum_{r=1}^q A_r r_r \end{aligned} \quad (1.176)$$

The entropy equation can now be used to express the Clausius' form of the second law of thermodynamics for open flow systems (e.g., [7]; [146], p. 126). The inequality expresses that irreversible phenomena (diffusive momentum transfer, energy transfer, mass transfer, and chemical reactions) lead to entropy production (i.e., energy dissipation):

$$\Phi_{\text{total}} \geq 0 \quad (1.177)$$

The way in which the separation of the terms of the right hand side of the entropy equation into the divergence of a flux and a source term has been achieved may at first sight seem to be to some extent arbitrary. The two groups of terms must, however, satisfy a number of requirements which determine this separation uniquely. First, one such requirement is that the entropy source term  $\Phi_{\text{total}}$  must be zero if the thermodynamic equilibrium conditions are satisfied within the system. Another requirement the source term must satisfy is that it should be invariant under a Galilean transformation (e.g., [148]), since the notations of reversible and irreversible behavior must be invariant under such a transformation. The terms included in the source term satisfy this requirement [32].

The physical meaning of the terms (or group of terms) in the entropy equation is not always obvious. However, *the term on the LHS* denotes the rate of accumulation of entropy within the control volume per unit volume. On the RHS the entropy flow terms included in  $\mathbf{J}_s$  show that for open systems the entropy flow consists of two parts: one is the reduced heat flow  $\frac{q}{T}$ , the other is connected with the diffusion flows of matter  $\mathbf{j}_c$ . Secondly, the entropy production terms included in  $\Phi_{\text{total}}$  demonstrates that the entropy production contains four different contributions. (*The third term on the RHS* vanishes by use of the continuity equation, but retained for the purpose of indicating possible contributions from the interfacial mass transfer in multiphase flows, discussed later). The first term in  $\Phi_{\text{total}}$  arises from heat fluxes as conduction and radiation, the third from diffusion, the fourth is connected to the gradients of the velocity field, giving rise to viscous flow, and the fifth is due to chemical reactions.

The structure of the expression for  $\Phi_{\text{total}}$  is that of a bilinear form: it consists of a sum of products of two factors. One of these factors in each term is a flow quantity (heat flux  $\mathbf{q}$ , mass diffusion flux  $\mathbf{j}_c$ , momentum flux expressed by the viscous stress tensor  $\boldsymbol{\sigma}$ , and chemical reaction rate  $r_r$ ). The other factor in each term is related to a gradient of an intensive state variable (gradients of temperature, chemical potential and velocity) and may contain the external force  $\mathbf{g}_c$  or a difference of thermodynamic state variables, viz. the chemical affinity  $A_r$ . These quantities which multiply the fluxes in the expression for the entropy production are called *thermodynamic forces* or *affinities*. Even if the entropy equation formulated in this section is not independent of the other energy equations, the solution of this equation can provide some useful information:

- The second law of thermodynamics set important constraints on apparently possible physiochemical processes as for example minimum work to separate a mixture, maximum possible efficiency of various unit operations often applied in chemical engineering and minimum electrical energy needed for production of various metals via electrolysis.
- This law may also provide a basis for process optimization analysis of engineering devices involving simultaneous transport phenomena and chemical reactions by use of *the principle of minimum entropy production*.
- The thermodynamic inequality may also guide the selection of *general constitutive laws* governing the diffusion of momentum, energy, and species mass in non-equilibrium chemical reacting mixtures.

### 1.2.4.8 Remarks on the Angular Momentum Equation

In this chapter it has been shown that all the balance equations formulated for an Eulerian CVs can be cast in a generalized form, which is applicable in any coordinate system. The coordinate system is thus chosen to proceed with the solution of the problem in question in a convenient way. However, not all of the balance equations are independent of one another, thus the set of equation used to solve particular problems is not solely a matter of convenience. For instance, the angular momentum- and linear momentum equations are not independent for flow of a simple fluid.<sup>19</sup>

In continuum mechanics, provided that the total stress tensor  $T_{ij}$  is symmetric, the linear momentum equation may be used to derive the angular momentum equation and they are thus not independent.<sup>20</sup> To prove this relationship the angular momentum equation can derived including a term for microscopic angular momentum. It can then be shown that the existence of a net microscopic angular momentum implies that the stress tensor is anti-symmetric. Conversely, if the net microscopic angular momentum vanishes, then the stress tensor is symmetric and the angular momentum equation is identical with the moment of the linear momentum equation. It follows that for a system the angular momentum conservation law can be stated as: *The rate of change of the angular momentum of a material volume  $V(t)$  is equal to the sum of the torques.* Let the vector  $r_j$  be the position of a point on the Lagrangian control volume surface with respect to a fixed origin. The relevant terms can then be expressed as follows [13, 119, 135]:

- Angular momentum of material in element  $dv$  about origin:  $\mathbf{r} \times (\rho \mathbf{v}) dv$  or  $\rho \epsilon_{ijk} r_j v_k dv$
- Torque of body force about origin:  $\sum_{c=1}^N \mathbf{r} \times \rho_c \mathbf{g}_c dv$  or  $\sum_{c=1}^N \epsilon_{ijk} r_j \rho_c g_{c,k} dv$
- Torque of surface force about origin:  $\mathbf{r} \times (\mathbf{T} \cdot \mathbf{n}) da$  or  $\epsilon_{ijk} r_j n_p T_{pk} da$
- Net microscopic angular momentum:  $\mathbf{n} \cdot \mathbf{\Omega} da$  or  $n_k \Omega_{ki} da$

where the alternating unit tensor or *the permutation symbol*,  $\epsilon_{ijk} = (1/2)(i - j)(j - k)(k - i)$ , is defined as:

$$\epsilon_{ijk} = \begin{cases} +1 & \text{if } ijk = 123, 231, \text{ or } 312, \\ -1 & \text{if } ijk = 321, 132, \text{ or } 213, \text{ and} \\ 0 & \text{if two indices are alike.} \end{cases} \quad (1.178)$$

Following Panton [119], in the last term an angular momentum tensor  $\Omega_{ki}$  is postulated, giving the transport of  $i$ -direction angular momentum across a  $k$ -direction plane by microscopic processes.

The angular momentum law then takes the following form:

<sup>19</sup> A *simple fluid* is defined as a fluid that can be described by a linear velocity law, a linear conduction law, and a state fixed by two thermodynamic variables [169].

<sup>20</sup> On a microscopic scale perspective the angular momentum equation is an independent law [119] (see also Sect. 2.4.2 for further details).

$$\frac{D}{Dt} \int_V \rho \epsilon_{ijk} r_j v_k dv = \sum_{c=1}^N \int_V \epsilon_{ijk} r_j \rho_c g_{k,c} dv + \int_A [\epsilon_{ijk} r_j n_p T_{pk} + n_k \Omega_{ki}] da \quad (1.179)$$

The term on the LHS can be transformed using Reynold's theorem, while the last integral on the right-hand side is changed to a volume integral by Gauss's theorem. Since the region of integration is arbitrary, the integrand must equal zero:

$$\epsilon_{ijk} \frac{\partial}{\partial t} (\rho r_j v_k) + \epsilon_{ijk} \frac{\partial}{\partial x_p} (v_p \rho r_j v_k) = \sum_{c=1}^N \epsilon_{ijk} r_j \rho_c g_{k,c} + \epsilon_{ijk} \frac{\partial}{\partial x_p} (r_j T_{pk}) + \frac{\partial \Omega_{ki}}{\partial x_k} \quad (1.180)$$

The equation for the position vector  $r_i = x_i$  is independent of time, and its space derivative is  $\frac{\partial r_j}{\partial x_i} = \delta_{ij}$ . Using these facts, the equation above may be rearranged to:

$$\epsilon_{ijk} r_j \left[ \frac{\partial}{\partial t} (\rho v_k) + \frac{\partial}{\partial x_p} (\rho v_p v_k) - \sum_{c=1}^N \rho_c g_{k,c} - \frac{\partial T_{pk}}{\partial x_p} \right] = \epsilon_{ijk} T_{jk} + \frac{\partial \Omega_{ki}}{\partial x_k} \quad (1.181)$$

The term in brackets is the linear momentum equation and is equal to zero. The term  $\epsilon_{ijk} T_{jk}$  depends only on the anti-symmetric part of  $T_{jk}$ . Thus, a condition of stress tensor symmetry can be expressed as:

$$- \epsilon_{ijk} T_{jk} = \frac{\partial \Omega_{ki}}{\partial x_k} \quad (1.182)$$

If we assume that the net microscopic flux of angular momentum,  $\Omega_{ki}$ , is zero, then  $\epsilon_{ijk} T_{jk}$  is zero and we have proved that  $T_{jk}$  is symmetric (see, e.g., [11], p. 114; [105], p. 215; [135], Sect. 2.2.2; [180], app C; [184], Sect. 4.4). Furthermore, a second consequence of this assumption is that the angular momentum equation is exactly equal to  $\mathbf{r} \times$  the linear momentum equation. In fluid mechanics the net microscopic flux of angular momentum is usually ignored, thus the linear- and angular momentum equations are not independent (e.g., [13], Sect. 3.4; [150], Sect. 2.2.4). There is consensus in the literature that the stress tensor for fluids is symmetric except for a class of suspensions in which torques could be produced on each particle in the carrier fluid by an external field [90, 105]. This means, in practice, that for all chemical reactor systems of interest the stress tensor is symmetric.

The motion of such fluids can thus be determined by an Eulerian vector angular-momentum balance equation on the form:

$$\frac{\partial}{\partial t} \int_V \mathbf{r} \times (\rho \mathbf{v}) dv + \int_A \mathbf{r} \times \rho \mathbf{v} (\mathbf{v} \cdot \mathbf{n}) da = \int_A \mathbf{r} \times (\mathbf{T} \cdot \mathbf{n}) da + \sum_{c=1}^N \int_V \mathbf{r} \times (\rho_c \mathbf{g}_c) dv \quad (1.183)$$

which is particularly convenient for analyzing fluid flow in rotating turbo machinery like compressors, turbines, cyclones, etc.

The total energy equation expressing the physical law of conservation of total energy, can be reformulated into a set of energy transport equations expressing balance laws for the various forms of energy (i.e., kinetic, potential and internal energy). However, it has also been shown that the entropy transport equation can be obtained from the energy balance equations, thus the entropy equation is not independent of these equations. Moreover, compared to the momentum equation, the equation of change for kinetic energy and the equation for angular momentum do not introduce additional unknowns, nor do they include new information. It is common practice when applying computational fluid dynamics models to chemical reactor modeling, to solve a set of independent transport equations consisting of upto  $N - 1$  species transport equations, the mixture continuity equation, and the momentum equation and the internal (or thermal) energy equation formulated in terms of temperature. However, considering flow situations where the kinetic energy and/or the potential energy contributions become significant (e.g., high speed velocity flows within electrical fields), it may be beneficial to solve the transport equations for these variables as well.

### ***1.2.5 Some Useful Simplifications of the Governing Equations***

In chemical engineering we are usually not using the governing equations in their most fundamental forms, but apply suitable simplifications giving sufficient predictions of the different process units with minimum costs.

The ability to establish such quantitative links between measures of reactor performance and input and operating variables is essential in optimizing the operating conditions, in determining proper reactor scale-up and design, and in interpreting data in research and pilot-plant work.

#### **1.2.5.1 Steady Flows**

In many cases we consider steady flows. A *steady flow* is defined to be one for which, at any fixed point in the flow field, all the flow variables are independent of time. Thus, in a steady flow all partial derivatives with respect to time vanish.

#### **1.2.5.2 Incompressible-, Compressible- and Variable Density Flows**

The term *incompressible flow* is applied to any situation where changes in the density of a fluid particle are negligible [119]. A mathematical definition is:

$$\frac{1}{\rho} \frac{D\rho}{Dt} = 0 \quad (1.184)$$

From the continuity equation we have:

$$\frac{1}{\rho} \frac{D\rho}{Dt} = -\nabla \cdot \mathbf{v} \quad (1.185)$$

This shows that an alternative definition is that  $\nabla \cdot \mathbf{v} = 0$  (the rate of expansion is zero). An equivalent condition is to require that the fluid particles have constant volume, but not necessary constant shape. Furthermore, the different fluid particles do not need to have the same density. The only requirement is that the density of each individual fluid particle remain unchanged. The incompressible flow limit is approached when the density is constant along any streamline (i.e.,  $\frac{D\rho}{Dt} = -\rho(\nabla \cdot \mathbf{v}) \approx 0$ ). The resulting or derived constant volume condition, which occur in flow situations where density changes can be neglected, has sometimes erroneously been used defining incompressible flows in general. Such a procedure may lead to mathematical inconsistencies. The main criterion for incompressible flow (as defined in the non-reactive gas dynamics literature) is rather that the Mach number is low, and that no significant density changes occur due to changes in temperature. In other cases the fluid velocity vector may be considered solenoidal<sup>21</sup> even though the mixture density is not constant. Most chemical engineers relate the term *incompressible flow* to incompressible fluid systems. For non-reactive ideal liquid mixtures operated at nearly constant temperatures, the incompressible flow limit is obviously a reasonable approximation in practice. However, for compressible systems, the gas dynamics analysis may not be that obvious although very important in the chemical process industry. To learn more about gas dynamics we are characterizing three seemingly very similar flow systems reflecting somewhat divergent behavior, starting out with a relatively simple incompressible non-reacting adiabatic gas flow in a vertical tube (i.e., representing an idealized design of chemical reactors), then we expand our analysis to a non-adiabatic system, and finally a reactive mixture is considered. The first system constitutes a low Mach number internal gas flow with an adiabatic wall, i.e., an *incompressible flow* [119].

For such a one-component flow problem where the viscous dissipation is the only heat source, the density of the fluid is governed by the continuity equation and a thermodynamic equation of state (EOS). In the present case we write the EOS as:

$$\frac{1}{\rho} \frac{D\rho}{Dt} = \alpha \frac{Dp}{Dt} - \beta \frac{DT}{Dt} \quad (1.186)$$

where the isothermal compressibility (e.g., [7, 139]) is:

---

<sup>21</sup> A vector field  $\mathbf{v}$  satisfying  $\nabla \cdot \mathbf{v} = 0$  is called *solenoidal*. A volume-preserving motion is called *isochoric*, i.e., a motion for which the density in the neighborhood of any particle remains constant as the particle moves. The flow of an incompressible fluid is necessarily isochoric, but there may also be isochoric flows of compressible fluids [105] (p. 212).

$$\alpha(p, T) = \frac{1}{\rho} \frac{\partial \rho}{\partial p} \Big|_T \quad (1.187)$$

The bulk expansion coefficient (e.g., [119, 139]) is:

$$\beta(p, T) = -\frac{1}{\rho} \frac{\partial \rho}{\partial T} \Big|_p \quad (1.188)$$

The functions  $\alpha$  and  $\beta$  are thermodynamic variables that characterize the fluid. Physically  $\alpha$  and  $\beta$  always take non-zero values. The right hand side of (1.186) is thus small only if the pressure and temperature changes are small enough. In turn, the magnitudes of these variables are governed by dynamic processes occurring in the flow field. The energy and momentum equations will play a major role in fixing the pressure and temperature. The advantage of writing the equation of state in the form (1.186) is that the flow field effects are isolated in  $Dp/Dt$  and  $DT/Dt$  while the thermodynamic character of the fluid is isolated in  $\alpha$  and  $\beta$ .

The governing equations determining the evolution of single-component fluid flow are:

Thermodynamics:

$$\frac{1}{\rho} \frac{D\rho}{Dt} = \alpha \frac{Dp}{Dt} - \beta \frac{DT}{Dt} \quad (1.189)$$

with  $\alpha = \alpha(p, T)$ ,  $\beta = \beta(p, T)$ ,  $C_P = C_P(p, T)$ ,  $\mu = \mu(p, T)$ ,  $k = k(p, T)$ .

Continuity:

$$\frac{1}{\rho} \frac{D\rho}{Dt} = -\nabla \cdot \mathbf{v} \quad (1.190)$$

Momentum:

$$\rho \frac{D\mathbf{v}}{Dt} = -\nabla p - \nabla \cdot \boldsymbol{\sigma} + \rho \mathbf{g} \quad (1.191)$$

Net viscous stress:

$$\nabla \cdot \boldsymbol{\sigma} = -\nabla \cdot \{\mu[\nabla \mathbf{v} + (\nabla \mathbf{v})^T]\} + \nabla \cdot \left\{ \left( \frac{2}{3} \mu - \mu_B \right) (\nabla \cdot \mathbf{v}) \right\} \quad (1.192)$$

Energy:

$$\rho C_P \frac{DT}{Dt} = \nabla \cdot (k \nabla T) + \mu \Phi_{\text{viscous}} + \beta T \frac{Dp}{Dt} \quad (1.193)$$

The analysis rely on the boundary conditions specified. The boundary conditions at the inlet are  $v_i = (v_0, 0, 0)$ ,  $T = T_0$  and  $\rho = \rho_0$ . On the wall  $v_i = 0$  and  $n_i q_i = 0$ . That is, we have adopted the no-slip condition at the wall requiring that the velocity is

zero. Since the wall is said to be adiabatic, no heat enters the flow through the walls. For the outlet several conditions are possible (e.g., zero gradients for fully developed flow, pressure boundary, free surface, etc.), for convenience we may overlook their importance in this analysis. These fluid flow problems require that all these equations are solved. The dependent variables are  $\rho$ ,  $p$ ,  $T$  and  $v_i$ . The governing equations are all coupled together. For instance, the momentum equation contains the density and pressure variables, and the viscosity parameter. These quantities depend on the local temperature. The temperature in turn is governed by the energy equation, which contains the velocity in the advective and dissipation terms. However, not all the terms in the equations have the same importance in determining the flow solution. To determine which terms are large and which are small, we cast the equations into non-dimensional variables with scales that are governed by the dynamics of the flow. The appropriate scales for non-dimensionalizing the variables are usually found from the tube geometry (e.g., say, a characteristic length  $L$ ), the boundary conditions and from detailed analysis of the equations that govern the flow [119]. Most of the non-dimensional variables are then formed in a straightforward manner:

$$x_i^* = \frac{x_i}{L}, t^* = \frac{tv_0}{L}, v_i^* = \frac{v_i}{v_0}, \rho^* = \frac{\rho}{\rho_0}, \alpha^* = \frac{\alpha}{\alpha_0}, \beta^* = \frac{\beta}{\beta_0}, C_P^* = \frac{C_P}{C_{P0}}, \mu^* = \frac{\mu}{\mu_0}, k^* = \frac{k}{k_0} \text{ and } Fr = \frac{v_0^2}{|g|L}.$$

Nevertheless, the temperature and pressure variables need further consideration. The pressure scale is usually found indirectly by substituting all the other non-dimensional variable definitions into the momentum equation. Accordingly, after substituting the dimensionless variables into the momentum equation, the non-dimensional pressure is defined as  $p^* = \frac{p-p_0}{\rho_0 v_0^2}$ . If  $p_S$  symbolizes the pressure scale, we write  $p^* = \frac{p-p_0}{p_S} = \frac{p-p_0}{\rho_0 v_0^2}$ . Thus, when the pressure changes in the flow are dominated by momentum effects,  $p^*$  is the proper non-dimensional pressure variable [119]. A further observation is that for incompressible flow, pressure plays the role of a force in the momentum equation. Since the pressure variable occurs only within a pressure gradient term in this equation, a reference level may be substituted without any effect. That is,  $\nabla(p - p_0) = \nabla p$ . If we consider the thermal processes occurring in this problem, we expect that heat (thermal energy) is generated in the flow field by viscous dissipation. The heat will then be redistributed by conduction and carried to new places by advection. In this case a suitable temperature scale is given by  $T_{\text{scale}} = \mu_0 v_0^2 / k_0$ , [119]. This is an estimate of the temperature rise that one can expect because of viscous dissipation from a velocity gradient of order  $v_0/L$ . Thus, we define  $T^* = \frac{T-T_{\text{ref}}}{T_{\text{scale}}} = \frac{T-T_0}{\mu_0 v_0^2 / k_0} = \frac{T-T_0}{Pr v_0^2 / C_{P0}}$ . In the latter term, the Prandtl number ( $Pr = \mu_0 C_{P0} / k_0$ ) has been introduced.

After all the non-dimensional variables are substituted into the equations, several non-dimensional groups occur<sup>22</sup>:

---

<sup>22</sup> In formulating these non-dimensional parameters we have used the expression for the speed of sound of an ideal gas (e.g., [119]; [137], app 4),  $C_S^2 = \frac{\gamma_0}{\rho_0 \alpha_0}$ . The details of the substitution are also simplified by noting that;  $Ma^2 = \frac{v_0^2}{C_S^2} = \frac{v_0^2 \rho_0 \alpha_0}{\gamma_0}$ , and that;  $\frac{v_0^2}{C_{P0} T_0} = \frac{Ma^2 \gamma_0}{A}$ .

$Re = \frac{\rho_0 L v_0}{\mu_0}$ ,  $Pr = \frac{\mu_0 C_{p0}}{k_0}$ ,  $\gamma_0 = \frac{C_{p0}}{C_{v0}}$ ,  $Fr = \frac{v_0^2}{|g|L}$ ,  $Ma = \frac{v_0}{C_S}$ ,  $A = \alpha_0 \rho_0 C_{p0} T_0$  and  $B = \beta_0 T_0$ .

For any given flow problem these parameters have specific fixed values. If they are large or small, they magnify or diminish the effect of the terms in which they appear as coefficients. In non-dimensional variables the equations are written as:

Thermodynamics:

$$\frac{1}{\rho^*} \frac{D\rho^*}{Dt^*} = \gamma_0 Ma^2 \left[ \alpha^* \frac{Dp^*}{Dt^*} - \frac{Pr B \beta^*}{A} \frac{DT^*}{Dt^*} \right] \quad (1.194)$$

The thermodynamic functions  $\alpha^*$ ,  $\beta^*$ ,  $\mu^*$ ,  $k^*$  and  $C_p^*$  are still undetermined.

Continuity:

$$\frac{1}{\rho^*} \frac{D\rho^*}{Dt^*} = -\nabla^* \cdot \mathbf{v}^* \quad (1.195)$$

Momentum:

$$\rho^* \frac{D\mathbf{v}^*}{Dt^*} = -\nabla^* p^* - \nabla^* \cdot \boldsymbol{\sigma}^* + \rho^* \frac{\mathbf{g}}{Fr|g|} \quad (1.196)$$

Viscous stress:

$$\nabla^* \cdot \boldsymbol{\sigma}^* = -\frac{1}{Re} (\nabla^* \cdot \{\mu^* [\nabla^* \mathbf{v}^* + (\nabla^* \mathbf{v}^*)^T]\} + \nabla^* \cdot \{(\frac{2}{3}\mu^* - \mu_B^*) (\nabla^* \cdot \mathbf{v}^*)\}) \quad (1.197)$$

Energy:

$$\begin{aligned} \rho^* C_p^* \frac{DT^*}{Dt^*} &= \frac{1}{Re} \frac{1}{Pr} (\nabla^* \cdot (k^* \nabla^* T^*) + \mu^* \Phi_{\text{viscous}}^*) \\ &+ \beta^* B \left( \frac{1}{Pr} + \frac{\gamma_0 Ma^2}{A} T^* \right) \frac{Dp^*}{Dt^*} \end{aligned} \quad (1.198)$$

where  $\mu^* \Phi_{\text{viscous}}^* = \frac{\mu}{\mu_0} \frac{\Phi_{\text{viscous}}}{v_0^2/L}$ .

Sample inlet boundary conditions are:  $v_i^* = (1, 0, 0)$ ,  $T^* = 0$  and  $\rho^* = 1$ , and on the wall  $v_i^* = 0$  and  $n_i q_i^* = 0$ .

At this stage we can see that the incompressible flow limit results when the right side of the non-dimensionalized form of the thermodynamic relation (1.194) becomes small, that is, when  $Ma^2 \rightarrow 0$ . As a general rule of experience, if  $Ma < 1/3$ , then the incompressible flow assumption will give a fair result for external flows (e.g., [184], p. 221). When the non-dimensionalized term  $D\rho^*/Dt^* = 0$ , the density of a fluid particle is constant. From this result it follows that in the non-dimensionalized continuity equation the left side is zero, so that  $\nabla \cdot \mathbf{v}^* = 0$ . Terms containing  $\nabla \cdot \mathbf{v}^*$  in the viscous stress and dissipation relations become small, as does the term proceeded

by  $Ma^2$  in the energy equation. For ideal gas dynamics it has been shown, by Taylor series expansions, that all the thermodynamic fluid property functions are constants in the limit of small Mach numbers [119, 184]. It is concluded that in this case the main criterion for incompressible flow is that the Mach number is low ( $Ma \rightarrow 0$ ), denoting that all the velocities are small compared to the speed of sound. That is, when the speed of sound  $C_S = \sqrt{\frac{\partial p}{\partial \rho}}|_S$  appears in the compressible flow analysis, its role is not to tell how fast waves travel, but to indicate how much density change accompanies a certain pressure change due to the flow (e.g., [119, 135]). Using the pressure scale,  $\rho_0 v_0^2$ , a flow decelerated from  $v = v_0$  at one location in the flow to  $v = 0$  at another will undergo a pressure change  $\Delta p \propto \rho_0 v_0^2$  (neglecting viscosity). With these considerations the Mach number is interpreted as follows [119]:

$$Ma^2 = \frac{v_0^2}{C_S^2} = v_0^2 \frac{\partial \rho}{\partial p}|_S = \frac{\rho_0 v_0^2}{\rho_0} \frac{\partial \rho}{\partial p}|_S \approx \Delta p \frac{1}{\rho_0} \frac{\Delta \rho}{\Delta p} = \frac{\Delta \rho}{\rho_0} \quad (1.199)$$

The parameter  $Ma^2$  is a measure of the size of density changes compared to fluid density. As  $Ma^2 \rightarrow 0$ , density changes become only a small fraction of the fluid density. However, although  $Ma^2 \rightarrow 0$  is required for incompressible flow, it is not the only requirement. Some flows where  $Ma^2 \rightarrow 0$  are low speed compressible flows. However, in these cases density changes are usually caused by temperature and/or mixture composition changes. For the present one-component flow analysis such effects are not important as the wall boundary is considered adiabatic. There is then not enough heat generated by viscous dissipation to cause large temperature changes.

The governing equations for incompressible flow derived based on dimensional analysis yield [119]:

Thermodynamics:

$$\frac{D\rho^*}{Dt^*} = 0 \quad (1.200)$$

$$\alpha^* = \beta^* = \mu^* = k^* = C_p^* = \rho^* = 1$$

Continuity:

$$\nabla^* \cdot \mathbf{v}^* = 0 \quad (1.201)$$

Momentum:

$$\frac{D\mathbf{v}^*}{Dt^*} = -\frac{1}{\rho^*} \nabla^* p^* + \frac{1}{Re} \mu^* \nabla^{2*} \mathbf{v}^* + \frac{\mathbf{g}}{Fr|\mathbf{g}|} \quad (1.202)$$

Viscous stress:

$$\begin{aligned}
\nabla^* \cdot \boldsymbol{\sigma}^* &= -\frac{1}{Re} (\nabla^* \cdot \{\mu^* [\nabla^* \mathbf{v}^* + (\nabla^* \mathbf{v}^*)^T]\}) \\
&\quad + \nabla^* \cdot \left\{ \left( \frac{2}{3} \mu^* - \mu_B^* \right) (\nabla^* \cdot \mathbf{v}^*) \right\} \\
&\approx \frac{1}{Re} \mu^* \nabla^{2*} \mathbf{v}^*
\end{aligned} \tag{1.203}$$

Energy:

$$\frac{DT^*}{Dt^*} = \frac{1}{Re} \left( \frac{1}{Pr} \nabla^{2*} T^* + \mu^* \Phi_{\text{viscous}}^* \right) + \beta^* \frac{B}{Pr} \frac{Dp^*}{Dt^*} \tag{1.204}$$

The boundary conditions at the inlet are:

$v_i^* = (1, 0, 0)$ ,  $T^* = 0$ ,  $p^* = 0$  and  $\rho^* = 1$ , on the wall  $v_i^* = 0$  and  $n_i q_i^* = 0$ .

Inspection of these equations reveals quite a lot about incompressible flow. First of all, the density and all the thermodynamic coefficients are constants. Secondly, when the density and the transport properties are constants, the continuity and momentum equations are decoupled from the energy equation. This result is important, as it means that we may solve for the three velocities and the pressure without regard for the energy equation or the temperature. Third, for incompressible flows the pressure is determined by the momentum equation. The pressure thus plays the role of a mechanical force and not a thermodynamic variable. Fourth, another important fact about incompressible flow is that only two parameters, the Reynolds number and the Froude number occur in the equations. The Froude number,  $Fr$ , expresses the importance of buoyancy compared to the other terms in the equation. The Reynolds number indicates the size of the viscous force term relative to the other terms. It is mentioned that compressible flows are often high  $Re$  flows, thus they are often computed using the inviscid *Euler* (momentum) equations. In the incompressible energy equation only derivatives of the temperature variable occur. This means that in incompressible flow, only changes in temperature with respect to some reference state are important. As with pressure, the level of the reference temperature does not affect the solution. The actual temperature in such a incompressible flow doesn't change noticeably.

The second system constitutes a low Mach number internal gas flow with non-adiabatic walls, i.e., a *compressible gas flow* [119]. In the foregoing discussion we have seen how the case  $Ma \rightarrow 0$  with an adiabatic wall is an example of incompressible flow. In other instances there is significant heat transfer through the wall. In this case we can isolate the flow situation by imagining that the wall is held at some fixed temperature  $T_W$  that is different from  $T_0$ . The non-dimensional scale for the temperature is redefined, so we need to redo the analysis of the resulting dimensionless equations. The problem now has a characteristic temperature scale,  $T_0 - T_W$ , which is a driving force for the conduction of heat from the wall into the fluid. Since we expect that all temperatures will lie between these two values, the proper non-dimensional temperature is:  $\hat{T} = \frac{T-T_0}{T_W-T_0}$ . The temperature variable,  $T^*$ , for the adiabatic wall problem is related to  $\hat{T}$  by the equation:  $T^* = \frac{T_W-T_0}{T_0} \frac{A}{\gamma_0 Pr Ma^2} \hat{T}$ .

There is no change in the formulation for any of the other variables, thus we can substitute the new temperature variable into the governing equations and again let the Mach number approach zero. The temperature variable does not appear in the continuity and momentum equations, so the previous dimensionless equations obtained in the adiabatic wall analysis remain unchanged. The equation of state is revised by substituting the new temperature variable. The EOS yields:

$$\frac{1}{\rho^*} \frac{D\rho^*}{Dt^*} = \gamma_0 Ma^2 \alpha^* \frac{Dp^*}{Dt^*} - B\beta^* \left( \frac{T_W - T_0}{T_0} \right) \frac{D\hat{T}}{Dt^*} \quad (1.205)$$

When the new temperature variable is substituted into the energy equation, the equation changes to:

$$\begin{aligned} \rho^* C_P^* \frac{D\hat{T}}{Dt^*} = & \frac{1}{PrRe} \nabla^* \cdot (k^* \nabla^* \hat{T}) + \frac{\gamma_0 Ma^2}{ARe} \left( \frac{T_0}{T_W - T_0} \right) \mu^* \Phi_{\text{viscous}}^* \\ & + \frac{\beta^* B \gamma_0 Ma^2}{A} \left[ \frac{T_0}{T_W - T_0} + \hat{T} \right] \frac{Dp^*}{Dt^*} \end{aligned} \quad (1.206)$$

Sample inlet boundary conditions are  $v_i^* = 0$  and  $\hat{T} = 1$  (or a known function). The limit  $Ma^2 \rightarrow 0$  gives a low speed compressible flow where the thermodynamic state equation shows that the density changes occur only because of the large variations in temperature:

$$\frac{1}{\rho^*} \frac{D\rho^*}{Dt^*} = -B\beta^* \left( \frac{T_W - T_0}{T_0} \right) \frac{D\hat{T}}{Dt^*} \quad (1.207)$$

The energy equation for the flow shows that advection and conduction determine the temperature field:

$$\rho^* C_P^* \frac{D\hat{T}}{Dt^*} = \frac{1}{PrRe} \nabla^* \cdot (k^* \nabla^* \hat{T}) \quad (1.208)$$

The transport properties and the thermodynamic functions are not necessarily constants this time, but depend (weakly) on temperature. The flow is a low speed compressible flow as long as  $(T_0 - T_W)/T_0$  is finite. The continuity and momentum equations no longer simplify, but must be considered with their temperature dependence. The complete set of equations is coupled together through the transport properties and the density. These equations apply to flows where the wall supplies significant heating to the fluid, i.e., problems of natural convection. The further special case of small temperature differences will turn out to be an incompressible flow. This flow is governed by the same equations as the adiabatic case except that the energy equation is a little different. The energy equation has only advection and conduction terms while in the adiabatic case the energy equation also includes a viscous dissipation and a pressure term.

The third system constitutes a low Mach number internal gas flow of a reactive mixture, i.e., a *variable density flow* [78]. In this book variable density flows are considered compressible in accordance with the view of [119], i.e., even though the density variations are not necessarily induced by pressure or compressibility effects, the terms *variable density flow* and ‘compressible flow’ are then equivalent phrases. This view may not agree with all the textbooks of classical gas dynamics. In reactor modeling we are dealing with flow situations where the mixture density may vary both due to pressure and temperature changes, chemical reactions and non-ideal mixing. For these flow situations, we must consider additional heat sources, changes in composition due to chemical reactions and fluid mixing, and thereafter redo the non-dimensional scales and reanalyze the resulting equations. If we consider the physical processes occurring in this problem, we expect that heat is generated in the flow field by the heat of reaction and boundary temperatures at the wall and heating/cooling devices rather than viscous dissipation (as for the first case). In many systems pressure changes are dominated by chemistry rather than momentum effects, and density changes are caused by changes in composition rather than pressure and temperature changes. An extended thermodynamic state equation can be formulated assuming density to be a function of  $P$ ,  $T$  and  $\omega_c$  (e.g., [11, 13, 115, 135]):

$$\frac{1}{\rho} \frac{D\rho}{Dt} = \alpha \frac{Dp}{Dt} - \beta \frac{DT}{Dt} + \sum_c \gamma_c \frac{D\omega_c}{Dt} \quad (1.209)$$

where  $\gamma_c = \frac{1}{\rho} \frac{\partial \rho}{\partial \omega_c} |_{P, T, \omega_{s \neq c}}$  defines the dependence of fluid density upon chemical composition, a composition expansion coefficient (e.g., [135], p. 320).

The state relation is not often used in this form in thermodynamics literature, but it is useful in flow analyzes. The chemistry and flow field effects are isolated in  $D\omega_c/Dt$ , determined by solving additional species transport equations. The thermodynamic character of the multi-component fluid is isolated in  $\gamma$  (and  $\alpha$  and  $\beta$ ). All the thermodynamic quantities are in principle functions of both temperature, pressure and composition. An important question in reactive flow analysis is whether or not the density changes due to non-ideal mixing and reaction have significant effects on the flow. In many reactor systems both chemistry and flow scales are important. The formulation of proper non-dimensional scales is thus a difficult task. Therefore, in our subsequent analysis the pressure changes in the flow are supposedly dominated by momentum effects as in non-reactive systems. Analyzing chemical reactor flows the starting point is a list of the fairly rigorous equations, as found in most textbooks (e.g., [11, 13, 91]), that should govern the reactor modeling problem.

Thermodynamics:

$$\frac{1}{\rho} \frac{D\rho}{Dt} = \alpha \frac{Dp}{Dt} - \beta \frac{DT}{Dt} + \sum_c \gamma_c \frac{D\omega_c}{Dt} \quad (1.210)$$

with  $\alpha = \alpha(p, T, \omega_c)$ ,  $\beta = \beta(p, T, \omega_c)$ ,  $C_p = C_p(p, T, \omega_c)$ ,  $\mu = \mu(p, T, \omega_c)$ ,  $k = k(p, T, \omega_c)$  and  $\gamma_c = \gamma(p, T, \omega_c)$ .

Continuity:

$$\frac{1}{\rho} \frac{D\rho}{Dt} = -\nabla \cdot \mathbf{v} \quad (1.211)$$

Momentum:

$$\rho \frac{D\mathbf{v}}{Dt} = -\nabla p - \nabla \cdot \boldsymbol{\sigma} + \sum_{c=1}^N \rho_c \mathbf{g}_c \quad (1.212)$$

Net viscous stress:

$$\nabla \cdot \boldsymbol{\sigma} = -\nabla \cdot \{\mu[\nabla \mathbf{v} + (\nabla \mathbf{v})^T]\} + \nabla \cdot \left\{ \left( \frac{2}{3} \mu - \mu_B \right) (\nabla \cdot \mathbf{v}) \right\} \quad (1.213)$$

Energy:

$$\begin{aligned} \sum_{c=1}^N \rho_c C_{p,\omega_c} \frac{DT}{Dt} = & -\nabla \cdot \mathbf{q} - \frac{T}{\rho} \left( \frac{\partial \rho}{\partial T} \right)_{p,\omega_c} \frac{Dp}{Dt} \\ & - (\boldsymbol{\sigma} : \nabla \mathbf{v}) + \sum_{c=1}^N (\mathbf{j}_c \cdot \mathbf{g}_c) + \sum_{c=1}^N h_c \nabla \cdot \mathbf{j}_c + \sum_{r=1}^q \left( \frac{R_{r,c}}{M_{w_c}} \right) (-\Delta H_{r,c}) \end{aligned} \quad (1.214)$$

Species mass:

$$\rho \frac{D\omega_c}{Dt} = \nabla \cdot (\rho D_c \nabla \omega_c) + R_c \quad (1.215)$$

with  $\rho_c = \rho \omega_c$ .

The reference boundary conditions at the inlet are:

$v_i = (v_0, 0, 0)$ ,  $T = T_0$ ,  $\rho_c = \rho_{c,0}$  and  $\rho = \rho_0$ , and on the wall  $v_i = 0$  and either adiabatic  $n_i q_i = 0$  or non-adiabatic thus  $T = T_W$ .

Not all the terms in these equations have the same importance in determining the flow solution in chemical reactors. The only body force considered in most reactor models,  $\mathbf{g}_i$  (per unit mass), is gravitation which is the same for all chemical species,  $\mathbf{g}$ . The model equations for momentum and energy can then be simplified. In the momentum equation  $\sum_{c=1}^N \rho_c \mathbf{g}_c = \sum_{c=1}^N \rho_c \mathbf{g} = \rho \mathbf{g}$ . In the energy equation:  $\sum_{c=1}^N (\mathbf{j}_c \cdot \mathbf{g}_c) = \sum_{c=1}^N \mathbf{j}_c \cdot \mathbf{g} = 0$ . Furthermore, in most multicomponent flows, the energy or heat flux contributions from the inter-diffusion processes are in general believed to be small and omitted in most applications,  $\sum_{c=1}^N h_c \nabla \cdot \mathbf{j}_c \approx 0$  (e.g., [11], p. 566; [91], p. 198; [149], p. 816). To determine which of the remaining terms are

large and which are small, we must again cast the equations into non-dimensional variables. For an ideal gas system many of the non-dimensional variables can still be formed in a straightforward manner using the boundary values. In this way we can, as in the preceding examples, define  $x_i^* = x_i/L$ ,  $t^* = tv_0/L$ ,  $v_i^* = v_i/v_0$ ,  $\rho^* = \rho/\rho_0$ ,  $\alpha^* = \alpha/\alpha_0$ ,  $\beta^* = \beta/\beta_0$ ,  $\gamma_c^* = \gamma_c/\gamma_{c,0}$ ,  $C_P^* = C_P/C_{P0}$ ,  $\mu^* = \mu/\mu_0$ ,  $k^* = k/k_0$ ,  $Fr = v_0^2/|g|L$ ,  $D_c^* = D_c/D_{c,0}$  and  $R_c^* = R_c/R_{c,0}$ .

The temperature and pressure variables are more difficult to determine. If we assume that the pressure changes in the flow are dominated by momentum effects as in non-reactive systems, a proper non-dimensional pressure variable may be:  $p^* = \frac{p-p_0}{\rho_0 v_0^2}$ . Considering the physical and chemical processes occurring in this problem, one may expect that heat is generated in the flow field by chemical reactions or heating devices, rather than by viscous dissipation. The adiabatic temperature is an estimate of the maximum temperature ( $T_{ad} = T_0 + \frac{(-\Delta H_R)\omega_{c,0}}{C_{P0}}$ ) that can be obtained, due to the heat generated by reaction, in a reactor operating at adiabatic conditions (e.g., [52], p. 409). Using this quantity the problem is supposed to have a characteristic scale  $T_{ad} - T_0$ , which is a driving force for conduction of heat from the reactive zones into the bulk fluid field. Thus, one may define:  $T^* = \frac{T-T_{ref}}{T_{scale}} = \frac{T-T_0}{T_{ad}-T_0}$ . At this point one may argue that for multiple reaction systems, we cannot estimate the exact adiabatic temperature without solving the problem. This may, however, not be important. In such cases one can use an estimate such as the maximum possible adiabatic temperature based on only one (e.g., the most exothermic one) reaction. Further discussion on this issue is given by [135] (p. 420) and [4] (pp. 278–282 and 302). After suitable non-dimensional variables are substituted into the equations, the following non-dimensional groups occur:

$Re = \frac{\rho_0 L v_0}{\mu_0}$ ,  $Pr = \frac{\mu_0 C_{P0}}{k_0}$ ,  $\gamma_0 = \frac{C_{P0}}{C_{V0}}$ ,  $Fr = \frac{v_0^2}{|g|L}$ ,  $Ma = \frac{v_0}{C_S}$ ,  $A = \alpha_0 \rho_0 C_{P0} T_0$ ,  $B = \beta_0 T_0$ ,  $Da = \frac{t_{flow}}{t_{chem}} = \frac{(L/v_0)}{(\rho_0/R_{c,0})}$  (i.e., a Damköhler number (e.g., [18]; [135], pp. 426–427)), and  $Q = \frac{(L/v_0)}{\rho_0 C_{P,0}(T_{ad}-T_0)} \sum_{r=1}^q \left( \frac{R_{r,c}}{M_{w_c}} \right) (-\Delta H_{r,c})$  (i.e., a dimensionless heat of reaction term referred to as a Damköhler number (e.g., [18]; [135], p. 421).

The final form of the mathematical problem statement in non-dimensional variables is as follows:

Thermodynamics:

$$\frac{1}{\rho^*} \frac{D\rho^*}{Dt^*} = \gamma_0 Ma^2 \left[ \alpha^* \frac{Dp^*}{Dt^*} \right] - B\beta^* \left( \frac{T_{ad} - T_0}{T_0} \right) \frac{DT^*}{Dt^*} + \sum_c \gamma_c^* \gamma_{c,0} \frac{D\omega_c}{Dt^*} \quad (1.216)$$

Continuity:

$$\frac{1}{\rho^*} \frac{D\rho^*}{Dt^*} = -\nabla^* \cdot \mathbf{v}^* \quad (1.217)$$

Momentum:

$$\rho^* \frac{D\mathbf{v}^*}{Dt^*} = -\nabla^* p^* - \nabla^* \cdot \boldsymbol{\sigma}^* + \rho^* \frac{\mathbf{g}}{Fr|\mathbf{g}|} \quad (1.218)$$

Viscous stress:

$$\nabla^* \cdot \boldsymbol{\sigma}^* = -\frac{1}{Re} (\nabla^* \cdot \{\mu^* [\nabla^* \mathbf{v}^* + (\nabla^* \mathbf{v}^*)^T]\} + \nabla^* \{(\frac{2}{3}\mu^* - \mu_B^*)(\nabla^* \cdot \mathbf{v}^*)\}) \quad (1.219)$$

Energy:

$$\begin{aligned} \rho^* C_P \frac{DT^*}{Dt^*} = & \frac{1}{Re} \frac{1}{Pr} \nabla^* \cdot (k^* \nabla^* T^*) + \frac{\gamma_0}{A} \frac{Ma^2}{Re} \left( \frac{T_0}{T_{ad} - T_0} \right) \mu^* \Phi_{\text{viscous}}^* \\ & + \beta^* B \frac{\gamma_0 Ma^2}{A} \left( \frac{T_0}{T_{ad} - T_0} + T^* \right) \frac{Dp^*}{Dt^*} + Q \end{aligned} \quad (1.220)$$

where  $\mu^* \Phi_{\text{viscous}}^* = \frac{\mu}{\mu_0} \frac{\Phi_{\text{viscous}}}{v_0^2/L}$ .

Species mass:

$$\rho^* \frac{D\omega_c}{Dt^*} = \frac{1}{Re} \frac{1}{Sc} \nabla^* \cdot (\rho^* D_c^* \nabla^* \omega_c) + Da R_c^* \quad (1.221)$$

The governing equations for low Mach number flow derived based on the dimensional analysis can then be expressed as:

Thermodynamics:

$$\frac{1}{\rho^*} \frac{D\rho^*}{Dt^*} = -B\beta^* \left( \frac{T_{ad} - T_0}{T_0} \right) \frac{DT^*}{Dt^*} + \sum_c \gamma_c^* \gamma_{c,0} \frac{D\omega_c}{Dt^*} \quad (1.222)$$

Continuity:

$$\frac{1}{\rho^*} \frac{D\rho^*}{Dt^*} = -\nabla^* \cdot \mathbf{v}^* \quad (1.223)$$

Momentum:

$$\rho^* \frac{D\mathbf{v}^*}{Dt^*} = -\nabla^* p^* - \nabla^* \cdot \boldsymbol{\sigma}^* + \rho^* \frac{\mathbf{g}}{Fr|\mathbf{g}|} \quad (1.224)$$

Viscous stress:

$$\nabla^* \cdot \boldsymbol{\sigma}^* = -\frac{1}{Re} (\nabla^* \cdot \{\mu^* [\nabla^* \mathbf{v}^* + (\nabla^* \mathbf{v}^*)^T]\} + \nabla^* \{(\frac{2}{3}\mu^* - \mu_B^*)(\nabla^* \cdot \mathbf{v}^*)\}) \quad (1.225)$$

Energy:

$$\rho^* C_P^* \frac{DT^*}{Dt^*} = \frac{1}{Re} \frac{1}{Pr} \nabla^* \cdot (k^* \nabla^* T^*) + Q \quad (1.226)$$

Species mass:

$$\rho^* \frac{D\omega_c}{Dt^*} = \frac{1}{Re} \frac{1}{Sc} \nabla^* \cdot (\rho^* D_c^* \nabla^* \omega_c) + Da R_c^* \quad (1.227)$$

A comparison of the two last mentioned sets of equations reveals the background for several classical reactor model simplifications. Most reactor systems are low velocity flows so that the terms with a pre factor containing the Mach number can be neglected. Then we see that the density is not significantly dependent on the pressure changes due to the flow, and the viscous dissipation and pressure terms in the temperature equation can be neglected. However, the density and thermodynamic coefficients are not constants, but may be functions of both temperature and mixture species composition. Therefore, the gas flows occurring in chemical reactors can in general be characterized as low velocity compressible flows.

Accordingly, a good starting point for the description of most chemical reactor systems is the following set of simplified conservation equations written in dimensionalized form:

Continuity:

$$\frac{1}{\rho} \frac{D\rho}{Dt} = -\nabla \cdot \mathbf{v} \quad (1.228)$$

Momentum:

$$\rho \frac{D\mathbf{v}}{Dt} = -\nabla p - \nabla \cdot \boldsymbol{\sigma} + \rho \mathbf{g} \quad (1.229)$$

Net viscous stress:

$$\nabla \cdot \boldsymbol{\sigma} = -\nabla \cdot \{\mu[\nabla \mathbf{v} + (\nabla \mathbf{v})^T]\} + \nabla \cdot \left\{ \left( \frac{2}{3} \mu - \mu_B \right) (\nabla \cdot \mathbf{v}) \right\} \quad (1.230)$$

Energy:

$$\sum_{c=1}^N \rho_c C_{p,\omega_c} \frac{DT}{Dt} = -\nabla \cdot \mathbf{q} + \sum_{r=1}^q \left( \frac{R_{r,c}}{M_{w_c}} \right) (-\Delta H r_{r,c}) \quad (1.231)$$

Species mass:

$$\rho \frac{D\omega_c}{Dt} = \nabla \cdot (\rho D_c \nabla \omega_c) + R_c \quad (1.232)$$

Together with the corresponding thermodynamic constitutive relations:

Equation of state:

$$\frac{1}{\rho} \frac{D\rho}{Dt} \approx -\beta \frac{DT}{Dt} + \sum_c \gamma_c \frac{D\omega_c}{Dt} \quad (1.233)$$

with  $\alpha \approx \alpha(T, \omega_c)$ ,  $\beta \approx \beta(T, \omega_c)$ ,  $C_P \approx C_P(T, \omega_c)$ ,  $\mu \approx \mu(T, \omega_c)$ ,  $k \approx k(T, \omega_c)$  and  $\gamma_c \approx \gamma_c(T, \omega_c)$ .

### 1.2.5.3 Bernoulli Equation

For one component fluids the *Bernoulli equation* for inviscid<sup>23</sup> flow along a streamline can either be formulated by direct application of Newton's second law to a fluid particle moving along a streamline [10, 114] or derived projecting the generalized momentum equation (1.86) onto a streamline (e.g., [13], pp. 85–86; [184], pp. 247–248).

Applying the latter approach, the Navier-Stokes equation for non-viscous fluids becomes:

$$\rho \frac{D\mathbf{v}}{Dt} = -\nabla p + \rho \mathbf{g} \quad (1.234)$$

This form of the equation of motion is called the Euler equation for inviscid flow and is often employed in gas dynamics.

Introducing vorticity<sup>24</sup> into the acceleration term, using the vector identity [114, 183]:

$$\mathbf{v} \cdot \nabla \mathbf{v} = \nabla \frac{v^2}{2} - \mathbf{v} \times \nabla \times \mathbf{v} = \nabla \frac{v^2}{2} - \mathbf{v} \times \boldsymbol{\omega} \quad (1.235)$$

and let  $\mathbf{g} = -\nabla \Phi = -g \nabla z$ , where  $z$  is the elevation in the gravitational field. The result is:

$$\rho \frac{\partial \mathbf{v}}{\partial t} + \frac{1}{2} \rho \nabla v^2 + \nabla p + \rho g \nabla z = \rho \mathbf{v} \times \boldsymbol{\omega} \quad (1.236)$$

The LHS is the sum of the classical Euler terms of inviscid flow. We restrict our attention to steady flow, so the steady Euler equation in vector form becomes:

$$\frac{1}{2} \rho \nabla v^2 + \nabla p + \rho g \nabla z = \rho \mathbf{v} \times \boldsymbol{\omega} \quad (1.237)$$

<sup>23</sup> In an inviscid flow the fluid is treated as non-viscous and non-conducting.

<sup>24</sup> The vorticity vector,  $\boldsymbol{\omega}$ , is a measure of rotational effects, being equal to twice the local rate of rotation (angular velocity) of a fluid particle (i.e.,  $\boldsymbol{\omega} = \text{curl}(\mathbf{v}) = \text{rot}(\mathbf{v}) = \nabla \times \mathbf{v} = 2\boldsymbol{\Omega}$ ) [169]. Many flows have negligible vorticity,  $\boldsymbol{\omega} \approx \text{curl}(\mathbf{v}) \approx 0$ , and are appropriately called *irrotational flows*.

The Euler equation on the form (1.237) is further divided by  $\rho$ , and then we form the dot product with the unit tangent vector to the stream line, i.e.,  $\mathbf{t}_s = \mathbf{v}/|\mathbf{v}|$ , in the flow direction. This means that we project the entire Euler equation into a vector displacement  $d\mathbf{s}$  along the curvilinear  $d\mathbf{s} = \mathbf{v}dt/|\mathbf{v}| = \mathbf{t}_s dt$ . Hence,

$$\frac{1}{2} \nabla v^2 \cdot d\mathbf{s} + \frac{\nabla p}{\rho} \cdot d\mathbf{s} + g \nabla z \cdot d\mathbf{s} = \mathbf{v} \times \boldsymbol{\omega} \cdot d\mathbf{s} \quad (1.238)$$

Since  $d\mathbf{s}$  has a direction along the streamline, the vectors  $d\mathbf{s}$  and  $\mathbf{v}$  are parallel. It follows that the vector  $\mathbf{v} \times \boldsymbol{\omega}$  is perpendicular to  $\mathbf{v}$ , thus  $\mathbf{v} \times \boldsymbol{\omega} \cdot d\mathbf{s} = 0$ .

Moreover,  $\mathbf{t}_s \cdot \nabla$  can be replaced by  $d/ds$  where  $s$  is the distance along a streamline.<sup>25</sup> The steady Euler equation can thus be written as:

$$\frac{1}{2} \frac{dv^2}{ds} + \frac{1}{\rho} \frac{dp}{ds} + g \frac{dz}{ds} = \mathbf{v} \times \boldsymbol{\omega} \cdot d\mathbf{s} = 0 \quad (1.240)$$

or, if we multiply (1.240) by  $ds \neq 0$  yields:

$$\frac{dp}{\rho} + \frac{1}{2} d(v^2) + g dz = 0 \quad (1.241)$$

where the changes in  $p$ ,  $v$  and  $z$  are along the streamline. Integrating (1.241) gives:

$$\int \frac{dp}{\rho} + \frac{v^2}{2} + gz = \text{Constant} \quad (1.242)$$

which indicates that the sum of the three terms on the LHS of the equation must retain a constant along a given streamline. The equation is also valid for both compressible and incompressible inviscid flows. However, for compressible fluids the variation in  $\rho$  with  $p$  must be specified before the first term in (1.242) is evaluated. Compressible flow is not of primary concern at this stage in the book, so we restrict the present analysis to incompressible flows. For further studies on compressible flows, the reader may consult the textbooks by [114, 184].

For inviscid, incompressible fluids (commonly called ideal fluids) (1.242) yields:

$$\frac{p}{\rho} + \frac{v^2}{2} + gz = \text{Constant} \quad (1.243)$$

---

<sup>25</sup> The relationship  $\frac{d}{ds} = \mathbf{t}_s \cdot \nabla$  can be derived considering a tangent to a streamline. Introducing an arbitrary scalar field, e.g.,  $f = f(\mathbf{r})$ , we may define the gradient or derivative of  $f$  along a streamline and approximate it in terms of a truncated Taylor series around  $\mathbf{r}$ :

$$\frac{df}{ds} = \lim_{\Delta s \rightarrow 0} \frac{f(\mathbf{r} + \Delta s \mathbf{t}_s) - f(\mathbf{r})}{\Delta s} \approx \lim_{\Delta s \rightarrow 0} \frac{f(\mathbf{r}) + \nabla f \cdot (\Delta s \mathbf{t}_s) - f(\mathbf{r})}{\Delta s} = \mathbf{t}_s \cdot \nabla f \quad (1.239)$$

It is often convenient to write (1.243) between two points (1) and (2) along a streamline and to express the equation in the head form by dividing each term by  $g$  so that:

$$\frac{p_1}{\rho g} + \frac{v_1^2}{2g} + z_1 = \frac{p_2}{\rho g} + \frac{v_2^2}{2g} + z_2 \quad (1.244)$$

It is emphasized that the Bernoulli equation, derived from the Euler equation, is restricted to steady-, inviscid- and incompressible flow along a streamline.

For incompressible flows the same equation is valid even for viscous fluids if the flow is irrotational. This is shown next, starting out from the Navier-Stokes equation (1.86). If the fluid is incompressible, with constant  $\mu$  and  $\rho$ , the Navier-Stokes equation becomes:

$$\rho \frac{D\mathbf{v}}{Dt} = -\nabla p + \mu \nabla^2 \mathbf{v} + \rho \mathbf{g} \quad (1.245)$$

Introducing vorticity into both the acceleration and the viscous terms, using the vector identity (1.235) for the acceleration and a similar one for the viscous term [11, 183]:

$$\nabla^2 \mathbf{v} = \nabla(\nabla \cdot \mathbf{v}) - \text{curl}(\boldsymbol{\omega}), \quad (1.246)$$

The result is:

$$\rho \frac{\partial \mathbf{v}}{\partial t} + \nabla(p + \frac{1}{2} \rho v^2 + \rho g z) = \rho \mathbf{v} \times \boldsymbol{\omega} - \mu \text{curl}(\boldsymbol{\omega}) \quad (1.247)$$

The LHS is the sum of the classical Euler terms of inviscid flow. The RHS vanishes if the vorticity is zero, regardless of the value of viscosity. Thus, if  $\boldsymbol{\omega} = 0$  which is the classic assumption of irrotational flow, the steady momentum equation reduces to the Bernoulli equation for steady incompressible flow:

$$\nabla(p + \frac{1}{2} \rho v^2 + \rho g z) = 0 \quad (1.248)$$

Under the given conditions, it is not necessary to integrate the equation along a streamline. Therefore, the Bernoulli equation can be written between any two points in the flow field:

$$\frac{p_1}{\rho g} + \frac{v_1^2}{2g} + z_1 = \frac{p_2}{\rho g} + \frac{v_2^2}{2g} + z_2 \quad (1.249)$$

Equation (1.249) is seemingly exactly the same form as (1.244), but is not limited to application along a streamline. It is emphasized that the Bernoulli equation (1.249), as derived from the Navier-Stokes equation, is still restricted to steady-, irrotational- and incompressible flow. It may also be worthwhile noting that many more classical flow

analysis are based on similar simplifications. Inviscid, incompressible and irrotational flow fields are governed by Laplace's equation and are called *potential flows*, as the velocity in such flows can be expressed as the gradient of a scalar function called the velocity potential. A difficulty performing potential flow analysis is that these models do not satisfy the no-slip condition at a solid wall, which requires that both the normal and tangential velocity components vanish. This is because the assumption of irrotationality eliminates the second order velocity derivatives from the basic equation leaving only first order derivatives, so that only one velocity condition can be satisfied at a solid wall. In potential flow, then, we require only the normal velocity to vanish at a wall and put no restriction on the tangential velocity, which commonly slips at the wall. Apparently, at first sight potential solutions may not seem very useful in viscous analysis, but in fact at high Reynolds numbers a viscous flow past a solid body is primarily a potential flow everywhere except close to the body, where the velocity drops off sharply through a thin viscous boundary layer to satisfy the no slip condition. In many cases, the boundary layer is so thin that it does not really disturb the outer potential flow, which can be calculated by the methods of classical fluid dynamics. This approximation has been applied deriving expressions for many of the forces acting on solid and fluid particles (e.g., Magnus and Saffman lift forces) in dispersed flows.

Another equation that resembles the Bernoulli equation very much is derived from the total energy balance [169]. For one component fluids the total energy equation (1.104) can be written:

$$\rho \frac{D}{Dt} \left( e + \frac{1}{2} v^2 + \Phi \right) = -\nabla \cdot \mathbf{q} - p \nabla \cdot \mathbf{v} - \mathbf{v} \cdot \nabla p - \nabla \cdot (\boldsymbol{\sigma} \cdot \mathbf{v}) \quad (1.250)$$

This equation can be reformulated by use of the continuity equation, to obtain the following relationship:

$$p \nabla \cdot \mathbf{v} = -\frac{p}{\rho} \frac{D\rho}{Dt} = \rho \frac{D}{Dt} \left( \frac{p}{\rho} \right) - \frac{Dp}{Dt} \quad (1.251)$$

which yields:

$$\rho \frac{D}{Dt} \left( e + \frac{p}{\rho} + \frac{1}{2} v^2 + gz \right) = -\nabla \cdot \mathbf{q} + \frac{\partial p}{\partial t} - \nabla \cdot (\boldsymbol{\sigma} \cdot \mathbf{v}) \quad (1.252)$$

where we have assumed that the only body force acting on the system is the gravity force.

In process engineering the energy equation (1.252) is often expressed in terms of enthalpy,  $h = e + \frac{p}{\rho}$ , hence<sup>26</sup>:

---

<sup>26</sup> As the essential function of pumps, compressors, and turbines is to change the Bernoulli constant ( $h + \frac{1}{2} v^2 + \Phi$ ) of a flow, one conclusion from this equation is that such a device cannot operate without viscous forces and heat transfer in the absence of unsteadiness.

$$\rho \frac{D}{Dt} \left( h + \frac{1}{2} v^2 + gz \right) = -\nabla \cdot \mathbf{q} + \frac{\partial p}{\partial t} - \nabla \cdot (\boldsymbol{\sigma} \cdot \mathbf{v}) \quad (1.253)$$

Furthermore, if the flow is both steady and inviscid, the energy equation (1.253) reduces to:

$$\rho \mathbf{v} \cdot \nabla \left( h + \frac{1}{2} v^2 + gz \right) = 0 \quad (1.254)$$

These inviscid flows are said to be *reversible adiabatic* or *isentropic*.<sup>27</sup>

For isentropic flow, the Gibb's equation (e.g., see (1.147) and set  $dS = 0$  and  $d\omega_c = 0$ , for  $c = 1, N$ ) gives  $dh = \frac{dp}{\rho}$ , and the energy equation (1.254) becomes:

$$\rho \mathbf{v} \cdot \nabla \left( \frac{p}{\rho} + \frac{v^2}{2} + gz \right) = 0 \quad (1.256)$$

That is, for incompressible flows the quantity  $\left( \frac{p}{\rho} + \frac{v^2}{2} + gz \right)$  has no variation in the direction of  $\mathbf{v}$  denoting a streamline. Therefore, under these conditions integration yields:

$$\frac{p_1}{\rho g} + \frac{v_1^2}{2g} + z_1 = \frac{p_2}{\rho g} + \frac{v_2^2}{2g} + z_2 \quad (1.257)$$

This relation is seemingly identical to the classical Bernoulli equation (1.244) along a given streamline. It is emphasized that the Bernoulli equation (1.257), as derived from the energy balance (1.104), is restricted to steady-, incompressible- and isentropic flows.

From the former discussion we conclude that proper use of the various forms of the Bernoulli equation requires close attention to the assumptions used in their derivation. In addition, real process units are neither completely inviscid, irrotational or isentropic, thus several extended forms of the Bernoulli equation are used in practice constituting various forms of energy balances containing loss and/or work terms. Two important variants of the original relation are outlined in the following paragraphs.

---

<sup>27</sup> The origin of this phrase is revealed analyzing the entropy equation. For isentropic flows the entropy equation (1.171) for one component fluid reduces to:

$$\frac{Ds}{Dt} = 0 \quad (1.255)$$

where both the heat conduction,  $\mathbf{q}$ , and the dissipation,  $\mu \Phi_{\text{viscous}}$ , are neglected. It is seen that for isentropic flows the entropy of a given fluid particle is constant. Further note that the terms adiabatic and isentropic are not synonymous. By definition, an *adiabatic* flow has  $\mathbf{q} = 0$  everywhere within the flow field. By virtue of the entropy equation (1.171), an adiabatic flow is isentropic only if the dissipation  $\mu \Phi_{\text{viscous}}$  is also zero.

For steady incompressible flow with one inlet and one outlet, both assumed 1D, the integral form of (1.252) reduces to a simple relation between the flow at two cross section planes (1) and (2) as used in engineering calculations:

$$e_1 + \frac{p_1}{\rho} + \frac{v_1^2}{2} + gz_1 = e_2 + \frac{p_2}{\rho} + \frac{v_2^2}{2} + gz_2 - q + w_s + w_v \quad (1.258)$$

where  $q$  denotes the heat transferred to the fluid per unit mass,  $w_s$  denotes the shaft work performed by pumps, turbines, etc and  $w_v$  denotes the viscous work. If we divide through by  $g$ , we express the equation in the head (length) form as:

$$\frac{e_1}{g} + \frac{p_1}{\rho g} + \frac{v_1^2}{2g} + z_1 = \frac{e_2}{g} + \frac{p_2}{\rho g} + \frac{v_2^2}{2g} + z_2 - \frac{q}{g} + \frac{w_s}{g} + \frac{w_v}{g} \quad (1.259)$$

Applying the steady energy equation to low speed liquid flow in pipes with no shaft work and negligible viscous work, yields:

$$\frac{p_1}{\rho g} + \frac{v_1^2}{2g} + z_1 = \frac{p_2}{\rho g} + \frac{v_2^2}{2g} + z_2 + \frac{e_2 - e_1 - q}{g} \quad (1.260)$$

The last term on the RHS represents the loss of useful or available energy that occurs in an incompressible fluid because of friction [114, 184]. With the given restrictions this equation is identical to the 1D mechanical energy equation for the flow between the two points (1) and (2), as can be derived directly from (1.133) [11, 103]:

$$\frac{p_1}{\rho g} + \frac{v_1^2}{2g} + z_1 = \frac{p_2}{\rho g} + \frac{v_2^2}{2g} + z_2 + \frac{\Delta p_f}{\rho g} \quad (1.261)$$

where  $\Delta p_f$  denotes the pressure drop due to friction. Equation (1.261) is sometimes referred to as the extended Bernoulli equation for viscous flows.

Anyhow, (1.261) is not properly closed yet as the pressure drop variable is still undetermined. Therefore, before we can apply (1.261) we need to parameterize the losses in terms of known flow parameters in pipes, valves, fittings, and other internal flow devices. Assuming that the viscous stress tensor reduces to a single shear stress component per unit wall surface (e.g., [103, 184]),  $\Delta p_f$  per unit cross sectional area can be related directly to the friction drag force on the tube wall surface  $-\sigma_w \pi DL$ . That is, since the friction drag force in a horizontal tube with a constant rate of flow is given by  $\Delta p_f (\frac{\pi}{4}) D^2$ , the wall shear stress yields:

$$-\sigma_w = \frac{\Delta p_f \frac{\pi}{4} D^2}{\pi DL} = \frac{\Delta p_f D}{4L} = \mu \left( \frac{dv}{dy} \right)_w \quad (1.262)$$

or

$$\Delta p_f = -4 \frac{L}{D} \sigma_w \quad (1.263)$$

where the distance between the two points (1) and (2) is denoted by  $L$ , and the tube diameter is denoted by  $D$ .

Experience shows that the wall shear stress,  $-\sigma_w$ , is nearly proportional to the kinetic energy,  $\rho \frac{v^2}{2}$ . Hence, the pressure drop can be expressed:

$$\Delta p_f \approx 4f \rho \frac{L}{D} \frac{v^2}{2} \quad (1.264)$$

where  $f = \frac{-\sigma_w}{\rho \frac{v^2}{2}}$  is the Fanning friction factor which can be found from friction factor charts as a function of both the Reynolds number and the surface roughness of the tube. Such charts are given in most basic textbooks on transport processes [103, 184]. Equation (1.264) is valid for duct flows of any cross section (i.e., if the diameter  $D$  is replaced by the hydraulic diameter  $D_h$ ) and for laminar and turbulent flow. For other flow devices equivalent tube friction lengths can be determined experimentally [103].

### 1.2.6 Gross Scale Average Forms of the Governing Equations

The microscopic transport equations are often considered too complex for practical applications considering reactor optimization, scale-up and design. In engineering practice integral averages of the equations over one, two or three spatial directions are used reducing the model to that of an ideal reactor model type.

It is, for example, very common in reactors to have flow predominantly in one direction, say,  $z$  in a tubular reactor. The major gradients then occur in that direction. For many cases the cross-sectional average transport equations may thus be very useful. A detailed derivation of the area-averaged single phase transport equations is presented in this section.

#### 1.2.6.1 Area-Averaged Single Phase Transport Equations

The area averaging procedure that is examined in this section is based on the theory given by [14, 33–35]. The primary aim is to provide the necessary theorems to derive the cross-sectional averaged equations that coincide with the conventional 1D chemical reactor model from first principles. To formulate these theorems we chose to adopt the same concepts as are later used deriving the corresponding multiphase equations in Sect. 3.5.6. Following the approach of Delhaye and Achard we start out from an analysis of a small volume of a pipe with variable cross-section area and deduce the limiting forms of the Leibnitz' and Gauss' theorems for area considered valid in the limit  $\Delta z \rightarrow 0$ . For this reason it is emphasized that these theorems are actually derived for a volume but reduces to an area formulation introducing certain simplifying approximations.

**Fig. 1.4** Sketch of the control volume determining the basis for area-averaging of the single phase equations. For the mathematical derivation of the limiting form of the Leibnitz rule and of the Gauss theorem, note that  $\mathbf{n}_l \perp \mathbf{n}_{A1}$  and  $\Delta Z = \Delta s \cos \theta = \Delta s(\mathbf{n}_{A3} \cdot \mathbf{n}_l)$

Given a tube, axis  $Oz$  (unit vector  $\mathbf{e}_z$ ) in which a volume  $V$  is cut by a fixed cross section plane over area,  $A$ , as sketched in Fig. 1.4. The lateral dimensions of the control volume extend to the conduit walls. In this notation,  $\mathbf{n}$ , is the outward directed unit vector normal to the surface of the control volume.  $\mathbf{n}_l$  is the outward directed unit vector normal to the closed curve,  $l_W(t, z)$ , bounding the cross section plane.  $l_W(t, z)$  is the intersection of the control volume wall interface with the cross sectional plane.

The local instantaneous balance equation (1.3) is integrated over the cross section area  $A$  limited by the pipe wall boundary  $l_W(t, z)$ . The pipe cross section is not necessary uniform but it is assumed that there is no mass flow through the pipe wall. The basic averaging problem is defined by:

$$\int_{A(t,z)} \frac{\partial(\rho\psi)}{\partial t} da + \int_{A(t,z)} \nabla \cdot (\rho \mathbf{v} \psi) da + \int_{A(t,z)} \nabla \cdot \mathbf{J} da - \int_{A(t,z)} \sum_c \rho_c \phi_c da = 0 \quad (1.265)$$

To proceed we need to apply some particular forms of the Leibnitz rule and of the Gauss theorems.

For small  $\Delta z$  the Leibnitz theorem can be expressed as (see Fig. 1.4):

$$\begin{aligned}
\frac{d}{dt} \int_{A(t,z)} f(t, \mathbf{r}) da \Delta z &= \int_{A(t,z)} \frac{\partial f(t, \mathbf{r})}{\partial t} da \Delta z + \int_{A_1(t,z+\Delta z)} f(t, \mathbf{r}) \mathbf{v}_{A_1} \cdot \mathbf{n}_{A_1} da \\
&\quad - \int_{A_2(t,z)} f(t, \mathbf{r}) \mathbf{v}_{A_2} \cdot \mathbf{n}_{A_2} da + \int_{l(t,z)} f(t, \mathbf{r}) \mathbf{v}_{A_3} \cdot \mathbf{n}_{A_3} \Delta s dl \\
&= \int_{A(t,z)} \frac{\partial f(t, \mathbf{r})}{\partial t} da \Delta z + \int_{l(t,z)} f(t, \mathbf{r}) \mathbf{v}_{A_3} \cdot \mathbf{n}_{A_3} \frac{\Delta z}{\mathbf{n}_{A_3} \cdot \mathbf{n}_l} dl
\end{aligned} \tag{1.266}$$

where we have considered the control volume surfaces at  $z = z$  and at  $z = z + \Delta z$  to be stationary (i.e.,  $\mathbf{v}_{A_1} = \mathbf{v}_{A_2} = 0$ ). In certain physical situations the outer boundary face ( $A_3$ ) may not be stationary.

Dividing by  $\Delta z$ , the equation can be slightly reformulated:

$$\frac{d}{dt} \int_{A(t,z)} f(t, \mathbf{r}) da = \int_{A(t,z)} \frac{\partial f(t, \mathbf{r})}{\partial t} da + \int_{l(t,z)} f(t, \mathbf{r}) \mathbf{v}_{A_3} \cdot \mathbf{n}_{A_3} \frac{dl}{\mathbf{n}_{A_3} \cdot \mathbf{n}_l} \tag{1.267}$$

In the limit as  $\Delta z \rightarrow 0$ :

$$\frac{d}{dt} \int_{A(t,z)} f(t, \mathbf{r}) da = \int_{A(t,z)} \frac{\partial f(t, \mathbf{r})}{\partial t} da + \int_{l(t,z)} f(t, \mathbf{r}) \mathbf{v}_{A_3} \cdot \mathbf{n}_{A_3} \frac{dl}{\mathbf{n}_{A_3} \cdot \mathbf{n}_l} \tag{1.268}$$

In several papers the term on the left hand side in the above equation is reformulated using the partial derivative operator rather than the total derivative operator:

$$\frac{\partial}{\partial t} \int_{A(t,z)} f(t, \mathbf{r}) da = \int_{A(t,z)} \frac{\partial f(t, \mathbf{r})}{\partial t} da + \int_{l(t,z)} f(t, \mathbf{r}) \mathbf{v}_{A_3} \cdot \mathbf{n}_{A_3} \frac{dl}{\mathbf{n}_{A_3} \cdot \mathbf{n}_l} \tag{1.269}$$

The justification of this reformulation is apparently related to the physical interpretation of the mathematical operators used here. In this case the total derivative notation is adopted for an operator determining the time derivation at a fixed point in space, and not for a time derivative along a fluid particle trajectory (see [83], p. 13; [181], p. 79; [182], p. 51).

In a slightly generalized notation the limiting form of the Leibnitz theorem is given by:

$$\frac{\partial}{\partial t} \int_{A(t,z)} f(\mathbf{r}, t) da = \int_{A(t,z)} \frac{\partial f(\mathbf{r}, t)}{\partial t} da + \int_{l_W(t,z)} f(\mathbf{r}, t) \mathbf{v}_W \cdot \mathbf{n}_W \frac{dl}{\mathbf{n}_W \cdot \mathbf{n}_l} \tag{1.270}$$

where  $\mathbf{v}_W \cdot \mathbf{n}_W$  is the displacement velocity of a point on the boundary face,  $A_W$ .

For a control volume varying in the space dimensions only, this relation can be further simplified:

$$\frac{\partial}{\partial t} \int_{A(z)} f(\mathbf{r}, t) da = \int_{A(z)} \frac{\partial f(\mathbf{r}, t)}{\partial t} da \quad (1.271)$$

Similarly, for small  $\Delta z$  the Gauss theorem can be expressed as (see Fig 1.4):

$$\begin{aligned} \int_{A(t,z)} \nabla \cdot \mathbf{B} da \Delta z &= \int_{A_1(t,z+\Delta z)} \mathbf{n}_{A_1} \cdot \mathbf{B} da + \int_{A_2(t,z)} \mathbf{n}_{A_2} \cdot \mathbf{B} da + \int_{l(t,z)} \mathbf{n}_{A_3} \cdot \mathbf{B} \Delta s dl \\ &= \int_{A_1(t,z+\Delta z)} \mathbf{e}_z \cdot \mathbf{B} da - \int_{A_2(t,z)} \mathbf{e}_z \cdot \mathbf{B} da + \int_{l(t,z)} \mathbf{n}_{A_3} \cdot \mathbf{B} \frac{\Delta z dl}{\mathbf{n}_{A_3} \cdot \mathbf{n}_l} \end{aligned} \quad (1.272)$$

or

$$\int_{A(t,z)} \nabla \cdot \mathbf{B} da = \frac{1}{\Delta z} \left[ \int_{A_1(t,z+\Delta z)} \mathbf{e}_z \cdot \mathbf{B} da - \int_{A_2(t,z)} \mathbf{e}_z \cdot \mathbf{B} da \right] + \int_{l(t,z)} \mathbf{n}_{A_3} \cdot \mathbf{B} \frac{dl}{\mathbf{n}_{A_3} \cdot \mathbf{n}_l} \quad (1.273)$$

In the limit as  $\Delta z \rightarrow 0$

$$\int_{A(t,z)} \nabla \cdot \mathbf{B} da = \frac{\partial}{\partial z} \int_{A(t,z)} \mathbf{e}_z \cdot \mathbf{B} da + \int_{l(t,z)} \mathbf{n}_{A_3} \cdot \mathbf{B} \frac{dl}{\mathbf{n}_{A_3} \cdot \mathbf{n}_l} \quad (1.274)$$

In a slightly generalized notation the limiting form of the Gauss theorem (where we let  $\mathbf{B}$  be a vector or a tensor) is given by:

$$\int_{A(t,z)} \nabla \cdot \mathbf{B} da = \frac{\partial}{\partial z} \int_{A(t,z)} \mathbf{e}_z \cdot \mathbf{B} da + \int_{l_W(t,z)} \mathbf{n}_W \cdot \mathbf{B} \frac{dl}{\mathbf{n}_W \cdot \mathbf{n}_l} \quad (1.275)$$

In the case of  $\mathbf{B}$  being a vector, the component of the vector  $\mathbf{B}$  on  $Oz$  is given by  $\mathbf{e}_z \cdot \mathbf{B} = B_z$ .

If we take  $\mathbf{B} = \mathbf{e}_z$  we obtain:

$$\int_{A(t,z)} \nabla \cdot \mathbf{e}_z da = \frac{\partial}{\partial z} \int_{A(t,z)} \mathbf{e}_z \cdot \mathbf{e}_z da + \int_{l(t,z)} \mathbf{n} \cdot \mathbf{e}_z \frac{dl}{\mathbf{n} \cdot \mathbf{n}_l} \quad (1.276)$$

which gives the following definition:

$$\frac{\partial A(t, z)}{\partial z} = - \int_{l(t, z)} \mathbf{n} \cdot \mathbf{e}_z \frac{dl}{\mathbf{n} \cdot \mathbf{n}_l} \quad (1.277)$$

Introducing these relations into the cross section area averaged equation (1.265) yields:

$$\begin{aligned} & \frac{\partial}{\partial t} \int_{A(t, z)} (\rho\psi) da + \frac{\partial}{\partial z} \int_{A(t, z)} (\rho v_z \psi) da + \frac{\partial}{\partial z} \int_{A(t, z)} (\mathbf{e}_z \cdot \mathbf{J}) da - \sum_c \int_{A(t, z)} (\rho_c \phi_c) da \\ &= - \int_{l_W(t, z)} \mathbf{n}_W \cdot \mathbf{J} \frac{dl}{\mathbf{n}_W \cdot \mathbf{n}_l} + \int_{l_W(t, z)} \rho \psi \mathbf{n}_W \cdot (\mathbf{v}_W - \mathbf{v}) \frac{dl}{\mathbf{n}_W \cdot \mathbf{n}_l} \end{aligned} \quad (1.278)$$

where  $v_z$  is the  $z$ -component of the velocity vector,  $\mathbf{v}$ .

As we assume no mass flow through the pipe wall and adopt the no-slip condition, the wall convection in the last term equals zero as  $\mathbf{n}_W \cdot (\mathbf{v}_W - \mathbf{v}) = 0$  at the wall. The area averaging operator is defined by:

$$\langle \psi \rangle_A = \frac{1}{A} \int_{A(t, z)} \psi da \quad (1.279)$$

If we apply (1.279) to the area averaged generic equation (1.278), the generic equation can be expressed as follows in terms of area averaged quantities:

$$\begin{aligned} & \frac{\partial (A \langle \rho \psi \rangle_A)}{\partial t} + \frac{\partial}{\partial z} (A \langle \rho v_z \psi \rangle_A) + \frac{\partial}{\partial z} (A \langle \mathbf{e}_z \cdot \mathbf{J} \rangle_A) - \sum_c A \langle \rho_c \phi_c \rangle_A \\ &= - \int_{l_W(t, z)} \mathbf{n}_W \cdot \mathbf{J} \frac{dl}{\mathbf{n}_W \cdot \mathbf{n}_l} \end{aligned} \quad (1.280)$$

For each balance law, the values of  $\psi$ ,  $\mathbf{J}$  and  $\phi$  defines the transported quantity, the diffusion flux and the source term, respectively.  $\mathbf{v}$  denotes the velocity vector,  $\mathbf{T}$  the total stress tensor,  $\mathbf{g}_c$  the net external body force per unit of mass,  $e$  the internal energy per unit of mass,  $\mathbf{q}$  the heat flux,  $s$  the entropy per unit mass,  $h$  the enthalpy per unit mass,  $\omega_s$  the mass fraction of species  $s$ , and  $T$  the temperature.

By means of these definitions, (1.280) gives the instantaneous area-averaged equations for the balance of total mass, momentum, total energy, and species mass.

*Continuity Equation:*

To achieve the mass balance the values of the generic quantities are defined as specified in Table 1.1:  $\psi = 1$ ,  $\mathbf{J} = 0$ , and  $\phi_c = 0$ .

$$\frac{\partial (A \langle \rho \rangle_A)}{\partial t} + \frac{\partial}{\partial z} (A \langle \rho v_z \rangle_A) = 0 \quad (1.281)$$

*Momentum Equation:*

To obtain the momentum balance the values of the generic quantities are defined as specified in Table 1.1:  $\psi = \mathbf{v}$ ,  $\mathbf{J} = \mathbf{T}$ , and  $\phi_c = \mathbf{g}_c$ .

$$\begin{aligned} & \frac{\partial(A\langle\rho\mathbf{v}\rangle_A)}{\partial t} + \frac{\partial}{\partial z}(A\langle\rho v_z\mathbf{v}\rangle_A) + \frac{\partial}{\partial z}(A\langle\mathbf{e}_z \cdot \mathbf{T}\rangle_A) \\ &= \sum_c A\langle\rho_c\mathbf{g}_c\rangle_A - \int_{l_W(t,z)} \mathbf{n}_W \cdot \mathbf{T} \frac{dl}{\mathbf{n}_W \cdot \mathbf{n}_l} \end{aligned} \quad (1.282)$$

If we split the total stress tensor  $\mathbf{T}$  into a pressure term  $p\mathbf{e}$  and a viscous stress tensor  $\boldsymbol{\sigma}$  term, the vector equation can be expressed as:

$$\begin{aligned} & \frac{\partial(A\langle\rho\mathbf{v}\rangle_A)}{\partial t} + \frac{\partial}{\partial z}(A\langle\rho v_z\mathbf{v}\rangle_A) + \frac{\partial}{\partial z}(A\langle p\mathbf{e}_z\rangle_A) + \frac{\partial}{\partial z}(A\langle\mathbf{e}_z \cdot \boldsymbol{\sigma}\rangle_A) \\ &= \sum_c A\langle\rho_c\mathbf{g}_c\rangle_A - \int_{l_W(t,z)} \mathbf{n}_W \cdot \mathbf{T} \frac{dl}{\mathbf{n}_W \cdot \mathbf{n}_l} \end{aligned} \quad (1.283)$$

The momentum equation of interest in 1D engineering analysis is normally the linear momentum equation in the axial direction. It is therefore customary to project the terms in the equation along the tube axis. This operation is done by taking the scalar vector product of all the terms in (1.283) with the unit vector  $\mathbf{e}_z$ . The result is:

$$\begin{aligned} & \frac{\partial(A\langle\rho v_z\rangle_A)}{\partial t} + \frac{\partial}{\partial z}(A\langle\rho v_z v_z\rangle_A) + \frac{\partial}{\partial z}(A\langle p\rangle_A) + \frac{\partial}{\partial z}(A\langle(\mathbf{e}_z \cdot \boldsymbol{\sigma}) \cdot \mathbf{e}_z\rangle_A) \\ &= \sum_c A\langle\rho_c g_{c,z}\rangle_A - \int_{l_W(t,z)} (\mathbf{n}_W \cdot \mathbf{T}) \cdot \mathbf{e}_z \frac{dl}{\mathbf{n}_W \cdot \mathbf{n}_l} \end{aligned} \quad (1.284)$$

It is noted that if the velocity is not constant but varies across the cross sectional area, (1.279) can be used calculating the average of the product occurring in the momentum equation:

$$\langle v_z^2 \rangle_A = \frac{1}{A} \int_{A(t,z)} v_z^2 da \quad (1.285)$$

To assess the physical deviation between the average of products and the product of averages a momentum velocity correction factor can be defined by  $C_M = \langle v_z^2 \rangle_A / \langle v_z \rangle_A^2$ . By use of the Hagen-Poiseuille law (1.359) and the power law velocity profile (1.360) it follows that at steady state  $C_M$  has a value of about 0.95 for turbulent flow and 0.75 for laminar flow [55]. In practice a value of 1 is used in turbulent flow so that  $\langle v_z^2 \rangle_A$  is simply replaced by the averaged bulk velocity  $\langle v_z \rangle_A^2$ . On the other hand, for laminar flows a correction factor is needed. For more precise calculations a simplified (not averaged!) 2D model is often considered for ideal axisymmetric pipe flows [52, 70].

Moreover, it is frequently assumed that the pressure  $p$  is almost constant along  $l_W$  and approximated by an average wall pressure  $\langle p \rangle_W$ . Therefore, by use of the definition (1.277), (1.284) can be written as:

$$\begin{aligned} & \frac{\partial(A\langle \rho v_z \rangle_A)}{\partial t} + \frac{\partial}{\partial z}(A\langle \rho v_z v_z \rangle_A) + A \frac{\partial \langle p \rangle_A}{\partial z} + \frac{\partial}{\partial z}(A\langle \sigma_{zz} \rangle_A) \\ &= \sum_c A\langle \rho_c g_{c,z} \rangle_A - \int_{l_W(t,z)} (\mathbf{n}_W \cdot \boldsymbol{\sigma}) \cdot \mathbf{e}_z \frac{dl}{\mathbf{n}_W \cdot \mathbf{n}_l} + (\langle p \rangle_W - \langle p \rangle_A) \frac{\partial A}{\partial z} \end{aligned} \quad (1.286)$$

A rough model closure can be achieved assuming that the averaged wall pressure  $\langle p \rangle_W$  is equal to the averaged pressure  $\langle p \rangle_A$ . The equation can then be slightly simplified:

$$\begin{aligned} & \frac{\partial(A\langle \rho v_z \rangle_A)}{\partial t} + \frac{\partial}{\partial z}(A\langle \rho v_z v_z \rangle_A) + A \frac{\partial \langle p \rangle_A}{\partial z} + \frac{\partial}{\partial z}(A\langle \sigma_{zz} \rangle_A) \\ &= \sum_c A\langle \rho_c g_{c,z} \rangle_A - \int_{l_W(t,z)} (\mathbf{n}_W \cdot \boldsymbol{\sigma}) \cdot \mathbf{e}_z \frac{dl}{\mathbf{n}_W \cdot \mathbf{n}_l} \end{aligned} \quad (1.287)$$

The last term on the RHS is the component of the averaged wall shear stress in the  $z$  direction. The wall shear stress term is often rewritten as:

$$- \int_{l_W(t,z)} (\mathbf{n}_W \cdot \boldsymbol{\sigma}) \cdot \mathbf{e}_z \frac{dl}{\mathbf{n}_W \cdot \mathbf{n}_l} = -\langle (\mathbf{n} \cdot \boldsymbol{\sigma}) \cdot \mathbf{e}_z \rangle_{l_W} S_I \quad (1.288)$$

where  $\langle (\mathbf{n} \cdot \boldsymbol{\sigma}) \cdot \mathbf{e}_z \rangle_{l_W}$  is the perimeter averaged wall stress, and  $S_I$  denotes the perimeter which is defined by  $S_I = \int_{l_W(t,z)} \frac{dl}{\mathbf{n}_W \cdot \mathbf{n}_l}$ . The averaged wall shear stress is approximated by the expression for steady flow given by

$$\begin{aligned} -\langle (\mathbf{n} \cdot \boldsymbol{\sigma}) \cdot \mathbf{e}_z \rangle_{l_W} \frac{S_I}{A} &\approx -\frac{1}{2} f_{D,W} \langle \rho \rangle_A \langle v_z \rangle_A \langle v_z \rangle_A \frac{S_I}{4A} \\ &= -\frac{1}{2} f_{D,W} \langle \rho \rangle_A \langle v_z \rangle_A \langle v_z \rangle_A \frac{1}{D_h}, \end{aligned} \quad (1.289)$$

where  $D_h$  is the hydraulic diameter, and  $f_{D,W}$  is the Darcy friction factor [6, 9, 75, 83, 179]. For fully developed flows in circular pipes and tubes the friction factor has been determined experimentally and presented in a so-called Moody diagram which can be found in most introductory textbooks on engineering fluid flows. The commonly used semi-empirical friction factor relations for pipe flows are [13, 114]:

$$f_{D,W} = \begin{cases} \frac{64}{Re} & \text{for } Re < 2100, \\ \frac{0.3164}{Re^{1/4}} & \text{for } 2100 \leq Re < 10^5, \text{ and} \\ \frac{4}{(4.0 \log(Re \sqrt{f}) - 0.4)^2} & \text{for } 2300 < Re < 4 \times 10^6. \end{cases} \quad (1.290)$$

in which the Reynolds number is defined by:  $Re = \frac{\rho \langle v_z \rangle_A d_r}{\mu}$ .

### Energy Equation

To achieve the energy balance the values of the generic quantities are defined as specified in Table 1.1:  $\psi = (\frac{1}{2}v^2 + e)$ ,  $\mathbf{J} = (\mathbf{q} + \mathbf{T} \cdot \mathbf{v})$ ,  $\phi = \mathbf{g} \cdot \mathbf{v}$ .

$$\begin{aligned} & \frac{\partial(A\langle\rho(\frac{1}{2}v^2 + e)\rangle_A)}{\partial t} + \frac{\partial}{\partial z}(A\langle\rho v_z(\frac{1}{2}v^2 + e)\rangle_A) \\ & + \frac{\partial}{\partial z}(A\langle(\mathbf{T} \cdot \mathbf{v}) \cdot \mathbf{e}_z\rangle_A) + \frac{\partial}{\partial z}(A\langle\mathbf{q} \cdot \mathbf{e}_z\rangle_A) \\ & = \sum_c A\langle\rho_c \mathbf{g}_c \cdot \mathbf{v}_c\rangle_A - \int_{l_W(t,z)} \mathbf{n}_W \cdot \mathbf{q} \frac{dl}{\mathbf{n}_W \cdot \mathbf{n}_l} - \int_{l_W(t,z)} \mathbf{n}_W \cdot (\mathbf{T} \cdot \mathbf{v}) \frac{dl}{\mathbf{n}_W \cdot \mathbf{n}_l} \end{aligned} \quad (1.291)$$

Quite often  $\mathbf{v} \cdot \mathbf{v} = v^2 \approx v_z^2$  when the flow is dominant in the  $z$ -direction. This assumption is necessary in order to achieve a solvable set of equations considering that (1.286) is used calculating  $\langle v_z \rangle_A$ .

In engineering calculations of process units it is often convenient to introduce the enthalpy per unit of mass, i.e.,  $h = e + \frac{p}{\rho}$ , and rewrite the energy equation as:

$$\begin{aligned} & \frac{\partial(A\langle\rho(\frac{1}{2}v^2 + e)\rangle_A)}{\partial t} + \frac{\partial}{\partial z}(A\langle\rho v_z(\frac{1}{2}v^2 + h)\rangle_A) \\ & + \frac{\partial}{\partial z}(A\langle(\boldsymbol{\sigma} \cdot \mathbf{v}) \cdot \mathbf{e}_z\rangle_A) + \frac{\partial}{\partial z}(A\langle\mathbf{q} \cdot \mathbf{e}_z\rangle_A) \\ & = \sum_c A\langle\rho_c \mathbf{g}_c \cdot \mathbf{v}_c\rangle_A - \int_{l_W(t,z)} \mathbf{n}_W \cdot \mathbf{q} \frac{dl}{\mathbf{n}_W \cdot \mathbf{n}_l} \end{aligned} \quad (1.292)$$

It is noted that there is no work associated with the wall stresses since the velocity at the wall is zero (no-slip assumption) [13, 25].

### Species Mass Balance

For the species mass balance the values of the generic quantities are defined in accordance with Table 1.1:  $\psi = \omega_s$ ,  $\mathbf{J} = \mathbf{j}_s$ ,  $\phi = R_s/\rho_c$ .

$$\frac{\partial(A\langle\rho\omega_s\rangle_A)}{\partial t} + \frac{\partial}{\partial z}(A\langle\rho v_z\omega_s\rangle_A) + \frac{\partial}{\partial z}(A\langle\mathbf{e}_z \cdot \mathbf{j}_s\rangle_A) = A\langle R_s \rangle_A \quad (1.293)$$

#### 1.2.6.2 The Governing Instantaneous Area Averaged Equations

To obtain a solvable set of equations the averages of products have to be related to products of averages. One simple way of doing this operation is to approximate

the averages of products by the products of averages.<sup>28</sup> A closed set of modeled instantaneous area averaged equations is listed below.

*Continuity Equation:*

The instantaneous area averaged continuity equation deduced from (1.281) is expressed as:

$$\frac{\partial}{\partial t} \left( \langle \rho \rangle_A \right) + \frac{1}{A} \frac{\partial}{\partial z} \left( A \langle \rho \rangle_A \langle v_z \rangle_A \right) = 0 \quad (1.294)$$

*Momentum Equation:*

The instantaneous area averaged momentum equation deduced from (1.286) is expressed as:

$$\begin{aligned} & \frac{\partial}{\partial t} \left( \langle \rho \rangle_A \langle v_z \rangle_A \right) + \frac{1}{A} \frac{\partial}{\partial z} \left( A \langle \rho \rangle_A \langle v_z \rangle_A \langle v_z \rangle_A \right) \\ &= - \frac{\partial \langle p \rangle_A}{\partial z} - \frac{1}{A} \frac{\partial}{\partial z} \left( A \langle \sigma_{zz} \rangle_A \right) + \sum_c \langle \rho_c g_{c,z} \rangle_A \\ & \quad - \frac{1}{2} f_{D,W} \langle \rho \rangle_A \langle v_z \rangle_A \langle v_z \rangle_A \frac{S_I}{4A} + \frac{1}{A} (\langle p \rangle_W - \langle p \rangle_A) \frac{\partial A}{\partial z} \end{aligned} \quad (1.295)$$

in which the last term is retained in case a more elaborated closure for the wall pressure is required.

*Energy Equation*

The instantaneous area averaged energy equation deduced from (1.291) is expressed as:

$$\begin{aligned} & \frac{\partial}{\partial t} \left( \langle \rho \rangle_A \left( \frac{1}{2} \langle v \rangle_A^2 + \langle e \rangle_A \right) \right) \\ &+ \frac{1}{A} \frac{\partial}{\partial z} \left( A \langle \rho \rangle_A \langle v_z \rangle_A \left( \frac{1}{2} \langle v \rangle_A^2 + \langle e \rangle_A \right) \right) \\ &+ \frac{1}{A} \frac{\partial}{\partial z} \left( A (\langle \mathbf{T} \rangle_A \cdot \langle \mathbf{v} \rangle_A) \cdot \mathbf{e}_z \right) + \frac{1}{A} \frac{\partial}{\partial z} \left( A \langle \mathbf{q} \cdot \mathbf{e}_z \rangle_A \right) \\ &= \sum_c \langle \rho_c \rangle_A \langle \mathbf{g}_c \rangle_A \cdot \langle \mathbf{v}_c \rangle_A - \langle \mathbf{n} \cdot \mathbf{q} \rangle_W \frac{S_I}{A} \end{aligned} \quad (1.296)$$

To be able to apply the 1D equations one often has to estimate terms that cannot be calculated directly without further empirical information, or we might simply neglect the insignificant terms for each particular application. The work associated with the term  $(\langle \mathbf{T} \rangle_A \cdot \langle \mathbf{v} \rangle_A) \cdot \mathbf{e}_z$  can be split into two contributions. In chemical reactor analysis

<sup>28</sup> There are also other more sophisticated methods available to relate the average of products to the products of average as discussed in Sect. 3.5. Nevertheless, the conventional model formulation used in chemical reaction engineering is normally derived in accordance with the procedure given in this section.

(and many other low Mach number flows in chemical engineering [13]) the viscous work  $(\langle \sigma \rangle_A \cdot \langle \mathbf{v} \rangle_A) \cdot \mathbf{e}_z$  is normally neglectable relative to the pressure work  $\langle p \rangle_A \langle v_z \rangle_A$ .

The wall heat flux term can be approximated in terms of the convective heat transfer coefficient:

$$-\langle \mathbf{n} \cdot \mathbf{q} \rangle_W \frac{S_I}{A} = -h_W (\langle T \rangle_A - \langle T \rangle_W) \frac{S_I}{A} \quad (1.297)$$

Alternatively, the wall heat transfer flux can be expressed in terms of an overall heat transfer coefficient. For reactors with constant cross-sectional area  $A$  the geometric factor reduces to  $\frac{S_I}{A} = \frac{2\pi R_r}{\pi R_r^2} = \frac{2}{R_r} = \frac{4}{d_r}$ . It is understood that  $R_r$  and  $d_r$  are the radius and diameter of the reactor (tube).

Formulating the equation in terms of the enthalpy per unit of mass,  $h = e + \frac{p}{\rho}$ , we obtain:

$$\begin{aligned} & \frac{\partial}{\partial t} \left( \langle \rho \rangle_A \left( \frac{1}{2} \langle v \rangle_A^2 + \langle e \rangle_A \right) \right) \\ & + \frac{1}{A} \frac{\partial}{\partial z} \left( A \langle \rho \rangle_A \langle v_z \rangle_A \left( \frac{1}{2} \langle v \rangle_A^2 + \langle h \rangle_A \right) \right) \\ & + \frac{1}{A} \frac{\partial}{\partial z} \left( A (\langle \sigma \rangle_A \cdot \langle \mathbf{v} \rangle_A) \cdot \mathbf{e}_z \right) + \frac{1}{A} \frac{\partial}{\partial z} \left( A \langle \mathbf{q} \cdot \mathbf{e}_z \rangle_A \right) \\ & = \sum_c \langle \rho_c \mathbf{g}_c \cdot \mathbf{v}_c \rangle_A - \langle \mathbf{n} \cdot \mathbf{q} \rangle_W \frac{S_I}{A} \end{aligned} \quad (1.298)$$

### Mechanical Energy Equation

The engineering mechanical energy equation is derived by multiplying (1.295) with the averaged velocity  $\langle v_z \rangle_A$ . That is,

$$\begin{aligned} & \langle v_z \rangle_A \left[ \frac{\partial}{\partial t} \left( \langle \rho \rangle_A \langle v_z \rangle_A \right) + \frac{1}{A} \frac{\partial}{\partial z} \left( A \langle \rho \rangle_A \langle v_z \rangle_A \langle v_z \rangle_A \right) \right. \\ & = - \frac{\partial \langle p \rangle_A}{\partial z} - \frac{1}{A} \frac{\partial}{\partial z} (A \langle \sigma_{zz} \rangle_A) + \sum_c \langle \rho_c g_{c,z} \rangle_A \\ & \quad \left. - \frac{\langle (\mathbf{n} \cdot \sigma) \cdot \mathbf{e}_z \rangle_W S_I}{A} + \frac{1}{A} (\langle p \rangle_W - \langle p \rangle_A) \frac{\partial A}{\partial z} \right] \end{aligned} \quad (1.299)$$

After a little manipulation of the terms, we get:

$$\begin{aligned} & \frac{\partial}{\partial t} \left( \langle \rho \rangle_A \frac{1}{2} (\langle v_z \rangle_A)^2 \right) + \frac{1}{A} \frac{\partial}{\partial z} \left( A \langle \rho \rangle_A \langle v_z \rangle_A \frac{1}{2} (\langle v_z \rangle_A)^2 \right) \\ & = - \langle v_z \rangle_A \frac{\partial \langle p \rangle_A}{\partial z} - \frac{\langle v_z \rangle_A}{A} \frac{\partial}{\partial z} (A \langle \sigma_{zz} \rangle_A) \end{aligned}$$

$$\begin{aligned}
& + \langle v_z \rangle_A \langle \rho \rangle_A \sum_c \langle \omega_c \rangle_A \langle g_{c,z} \rangle_A - \frac{1}{2} f_{D,W} |\langle v_z \rangle_A| \langle v_z \rangle_A^2 \frac{S_I}{4A} \\
& + \frac{1}{A} (\langle p \rangle_W - \langle p \rangle_A) \langle v_z \rangle_A \frac{\partial A}{\partial z}
\end{aligned} \tag{1.300}$$

A more rigorous formulation of the mechanical energy equation might be achieved by averaging the fundamental kinetic energy equation (1.133) over the cross-section area. If the velocity is not constant but varies across the cross sectional area we can use (1.279) to calculate the average of the products occurring in the corresponding 1D kinetic energy equation:

$$\langle v_z^3 \rangle_A = \frac{1}{A} \int_{A(t,z)} v_z^3 da \tag{1.301}$$

Again, to assess the physical deviation between the average of products and the product of averages a kinetic-energy velocity correction factor can be defined by  $C_K = \langle v_z^3 \rangle_A / \langle v_z \rangle_A^3$ . By use of the Hagen-Poiseuille law (1.359) and the power law velocity profile (1.360) it follows that at steady state  $C_K$  takes a value of about 0.95 for turbulent flow and 0.5 for laminar flow [55]. In practice a value of 1 is used in turbulent flow so  $\langle v_z^3 \rangle_A$  is simply replaced by the averaged bulk velocity  $\langle v_z \rangle_A^3$ .

#### Internal Energy Equation

The instantaneous area averaged internal energy equation can be derived by subtracting the mechanical energy equation (1.300) from the total energy equation (1.296). The result can be expressed as:

$$\begin{aligned}
& \frac{\partial}{\partial t} \left( \langle \rho \rangle_A \langle e \rangle_A \right) + \frac{1}{A} \frac{\partial}{\partial z} \left( A \langle \rho \rangle_A \langle v_z \rangle_A \langle e \rangle_A \right) \\
& = - \frac{\langle p \rangle_A}{A} \frac{\partial}{\partial z} (A \langle v_z \rangle_A) + \sum_c \langle \mathbf{j}_c \cdot \mathbf{g}_c \rangle_A \\
& \quad - \frac{1}{A} \frac{\partial}{\partial z} \left( A (\langle \boldsymbol{\sigma} \rangle_A \cdot \langle \mathbf{v} \rangle_A) \cdot \mathbf{e}_z \right) + \frac{\langle v_z \rangle_A}{A} \frac{\partial}{\partial z} (A \langle \boldsymbol{\sigma}_{zz} \rangle_A) \\
& \quad - \frac{1}{A} \frac{\partial}{\partial z} (A \langle \mathbf{q} \cdot \mathbf{e}_z \rangle_A) - \langle \mathbf{n} \cdot \mathbf{q} \rangle_W \frac{S_I}{A} + \frac{1}{2} f_{D,W} |\langle v_z \rangle_A| \langle v_z \rangle_A^2 \frac{S_I}{4A} \\
& \quad - \frac{1}{A} (\langle p \rangle_W - \langle p \rangle_A) \langle v_z \rangle_A \frac{\partial A}{\partial z} \\
& \approx - \frac{\langle p \rangle_A}{A} \frac{\partial}{\partial z} (A \langle v_z \rangle_A) + \sum_c \langle j_{c,z} \rangle_A \langle g_{c,z} \rangle_A \\
& \quad - \frac{1}{A} \frac{\partial}{\partial z} (A \langle q_z \rangle_A) - \langle \mathbf{n} \cdot \mathbf{q} \rangle_W \frac{S_I}{A} + \frac{1}{2} f_{D,W} |\langle v_z \rangle_A| \langle v_z \rangle_A^2 \frac{S_I}{4A} \\
& \quad - \frac{1}{A} (\langle p \rangle_W - \langle p \rangle_A) \langle v_z \rangle_A \frac{\partial A}{\partial z}
\end{aligned} \tag{1.302}$$

in which the bulk viscous dissipation terms are neglected. In addition, the work term given by the dot product between the species mass diffusion flux and the body forces other than gravity is approximated by the  $z$ -component of the actual term.

### Enthalpy Equation

The instantaneous enthalpy balance can be derived from (1.302) by introducing the area averaged enthalpy per unit of mass:  $\langle h \rangle_A = \langle e \rangle_A + \frac{\langle p \rangle_A}{\langle \rho \rangle_A}$ . The result is [75]:

$$\begin{aligned}
 & \frac{\partial}{\partial t} \left( \langle \rho \rangle_A \langle h \rangle_A \right) + \frac{1}{A} \frac{\partial}{\partial z} \left( A \langle \rho \rangle_A \langle v_z \rangle_A \langle h \rangle_A \right) \\
 & \approx \frac{\partial \langle p \rangle_A}{\partial t} + \langle v_z \rangle_A \frac{\partial \langle p \rangle_A}{\partial z} + \sum_c \langle j_{c,z} \rangle_A \langle g_{c,z} \rangle_A \\
 & - \frac{1}{A} \frac{\partial}{\partial z} (A \langle q_z \rangle_A) - \langle \mathbf{n} \cdot \mathbf{q} \rangle_W \frac{S_I}{A} + \frac{1}{2} f_{D,W} |\langle v_z \rangle_A| \langle v_z \rangle_A^2 \frac{S_I}{4A} \\
 & - \frac{1}{A} (\langle p \rangle_W - \langle p \rangle_A) \langle v_z \rangle_A \frac{\partial A}{\partial z}
 \end{aligned} \tag{1.303}$$

### Temperature Equation

The instantaneous temperature equation can be derived from (1.303) by use of the complete differential (1.151). The area averaged form of the complete differential can be approximated as:

$$\begin{aligned}
 \frac{D \langle h \rangle_A}{Dt} &= \langle C_p \rangle_A \frac{D \langle T \rangle_A}{Dt} \\
 &+ \left( \frac{1}{\langle \rho \rangle_A} + \frac{\langle T \rangle_A}{\langle \rho \rangle_A^2} \left( \frac{\partial \langle \rho \rangle_A}{\partial \langle T \rangle_A} \right)_{p,\omega} \right) \frac{D \langle p \rangle_A}{Dt} \\
 &- \frac{1}{\langle \rho \rangle_A} \left[ \sum_{c=1}^N \langle \bar{h}_c \rangle_A \frac{\partial}{\partial z} \left( \frac{\langle j_{c,z} \rangle_A}{M_{w_c}} \right) \right. \\
 &\left. + \sum_{r=1}^q \langle r_{r,c_{ref}} \rangle_A (-\Delta \langle \bar{H}_{r,c_{ref}} \rangle_A) \right]
 \end{aligned} \tag{1.304}$$

After reformulating the terms on the LHS of (1.303) by use of the area averaged continuity equation (1.294), we can eliminate the enthalpy quantity by use of the given relation (1.304). The area averaged enthalpy balance is then written as an equation for temperature:

$$\begin{aligned}
 & \langle \rho \rangle_A \langle C_p \rangle_A \left( \frac{\partial \langle T \rangle_A}{\partial t} + \langle v_z \rangle_A \frac{\partial \langle T \rangle_A}{\partial z} \right) \\
 & \approx - \frac{\langle T \rangle_A}{\langle \rho \rangle_A} \left( \frac{\partial \langle \rho \rangle_A}{\partial \langle T \rangle_A} \right)_{p,\omega} \frac{D \langle p \rangle_A}{Dt} + \sum_c \langle j_{c,z} \rangle_A \langle g_{c,z} \rangle_A
 \end{aligned}$$

$$\begin{aligned}
& + \sum_{c=1}^N \langle \bar{h}_c \rangle_A \frac{\partial}{\partial z} \left( \frac{\langle j_{c,z} \rangle_A}{M_{w_c}} \right) + \sum_{r=1}^q \langle r_{r,c_{\text{ref}}} \rangle_A (-\Delta \langle \bar{H}_{r,c_{\text{ref}}} \rangle_A) \\
& - \frac{1}{A} \frac{\partial}{\partial z} (A \langle q_z \rangle_A) - \langle \mathbf{n} \cdot \mathbf{q} \rangle_W \frac{S_I}{A} + \frac{1}{2} f_{D,W} |\langle v_z \rangle_A| \langle v_z \rangle_A^2 \frac{S_I}{4A} \\
& - \frac{1}{A} (\langle p \rangle_W - \langle p \rangle_A) \langle v_z \rangle_A \frac{\partial A}{\partial z}
\end{aligned} \tag{1.305}$$

### Species Mass Balance

The instantaneous species mass balance is deduced from (1.293) replacing the average of products with the products of average:

$$\begin{aligned}
& \frac{\partial (\langle \rho \rangle_A \langle \omega_s \rangle_A)}{\partial t} + \frac{1}{A} \frac{\partial}{\partial z} (A \langle \rho \rangle_A \langle v_z \rangle_A \langle \omega_s \rangle_A) \\
& = - \frac{1}{A} \frac{\partial}{\partial z} (A \langle j_{s,z} \rangle_A) + \langle R_s \rangle_A
\end{aligned} \tag{1.306}$$

## 1.2.7 Dispersion Models

In chemical reaction engineering single phase reactors are often modeled by a set of simplified 1D heat and species mass balances. In these cases the axial velocity profile can be prescribed or calculate from the continuity equation. The reactor pressure is frequently assumed constant or calculated from simple relations deduced from the area averaged momentum equation. For gases the density is normally calculated from the ideal gas law. Moreover, in situations where the velocity profile is neither flat nor ideal the effects of radial convective mixing have been lumped into the dispersion coefficient. With these model simplifications the semi-empirical correlations for the dispersion coefficients will be system- and scale specific and far from general.

### 1.2.7.1 Axial Dispersion models

The axial dispersion model is developed based on the 1D form of the governing equations given in Sect. 1.2.6.2. However, the instantaneous area averaged model equations are also Reynolds averaged to enable reactor simulations with practicable time resolutions. For the time after area averaged models, the instantaneous variables are decomposed and Reynolds averaged in the standard way. If we drop the averaging signs, the basic 1D species mass balance deduced from (1.306) is given by:

$$\frac{\partial}{\partial t} (\rho \omega_s) + \frac{\partial}{\partial z} (\rho v_z \omega_s) = \frac{\partial}{\partial z} (\rho D_{\text{eff}} \frac{\partial \omega_s}{\partial z}) + R_s \tag{1.307}$$

and the corresponding heat or temperature equation deduced from (1.305) yields:

$$\rho C_p \frac{\partial T}{\partial t} + \rho C_p v_z \frac{\partial T}{\partial z} = \frac{\partial}{\partial z} (k_{\text{eff}} \frac{\partial T}{\partial z}) + R_s (-\Delta H_{R_s}) + \frac{4U}{d_r} (T_{\text{sur}} - T) \quad (1.308)$$

where  $T_{\text{sur}}$  is the temperature of the surroundings and  $U$  is an overall heat transfer coefficient. In addition, the effective transport coefficients are included as a reminder that the temporal covariances resulting from the Reynolds averaging procedure are normally modeled adopting the gradient hypothesis and the Boussinesq turbulent viscosity concept.

The initial conditions used for dynamics reactor simulations depend upon the start-up procedure adopted in industry for each particular chemical process. A possible set of initial conditions corresponds to uniform variable fields given by the inlet values.

*The initial condition at  $t = 0$ :*

$$\begin{aligned} v_z &= v_{z,\text{in}} \\ \rho &= \rho_{\text{in}} \\ \omega_s &= \omega_{s,\text{in}} \\ T &= T_{\text{in}} \end{aligned} \quad (1.309)$$

The proper choice of boundary conditions has been extensively discussed in the literature. The conditions most frequently used those proposed by Danckwerts [26].

*The inlet boundary condition at  $z = 0$ :*

$$\begin{aligned} v_{z,\text{in}} \rho_{\text{in}} \omega_{s,\text{in}} &= \rho v_z \omega_s - \rho D_{\text{eff}} \frac{d\omega_s}{dz} \\ \rho_{\text{in}} v_{z,\text{in}} c_p T_{\text{in}} &= \rho v_z c_p T - k_{\text{eff}} \frac{dT}{dz} \end{aligned} \quad (1.310)$$

*The outlet boundary condition at  $z = L$ :*

$$\frac{d\omega_s}{dz} = \frac{dT}{dz} = 0 \quad (1.311)$$

Baerns et al. [4], Froment and Bischoff [52] and Fogler [48] discuss numerous applications of this model in chemical reaction engineering.

### 1.3 Application of the Governing Equations to Turbulent Flow

Most flows occurring in nature and engineering applications are said to be turbulent. Still it is difficult to provide a complete definition of this phenomenon. Hinze [67] presents the following definition: *Turbulent fluid motion is an irregular condition of flow in which the various quantities show a random variation with time and space*

coordinates, so that statistically distinct average values can be discerned. Tennekes and Lumley [168] find it more appropriate to list the characteristics of turbulent flow such as: *Irregularity (or randomness), diffusivity, large Reynolds numbers, three dimensional vorticity fluctuations and dissipation*. Turbulence is not a feature of fluids, but of fluid flows thus a continuum phenomenon. In the modern theory of fluid dynamic systems *the term turbulence is accepted to mean a state of spatiotemporal chaos* (e.g., [156], Chap. 5). That is, the fluid exhibits chaos on all scales in both space and time. Chaos theory involves the behavior of non-linear dynamical systems and their response to initial and boundary conditions. Using such methods it can be shown that although the solution of the Navier-Stokes is apparently random for turbulent flows, its behavior presents some orderly structures. In addition, the numerical solution of the Navier-Stokes equations is sometimes strongly dependent on the initial conditions, thus even very small inaccuracies in the initial conditions may be fatal providing completely erroneous results.<sup>29</sup> To quantitatively describe turbulent flows, we usually turn to the basic equations of fluid mechanics that describe the dynamics of the flow. This seems plausible because the average size of the turbulent structures is large in comparison with the mean free path of the molecules of the fluid. In principle, it is believed that single phase turbulent flows are exactly represented by these three dimensional time dependent transport equations (e.g., [15], chap 10; [67, 107, 112, 113, 122]). Based on these equations three theoretical methodologies have been suggested in the literature enabling numerical analyzes of turbulent flows (for further details, see for example the textbook of [122]). Those are the direct numerical simulation (DNS), the large eddy simulation (LES), and the statistical approach. In DNS, the ‘un-averaged’ governing equations are solved to determine  $\mathbf{v}(\mathbf{r}, t)$  for one realization of the flow. Statistical analysis of the resulting numerical data could theoretically provide information such as turbulent fluctuations, the root-mean-square velocity, the frequency and wavenumber spectra, and their mutual interaction. However, although the existing numerical methods are capable of solving these equations, the numerical solutions are also limited due to constraints in computer time and storage since all length—and timescales in the flow have to be resolved. DNS is thus extremely computationally expensive and restricted to low Reynolds number flows as the computational cost increases rapidly with increasing Reynolds numbers. In addition, these equations contain time and space derivatives that require initial and boundary conditions for their solution. Although the governing equations may be applied directly to turbulent flows, rarely do we have sufficient initial and boundary condition information to resolve all turbulent scales down to the smallest eddy. Therefore, in practice, this approach is not very

---

<sup>29</sup> The latter effect is often ‘nicely’ exemplified through poor weather forecasts. Naturally, the meteorologists are not able to define exact initial conditions based on their statistical analysis of the available weather observations. Consequently, poor forecasts are likely to be predicted for those regions or those times where the simulations are highly sensitive to the initial conditions. Fortunately, performing a large number of simulations of the same forecast, in which every single one of these simultaneous simulations is ran with small perturbations in the initial conditions, can provide information on the reliability of the forecast produced by use of an (ensemble) average model.

useful for chemical reactor analyzes. In LES, the governing equations are solved for a filtered velocity field which is representative of the larger scale turbulent motions. The equations solved usually include a model for the influence of the smaller scale motions which are not resolved. However, the LES approach still provides information on the dynamics and structure of turbulence on the larger scales. The filtering procedure is, of course, introduced to reduce the computational costs, compared to the DNS simulation approach. In practice, however, the method is still too computationally expensive for chemical reactor analyzes. Only a very limited number of preliminary reactor flow LES simulations have been performed in academia for research purposes so far, but the application of the LES concept (or LES hybrids) is expected to increase in the near future as the computer capacity continues to be improved. Therefore, the fundamental LES concepts are presented in the end of this chapter. Consequently, in quantifying turbulent effects one necessarily has to resort to the statistical Reynolds averaging approach. The Reynolds averaged equations are solved to determine the mean velocity field,  $\bar{\mathbf{v}}(\mathbf{r}, t)$ . In the simplest versions of these approaches, the Reynolds stresses are obtained from a turbulent viscosity model. In reactor model simulations the turbulent viscosity is either obtained from an algebraic relation (such as the mixing length model) or from turbulence quantities such as  $k$  and  $\varepsilon$  for which modeled transport equations are solved. In a limited number of papers, the Reynolds stress model is used, for which modeled transport equations are solved for the Reynolds stresses, thus obviating the need for a turbulent viscosity. The aim of this section is not to provide a comprehensive review of turbulence modeling, as can be found elsewhere (e.g., [15, 67, 107, 122, 140, 155, 185]). The intension is rather to outline the essential ingredients involved in single phase turbulence modeling, determining the basis theory for multiphase turbulent modeling in the context of engineering practice discussed in the subsequent chaps in this book. Although the main emphasis in this chap is put on the Reynolds averaging approach, some results obtained using more fundamental statistical approaches to turbulence are provided in an introductory paragraph. This highly theoretical work, together with experimental validation, has for example discovered the existence of a energy cascade mechanism, the characteristic length and time scales, the return to isotropy principle, etc. These are features of turbulence that could not be predicted by studying the conservation laws alone.

In the first three paragraphs of this chapter some of the important characteristics of fluid turbulence are described. This includes the turbulence energy spectrum and Fourier analysis in wave space. Some basic statistics for describing turbulence are also presented. The fourth paragraph gives a semi-empirical analysis of turbulent boundary layer flows. In the fifth paragraph Reynolds averaged models are discussed. In the last paragraph large eddy simulation (LES) models are discussed.

### 1.3.1 Origin and Characteristics of Turbulence

In flows which are originally laminar, turbulence arises from instabilities at large Reynolds numbers. Turbulence cannot maintain itself but depends on its environment to obtain energy. A common source of energy for turbulent velocity fluctuations in single phase flow is shear in the mean flow. Other sources such as buoyancy is very important in the geophysical sciences. Thus, if turbulence arrives in an environment where there is no shear or other maintenance mechanism, it decays, the Reynolds number decreases and the flow tends to become laminar again. Mathematically, the details of transition from laminar to turbulent flow are rather poorly understood (e.g., [38]). Much of the theory of instabilities in laminar flows is linearized theory, valid for very small disturbances. It cannot deal with the large fluctuation levels in turbulent flow. On the other hand, almost all of the theory of turbulent flow is asymptotic theory, fairly accurate at very high Reynolds numbers but inaccurate and incomplete for Reynolds numbers at which the turbulence cannot maintain itself. Experiments have shown that the transition from laminar to turbulent flow is commonly initiated by a primary instability mechanism. The primary instability produces secondary motions, which may become unstable themselves. A sequence of this nature generates intense localized disturbances, which arise at random positions at random times. These spots grow rapidly and merge with each other when they become large and numerous to form a field of developed turbulent flow. Many wake flows on the other hand become turbulent due to an instability that causes vortexes which subsequently become unstable. The latter mechanisms are very important in multi-phase flows.

Further discussions on the classical fluid dynamic stability theory can be found elsewhere (e.g., [38]; [112], Chap. 1; [140], Chap. 15).

Modern theories and concepts describing the initial dynamic evolution of fluid motions leading to the onset of turbulence, explaining experimental observations of instability phenomena, are typically rather theoretical and usually not considered by chemical reaction engineers. The interested reader is referred to texts on chaos theory and non-linear dynamics (e.g., [156], Chap. 5).

#### 1.3.1.1 Signature of Turbulence

Considering high resolution experimental data of velocity measured over a certain time period, as shown in Fig. 1.5, a number of features of turbulence stand out (e.g., [15], Chap. 2; [122]; [155], Chap. 1):

- The velocity varies in an irregular pattern, a characteristic signature of turbulence. This quasi-randomness is what makes turbulence different from other motions, like waves.
- The limited ability to find a statistically stable mean, or typical value, suggest that turbulence is not completely random (e.g., [112], Chap. 2).

The interpretation that the fluctuations in the flow quantities are randomly distributed has been modified with the discovery of orderly structures, sometimes called

**Fig. 1.5** A typical velocity signal recorded by a laser Doppler anemometer (LDA) in a liquid flow at NTNU.  $\langle v \rangle$  denotes the time average of the velocity over the time period displayed. The work was performed as a part of the strategic university program (SUP) entitled ‘CFD Applied to Reactor ProcEss Technology (CARPET)’

*coherent structures*, within the flow. Coherent structures within fluid flows, and the modeling of these phenomena, are further discussed by [71, 72].

- There is a measurable and definable intensity to the turbulence that shows up as the small scale spread of velocity.

Such a bounded characteristic of the velocity means that we can use statistics such as the variance or standard deviation to characterize the turbulence intensity.

- There appears to be a wide variety of time scales of velocity variations superimposed on top of each other.

For example, if we look closely at the high resolution experimental data we see that the time period between each little peak in the velocity profile has a certain characteristic small scale. The larger peaks seem to happen at another somewhat larger scale. There will also be other variations that indicate much larger time periods. If each of these time variations is associated with a different size turbulent eddy (i.e., the Taylor’s hypothesis [165]), then we can conclude that we are seeing the signature of eddies having different sizes. In other words, we are observing evidence of the spectrum of turbulence.

Perhaps an association to another physical phenomena which is more generally accepted, will help understanding this property of turbulence. The turbulence spectrum is analogous to the spectrum of colors that appears when you shine a light through a prism [165]. White light consists of many colors (i.e., many wavelengths or frequencies) superimposed on one another. The prism is a physical device that separates the colors. We could measure the intensity of each color to learn the magnitude of its contribution to the original light beam. We can performed a similar analysis on a turbulent signal using mathematical rather than physical devices to learn about the contribution of each different size eddy to the total turbulence

kinetic energy. Therefore, although the physical interpretation of the experimental data may indicate a labyrinth of motions, turbulence may be idealized as consisting of a variety of different sized eddies. In this mathematical context, the eddies behave in a well-ordered manner when displayed in the form of a spectrum.

### 1.3.2 Statistical Turbulence Theory

Introductory it is noted that the researchers developing the classical statistical turbulence theory were statisticians (statistical fluid mechanics), physicist and meteorologists rather than chemical engineers. This has the unfortunate consequence that the descriptions of this theory, as found in most textbooks on turbulence and statistical fluid mechanics, are not easily understood by chemical reaction engineers partly due to the unacquainted conceptual vocabulary and mathematical nomenclature adopted in these books. Another reason is language problems as much of the pertinent literature is not written in English, and so the references given in the english-language literature are often misleading as the original contents are neither precisely translated nor interpreted. At this point in our presentation it is thus obvious that we need to define a common language for the researchers working on the edge between these fields of science (i.e., fluid dynamics, statistics, meteorology and chemical engineering) to avoid any ambiguity. However, the statistical turbulence theory is rather involved mathematically and difficult to explain in only a few words. Therefore, it is found more convenient to present a brief historical survey of the main milestones and scientific concepts developed during the last century. Emphasis is put on the physical interpretations of these concepts, avoiding future developments of ill posed reactor model closures. The fundamental theory is available elsewhere, for example in the books by [8, 67, 112, 113]. The classic papers on statistical turbulence theory have been collected in a publication by [51]. An early review of the statistical theory of turbulence was published by [40].

Turbulent motions are irregular and seemingly unpredictable. This is the most spectacular characteristic which distinguishes turbulent flows from laminar flows. The first scientific study of turbulence, performed by Reynolds [127], relates to this difference. Reynolds did study flows through pipes of constant diameter and by using the ‘method of color bands’ clearly established that there are two fundamentally different flow regimes, laminar and turbulent flows. Reynolds also determined the conditions under which transition took place. This is now described in terms of the *critical Reynolds number*. The *Reynolds number* used in modeling fluid flow is thus named after him. Reynolds [128] provided the fundamental ideas about averaging and was the first to accomplish the formulation of the governing equations for turbulent flows in terms of mean and fluctuating flow quantities rather than instantaneous quantities. Reynolds stated the mathematical rules for forming mean values. That is, he suggested splitting a turbulent velocity field into its mean and fluctuating components, and wrote down the equations of motion for these two velocity quantities. The decomposition of the instantaneous velocity variable into its mean

and fluctuation is thus referred to as *Reynolds decomposition*. This procedure is still the most common method of analyzing turbulent flows, and it is known as *Reynolds averaging*.

According to the ideas of Boussinesq [19, 20], the first turbulent closures was based on the gradient hypothesis and the coefficient of eddy viscosity. The *eddy* concept was thus introduced. An eddy still eludes precise definition, but in one interpretation it is conceived to be a turbulent motion, localized within a region of a certain size, that is at least moderately coherent over this region. The region of a large eddy can also contain smaller eddies.

In an early study Taylor [158] put forth the mixing length ideas based on analogies with the discontinuous collisions between discrete entities that have been studied in the kinetic theory of gases (i.e., about ten years before Prandtl's similar ideas were published [124], but the idea has been traditionally attributed to Prandtl). However, logical difficulties arise considering the mixing length concept because there are no discrete fluid particles in the turbulent flow which retain their identity. Later Taylor began to search for more suitable means for the the description of turbulence [166]. The statistical approach to the study of turbulence was initiated by a paper by Taylor [159]. In the work of Taylor [159] on turbulent transport the important role of the Lagrangian<sup>30</sup> correlation function (i.e., the one point time correlation) of the velocity field was first demonstrated. Taylor showed that the turbulent diffusion of particles starting from a point depends on the correlation between the velocity of a fluid particle at any instant and that of the same particle after a certain correlation time interval.

For a statistically stationary process, the simplest multi-time statistic that can be considered is the *auto-covariance* (i.e., the one-point two-time correlation):

$$R_L(s) = \overline{v'(t)v'(t+s)} \quad (1.312)$$

or, in normalized form, the *autocorrelation coefficient* (e.g., [168], Sect. 6.4):

$$\rho_L(s) = \overline{v'(t)v'(t+s)} / \overline{v'^2(t)} \quad (1.313)$$

---

<sup>30</sup> The adjective 'Lagrangian' is used to indicate that the correlation relates to moving fluid particles (e.g., [113], p. 539; [168], p. 46). The adjective 'Eulerian' is used whenever correlations between two fixed points in a fixed frame of reference are considered.

Unfortunately, not all texts describing the turbulence correlation functions are using the same notation. Hinze ([67], p. 45) find it more logical to rename these functions using the opposite notation. That is, considering the correlation between the values of a velocity component in a given direction at a fixed point in the flow field at two different instants  $t'$  and  $t+t'$ , the resulting correlation was called Eulerian as the measurements were performed at one fixed point in space.

Subsequent textbooks considering statistical turbulence theory adopt either of the two notations possibly making some vagueness for the readers. The chemical engineering textbooks of Baldyga and Bourne [5] on turbulent mixing, and the interdisciplinary textbook of Biswas and Eswaran [15] on turbulent flow experiments and modeling both use the notation introduced by Hinze. However, the classical books (e.g., [113, 168]) and papers (e.g., Taylor's papers) on statistical turbulence theory use the other notation.

Therefore, to minimize the level of vagueness jumping from one notation to the other, in this book we adopt the original notation induced by Taylor as defined above.

where  $v'(t) = v(t) - \overline{v(t)}$  is the fluctuation.

Because we are working with stationary variables, the autocorrelation gives no information on the origin of time, so that it can only depend on the time difference:  $s$ . The autocorrelation coefficient is the correlation coefficient between the process at time  $t$  and  $t + s$ .

The *Lagrangian integral time scale* of the process is defined by:

$$\Gamma_L = \int_0^{\infty} \rho_L(s) ds \quad (1.314)$$

The value of  $\Gamma_L$  is a rough measure of the longest interval over which  $v(t)$  is correlated with itself.

The microscale  $\tau_L$ , which is defined by the curvature of the autocorrelation coefficient at the origin (i.e., for  $s = 0$ ):

$$\frac{d^2 \rho_L}{ds^2} \Big|_{s=0} = \frac{-2}{\tau_L^2} \quad (1.315)$$

Expanding  $\rho_L$  in a Taylor series about the origin, we can write, for small  $s$  ([159]; see also [67], Sect. 1–8; [168], Sect. 6.4):

$$\rho_L(s) = 1 + \frac{s^2}{2!} \left( \frac{\partial^2 \rho_L}{\partial s^2} \right) \Big|_{s=0} + \frac{s^4}{4!} \left( \frac{\partial^4 \rho_L}{\partial s^4} \right) \Big|_{s=0} + \cdots = 1 - \frac{s^2}{\tau_L^2} + O(s^4) \quad (1.316)$$

in which  $\tau_L$  is the Lagrangian time scale which characterize the most rapid changes of  $v_1(t)$ .

Richardson ([130], p. 66) introduced the idea of *the energy cascade*. Richardson's view of the energy cascade is that the turbulence can be considered to be composed of eddies of different sizes, and the energy is transferred from larger eddies to smaller eddies until it is drained out by viscous dissipation. Richardson's notation is that the large eddies are unstable and break up, transferring their energy to somewhat smaller eddies. However, Richardson did forward these general ideas only in qualitative form and did not make any deduction that could be formulated in precise mathematics.

In Taylor's analysis of turbulent flow the velocity field is considered random, in the sense that the variable does not have a unique value (i.e., the same value every time an experiment is repeated under the same set of conditions). Random functions of time in specific literature are also often called random processes. However, this does not mean that turbulence is a random phenomena.

The idea that the correlation functions and other statistical moments of the fluid mechanical fields must be recognized as the fundamental characteristics of turbulence was first stated by Keller and Friedmann ([81]; see also [8], Sect. 2.2; [112], Chap. 2), who proposed a general method of obtaining the differential equations for the moments of arbitrary order for the description of turbulent flow. The determination of

all such moments is equivalent to the determination of the corresponding probability distribution in the functional space. The total infinite Friedmann-Keller system of equations for all possible moments gives an analytical formulation of the problem of turbulence. However, analytical treatment of the problem is not feasible unless one confines attention to the very simplest kinds of averaged quantities (i.e., involving one- or two-point correlation functions). The desire to make practical calculations of complex flows has led to the development of approximate methods which make computer simulations of turbulent flows feasible. In one interpretation the hypothesis adopted in these theories permits the closure of a set of equations representing a lower order approximations to the infinite Friedmann-Keller system. A specific set of equations, the Reynolds equations, containing only single point first and second order moments of the fluid mechanical field is usually adopted. In statistical terms, the mean velocity and the Reynolds stresses are the first and second moments of the Eulerian probability distribution function (PDF) of velocity. Such a method doesn't provide much information about the structure (spectrum) of turbulence and the dynamics of interactions between the turbulent vortexes. The two-point correlations (or moments) contain more information about the structure of turbulence. Therefore, in the scientific literature it is implied that the methods employing the second-order two-point correlations (or even higher order functions) constitutes the fundamental, statistical approach to turbulence, while restricting the complexity to the use of the second-order one-point correlations only is considered an engineering approach. Nevertheless, the two-point structure function information is essential for improving the engineering models including second-order closures. In addition, the study of many physical phenomena in reactor systems requires information on the turbulence structure (e.g., phase and species mixing, coalescence and breakage of fluid particles).

A statistical theory of turbulence which is applicable to continuous movements and which satisfies the equations of motion was introduced by Taylor [160–162] and [163, 164], and further developed by von Kàrmàn [177, 178]. Most of the fundamental ideas and concepts of the statistical turbulence theory were presented in the series of papers published by Taylor in 1935. The two-point correlation function is a central mathematical tool in this theory. Considering the statistics of continuous random functions the complexity of the probability density functions needed in a generalized flow situations was found not tractable in practice. An idealized flow based on the assumption of statistical homogeneity greatly simplified the analysis. Taylor [160–162] went further still and considered isotropic turbulence.

The velocity field is *statistically homogeneous* if all statistics are invariants under a shift in position. If the field is also statistically invariant under rotations and reflections of the coordinate system, then it is *statistically isotropic*. In chemical reaction engineering these mathematical definitions are usually somewhat relaxed, since turbulence is said to be *isotropic* if the individual velocity fluctuations are equal in all the three space dimensions. Otherwise it is said to be *an-isotropic*. Similarly, a flow field where turbulence levels do not change from one point to another is called *homogeneous*.

*Homogeneous isotropic turbulence* is a mathematical idealization of real turbulence, that was introduced by [160], allowing us to simplify the analysis of turbulence considerably, and thus gain insight into its behavior. Nevertheless, real turbulent flows do rarely approach homogeneity and isotropy. However, by using the homogeneous and isotropic turbulence concept the mathematical problem simplifies considerably and it is possible to obtain many specific mathematical results which explain several aspects of turbulent flows. After Taylor's work was reported, von Kàrmàn [177] noticed that the mean values of the products of the velocities at two (or more points) were tensors. The realization of van Kàrmàn [177] that the correlation is a tensor simplified the analysis considerably because a known tensor in one coordinate system can be transformed into other coordinate systems simply by adopting the rules of such transformations for second order tensors. For the purposes of simplification, von Kàrmàn also introduced the assumption of *self-preservation* of the shape of the velocity product function during decay. In the following we will consider some basic results of the statistics of such a homogeneous isotropic turbulent field. The consequences of homogeneity and isotropy for the correlation functions were worked out by von Kàrmàn and Howarth [178] and the full derivations are available in classical books like [8, 67, 112, 113].

The simplest statistic containing information on the spatial structure of the random field is the two-point, one time auto-covariance:

$$R_{ij}(t, \mathbf{x}) = \overline{v_i(\mathbf{r} + \mathbf{x}, t)v_j(\mathbf{r}, t)} \quad (1.317)$$

which is often referred to as the *two-point correlation*. For homogeneous turbulence in particular the correlation tensor  $R_{ij}(t, \mathbf{x})$  is a function of the vector  $\mathbf{x}$  defining the separation of the two points in space, but independent of  $\mathbf{r}$ . From this correlation tensor it is possible to define several integral length scales.

According to von Kàrmàn and Howarth [178], a consequence of isotropy is that  $R_{ij}$  can be expressed in terms of two scalar functions  $f(t, \mathbf{x})$  and  $g(t, \mathbf{x})$  identified as the longitudinal and transverse autocorrelation functions, respectively. There are two distinct longitudinal length scales,  $\Lambda_f$  and  $\lambda_f$ , that can be defined from  $f$ , and there are also two corresponding transverse length scales  $\Lambda_g$  and  $\lambda_g$ , defined from  $g$ . The first of the Eulerian length scales obtained from  $f(t, \mathbf{x})$  is the longitudinal integral scale:

$$\Lambda_f(t) = \int_0^\infty f(t, \mathbf{x}) d\mathbf{x} \quad (1.318)$$

$\Lambda_f$  is a characteristic length of the larger eddies.

In isotropic turbulence, the transverse integral scale:

$$\Lambda_g(t) = \int_0^\infty g(t, \mathbf{x}) d\mathbf{x} \quad (1.319)$$

is just half of  $\Lambda_f$ .

The second length scale obtained from  $f(t, \mathbf{x})$  is the longitudinal *Taylor microscale*,  $\lambda_f$ . As  $f(t, \mathbf{x})$  and  $g(t, \mathbf{x})$  are even functions of  $\mathbf{x}$  because of isotropy (i.e.,  $f(t, \mathbf{x}) = f(-\mathbf{x}, t)$ , etc.), all the odd derivatives of  $f(t, \mathbf{x})$  and  $g(t, \mathbf{x})$  vanish as  $\mathbf{x} \rightarrow 0$ . Therefore, Taylor series expressions for  $f(t, \mathbf{x})$  and  $g(t, \mathbf{x})$ , around  $\mathbf{x} = 0$ , can be written as (e.g., [67], chap 1):

$$f(t, \mathbf{x}) = 1 + \frac{\mathbf{x}^2}{2!} \left( \frac{\partial^2 f}{\partial \mathbf{x}^2} \right) \Big|_{\mathbf{x}=0} + \frac{\mathbf{x}^4}{4!} \left( \frac{\partial^4 f}{\partial \mathbf{x}^4} \right) \Big|_{\mathbf{x}=0} + \cdots = 1 - \frac{\mathbf{x}^2}{\lambda_f^2} + O(\mathbf{x}^2) \quad (1.320)$$

and

$$g(t, \mathbf{x}) = 1 + \frac{\mathbf{x}^2}{2!} \left( \frac{\partial^2 g}{\partial \mathbf{x}^2} \right) \Big|_{\mathbf{x}=0} + \frac{\mathbf{x}^4}{4!} \left( \frac{\partial^4 g}{\partial \mathbf{x}^4} \right) \Big|_{\mathbf{x}=0} + \cdots = 1 - \frac{\mathbf{x}^2}{\lambda_g^2} + O(\mathbf{x}^2) \quad (1.321)$$

The Taylor microscale  $\lambda_f$  is now defined as a length scale which for a very small  $\mathbf{x}$  values gives:

$$f(t, \mathbf{x}) \approx 1 - \frac{\mathbf{x}^2}{\lambda_f^2} \quad (1.322)$$

where

$$\frac{1}{\lambda_f^2} = -\frac{1}{2} \left( \frac{\partial^2 f}{\partial \mathbf{x}^2} \right) \Big|_{\mathbf{x}=0} \quad (1.323)$$

and

$$g(t, \mathbf{x}) \approx 1 - \frac{\mathbf{x}^2}{\lambda_g^2} \quad (1.324)$$

where

$$\frac{1}{\lambda_g^2} = -\frac{1}{2} \left( \frac{\partial^2 g}{\partial \mathbf{x}^2} \right) \Big|_{\mathbf{x}=0} \quad (1.325)$$

It was shown by Taylor [160] that an analysis of the dissipation term occurring within the turbulent kinetic energy balance equation (derived later in this chap) shows that in isotropic turbulence the energy dissipation rate is equal to:

$$\varepsilon = 15\nu \overline{\left( \frac{\partial v'_1}{\partial x_1} \right)^2} \quad (1.326)$$

Taylor re-formulated the expression for the length scale (see, e.g., [67], sects. 1–6) such that:

$$\overline{\left(\frac{\partial v'_1}{\partial x_1}\right)^2} = \frac{2\overline{v'^2}}{\lambda_f^2} = \frac{2v_{\text{rms}}^2}{\lambda_f^2} \quad (1.327)$$

The turbulent velocity scale is often approximated by,  $v_{\text{rms}} = \sqrt{\overline{v'_i v'_i}/3}$ , the root-mean-square of the fluctuating velocity components.

In isotropic turbulence, it was shown that  $\lambda_f \approx \sqrt{2}\lambda_g$ . It then follows that the energy dissipation rate is given by:

$$\varepsilon = 15\nu \frac{\overline{v'^2}}{\lambda_g^2} \quad (1.328)$$

The *dissipation rate* can be defined as:

$$\varepsilon = 15\nu \frac{v_{\text{rms}}^2}{\lambda_g^2} = 30\nu \frac{v_{\text{rms}}^2}{\lambda_f^2} \quad (1.329)$$

Taylor [160] stated that  $\lambda_g$  can be regarded as a measure of the diameter of the smallest eddies which are responsible for the dissipation of turbulent energy. Pope ([122], p. 199) stated that this statement is incorrect, because it incorrectly supposes that  $v_{\text{rms}}$  is the characteristic velocity of the dissipative eddies. The characteristic length scale of the smallest eddies are the Kolmogorov scale,  $\eta = (\nu^3/\varepsilon)^{1/4}$  as will be further discussed shortly.

The Taylor microscale does not represent any distinct group of eddies, but the ratios  $\frac{v_{\text{rms}}}{\lambda_g}$  and  $\frac{v_{\text{rms}}}{\lambda_f}$  are fair estimates of the rate of strain characterizing viscous dissipation of energy (e.g., [5], p. 148). Further details on this theory are given by Tennekes and Lumley ([168], Sect. 3.2), Hinze ([67], Chap. 1) and Pope ([122], p. 198).

According to Taylor [160–162], the properties of the Lagrangian scales are similar to the Eulerian correlation scales. Although the statistical turbulence theory is derived in terms of the Eulerian correlation functions, accurate measurements of the Lagrangian scales and correlations are easier and direct. In contrast, the measurements of Eulerian correlations requires two probes simultaneously working at two different locations. Taylor [165] thus suggested that turbulence might be considered “frozen” in a wind field as it advects past a sensor. A physical interpretation of this statement is that, if  $\bar{v} \gg v'$ , the fluctuations at a fixed point of the field may be imagined to be caused by the whole turbulent flow field passing that point as a “frozen” field (i.e., the probe is assumed to be within a large almost homogeneous eddy during the time interval of sampling). The velocity fluctuations at that point will then be nearly identical to the instantaneous distribution of the velocity  $v'$  in a frame moving with the mean velocity (i.e., the probe follows the mean flow). Accordingly, as can be shown mathematically, the average wind speed could be used to translate Lagrangian turbulence measurements as a function of time to their corresponding Eulerian mea-

surements in space. In mathematical terms, the *frozen* turbulence approximation, known as Taylor's hypothesis, refers to a simple mathematical relation between statistical temporal auto-covariances and spatial correlation functions approximately valid for quasi-steady homogeneous turbulent flow. If we can assume that the homogeneous turbulent field has a constant mean velocity,  $\overline{v_1}$ , then we can express Taylor's hypothesis of frozen turbulence as:

$$\frac{\partial}{\partial t} = \overline{v_1} \frac{\partial}{\partial x_1} \quad (1.330)$$

The integral Lagrangian-Eulerian conversion relation yields:

$$\Lambda = \overline{v_1} \Gamma_L \quad (1.331)$$

and the corresponding microscale relation is:

$$\lambda = \overline{v_1} \tau_L \quad (1.332)$$

The mathematics involved is explained by several authors (e.g., [15], p. 205; [67], Sect. 1-8; [122], p. 223; [155], p. 5).

Experimentalists often rely on this hypothesis interpreting experimental turbulence data. However, turbulence is not really "frozen". The accuracy of this approximation depends both upon the properties of the flow and on the statistics being measured. Many experiments on complex turbulent flows have shown that Taylor's hypothesis can fail.

Taylor [160] also formulated a relation estimating the energy dissipation rate in terms of the larger scales of turbulence. Taylor didn't discuss the detailed derivation of this relation, but it may be derived in the following approximate manner ([168], p. 20). Assuming that the largest eddy sizes in turbulent flows do most of the transport of momentum and other quantities, these large eddies may be the relevant length scale in the analysis of the interaction of the turbulence with the mean flow. The amount of turbulent kinetic energy absorbed by the larger turbulent eddies per unit mass may then be proportional to the square of the characteristic turbulent velocity scale of the largest eddies,  $\overline{v'^2} = v_{\text{rms}}^2$ . The rate of energy transfer is assumed to be proportional to  $v/L$  (i.e., the reciprocal of the time scale of the large eddies), where  $L$  represents the size of the largest eddies. One may interpret the size of the large, energy containing eddies as the integral scale of turbulence,<sup>31</sup>  $\Lambda$  (e.g., [15], Sect. 2.2.5; [107, 168]), which can be measured by statistical methods. The rate of energy supply to the smaller scale eddies is thus of order  $v_{\text{rms}}^2 v_{\text{rms}} / \Lambda$ . It can be shown that the production of the kinetic energy of turbulence at the larger length scales ( $v_{\text{rms}}^3 / L$ ) determines

---

<sup>31</sup> The integral scales are those that correspond to the energy containing eddies, which also form the large (but not necessarily the largest) scales of the turbulent field (e.g., [67], Chap. 1). The integral length scales also roughly correspond to the distance over which the velocity fluctuations at one point are correlated with the velocity at another point, and the integral time-scales correspond to the time-intervals over which the velocity fluctuations at the same point are correlated.

the rate of energy dissipation,  $\epsilon$ , at small length scales when the cascade of kinetic energy is in some kind of equilibrium. Hence, the energy is dissipated at a rate  $\epsilon$  and this equals the supply rate. In accordance with Taylor [160], we can thus write:

$$\epsilon \sim \frac{v_{\text{rms}}^3}{\Lambda} \quad (1.333)$$

This means that we can get an inviscid estimate for the dissipation rate from the large scale dynamics which do not involve viscosity. This implies that only a small fraction of the kinetic energy contained in the larger eddies is lost by direct viscous dissipation effects.

Taylor [160] further speculated that there may exist very small scale eddies which, though they play a very small part of diffusion, yet may be principal agents in the dissipation of energy. Unfortunately, the simplified engineering method doesn't provide much information about the structure of turbulence and the dynamics of the interactions between the turbulent vortexes. The only structural information extracted from the second moments in relation to the structure of turbulence is the length scale,  $\Lambda$ , and the only information in relation to the dynamics of turbulence is the time constant representing the *eddy turnover time*,  $\tau_e \approx \frac{\Lambda}{v_{\text{rms}}} \approx \frac{\Lambda}{(\Lambda\epsilon)^{1/3}} = \frac{\Lambda^{2/3}}{\epsilon^{1/3}} \cdot \tau_e$  can be interpreted as the time necessary to decrease significantly the size of the structure having initially size  $\Lambda$ . Another interpretation is that it is the time constant for the rate of kinetic energy dissipation when the cascade is in dynamic equilibrium (steady state), and a third interpretation could be that it is an estimate of a time necessary to transfer the kinetic energy from the scale  $\Lambda$  to the scale of dissipation.

Further contributions to the subject were made by Taylor in 1938. Two important consequences of the non-linearity of the Navier-Stokes equations were identified: First, the skewness of the probability distribution of the difference between the velocities at two points, and the existence of an interaction or modulation between components of turbulence having different length scales. Secondly, the Fourier transform of the correlation between two velocities is an energy spectrum function in the sense that it describes the distribution of kinetic energy over the various Fourier wave-number components of the turbulence [165]. Taylor expressed in mathematical form the relation between the correlation function and the 1D spectrum function. The two-point one time correlation functions, in the form presented in the preceding discussion, are not suitable for analyzing motions at different scales and specifically they are not suitable for understanding relations between movements of fluid characterized by different length and time scales. That is why it is better to use the 3D Fourier transforms of two-point correlations and to decompose them into waves of different frequencies or wave numbers. Turbulence has by definition a 3D character so it is obvious that the spectrum has to be 3D as well, to characterize turbulence properly. The 1D spectrum of Taylor (see, e.g., [67]) oversimplifies the observed features of turbulence and may give misleading interpretations of the 3D field (see also, [113], p. 18). The differences and consequences of 1D and 3D spectrum analysis are discussed by Hinze ([67], Sects. 1–12 and 3–4) and Pope ([122], Sect. 6.5).

In the early investigations of the energy cascade by Richardson [130] and Taylor [160–162, 165], the transfer of energy to successively smaller scales was identified as a phenomenon of prime importance, but the precise mechanisms by which this transfer takes place was not identified or quantified. This was further accomplished by the work of Kolmogorov [84, 85]. The theory of Kolmogorov [84] was stated in the form of three hypotheses. The first hypothesis is apparently based on the homogeneous and isotropic concepts of Taylor [160–162]. Although the large eddies are in general anisotropic and affected by the boundaries of the flow, it was postulated by Kolmogorov [84], and later validated experimentally, that the smaller scales are less affected by the boundaries and thus demonstrate a certain degree of isotropy. In Kolmogorov's notation the orienting effect of the mean flow is weakened with each eddy breaking down, due to the chaotic nature of the energy transfer processes. The *theory of locally isotropic turbulence* thus constitutes an important addition to the assumptions on the energy cascade.

Approximately stated *Kolmogorov's hypothesis of local isotropy* yields ([84]; see also [122], p. 184): At sufficiently high Reynolds number, the small scale turbulent motions are statistically isotropic. The second hypothesis concerns the very smallest dissipative eddies. Kolmogorov's [84] universal equilibrium theory of the isotropic small scale structure of turbulence is based on the assumption that when the Reynolds number is sufficiently high, a range of high wave numbers is produced in which turbulence is in both statistical- and dynamic equilibrium. The phrase 'statistical equilibrium' denotes the postulate that the rate of energy transfer from the large scales determines an almost constant rate of energy transfer through the successively smaller scales until the energy is dissipated at the very smallest scales. Hence, the net rate of energy transfer at all the scales within this range of wave numbers is given by the dissipation rate. The phrase 'dynamic equilibrium' denotes the postulate that the small eddies will evolve much more rapidly than the large eddies which contain most of the energy. That is, within a certain range of wave numbers, i.e., the *universal equilibrium range of wave numbers*, the timescales  $\tau_{e,l} \approx l/v_{\text{rms}}(l)$  are small compared with  $\tau_e \approx \Lambda/v_{\text{rms}}(\Lambda)$  so that the small eddies can adapt quickly to changes in the large scale conditions. In this wavenumber range turbulence may be considered statistically quasi-steady. This statistically quasi-steady equilibrium state is said to be *universal* as turbulence in this wavenumber range is independent of the large scale conditions, thus any change in the length- and time scales of this part of turbulence can only be a result of the 'local' effect of the parameters  $\varepsilon$  and  $\nu$ .

Given these two parameters three unique length, velocity, and time scales can be formed from dimensional analysis, i.e., the Kolmogorov microscales:

$$\eta = \left(\frac{\nu^3}{\varepsilon}\right)^{1/4} \quad (1.334)$$

$$\tau = (\nu/\varepsilon)^{1/2} \quad (1.335)$$

$$v = (\nu\varepsilon)^{1/4} \quad (1.336)$$

Approximately stated *Kolmogorov's first similarity hypothesis* yields ([84]; see also [122], p. 185): In every turbulent flow at sufficiently high Reynolds number, the statistics of the small scale motions have a universal form that is uniquely determined by  $\nu$  and  $\varepsilon$ . The phrases 'similarity hypothesis' and 'universal form' refer to a mathematical consequence of the Kolmogorov hypothesis denoting that on the small scales all high-Reynolds-number turbulent velocity fields are statistically similar. That is, they are statistically identical when they are scaled by the Kolmogorov velocity scale ([122], p. 186).

The Kolmogorov *third hypothesis* concerns the motions of scale  $l$  in the range  $L \approx \Lambda \gg l \gg \eta$  assumed to prevail in the universal equilibrium range. Kolmogorov postulated that the universal equilibrium range extends to scales much larger than  $\eta$ . If the energy is expected to be dissipated at the very smallest scales only, there must exist an *inertial subrange* of scales in which the viscosity will no longer play any role. That is, the statistical regime will be determined by a single parameter  $\varepsilon$ .

Approximately stated *Kolmogorov's second similarity hypothesis* yields ([84]; see also [122], p. 186): In every turbulent flow at sufficiently high Reynolds numbers, the statistics of the motions of scale  $l$  in the range  $L \approx \Lambda \gg l \gg \eta$  have a universal form that is uniquely determined by  $\varepsilon$ , but independent of  $\nu$ .

Note that the Kolmogorov hypothesis, and deductions drawn from them, apparently have no direct connection to the Navier-Stokes equations.

Hinze ([67], Sect. 3–4) derived an analytical expression for the 3D spectrum  $E(k, t)$  as a function of wave number  $k$  and time  $t$ . This result shows that  $E(k = 0) \approx 0$ , then the spectrum function increases rapidly, reaches a maximum value, and decreases monotonously to zero as  $k$  increases. Figure 1.6 shows an example of such a velocity spectrum determining a generalized spectral energy distribution for single phase flow. The ordinate is a measure of the portion of turbulence energy that is associated with a particular size eddy. The abscissa gives the eddy size in terms of wave number ( $k$ ) which is proportional to the velocity fluctuation frequency ( $k \propto f/\bar{v}_1$ ). Small eddies have higher frequencies, thus larger wave numbers, than large eddies (using Taylor's hypothesis). According to Tennekes and Lumley ([168], p. 259), the eddy size  $l$  is roughly equal to  $2\pi/k$ . Peaks in the spectrum show which size eddies contribute the most to the turbulence kinetic energy. As seen from Fig. 1.6, the smaller high frequency eddies are very weak. The large primary eddies, which are formed as the flow builds up, are known as macro eddies and cause large velocity fluctuations of low frequency. This eddy size is comparable to the characteristic dimensions of the flow system concerned. Large eddy motions can create shear regions, which can generate smaller eddies as a result of disruptions.<sup>32</sup> Eddies with wave numbers in the region of ( $k_e$ ) (see Fig. 1.6) contain the largest part of the energy and contribute little to energy dissipation by internal friction. However, small eddies with wave numbers in the region of ( $k_d$ ) are produced from the non-ordered diffuse

<sup>32</sup> Tennekes and Lumley ([168], p. 258) presented a different mechanism. They imagined that the smaller eddies are exposed to the strain-rate field of the larger eddies. Because of the straining, the vorticity of the smaller eddies increases, with a consequent increase in their energy at the expense of the energy of the larger eddies.

**Fig. 1.6** Energy spectrum graph, taken from Hinze ([67], p. 229). The figure is reproduced with permission of the McGraw-Hill Companies, copyright date December 13, 2013

movement of the large high energy eddies. At the smallest size eddies, this cascade of energy is dissipated into heat by molecular viscosity. Hence, a turbulent flow situation is made up of macro eddies which act as an energy reservoir, these in turn producing micro eddies in which flux energy is dissipated by internal friction.

The hypotheses of Kolmogorov allow a number of additional deductions to be formulated on the statistical characteristics of the small-scale components of turbulence. The most important of them is the *two-third-law* deduced by Kolmogorov [85]. This law states that the mean square of the difference between the velocities at two points of a turbulent flow, being a distance  $\mathbf{x}$  apart,<sup>33</sup> equals  $C(\varepsilon\mathbf{x})^{2/3}$  when  $\mathbf{x}$  lies in the inertial subrange.  $C$  is a universal model constant. Another form of this assertion (apparently first put forward by Obukhov [116, 117]) is the *five-third law*. This law states that the spectral density of the kinetic energy of turbulence over the spectrum of wave numbers,  $k$ , has the form  $C_k\varepsilon^{2/3}k^{-5/3}$  in the inertial subrange.  $C_k$  is a new model constant (see e.g., [8], Sect. 6.4).

From the experimentally determined energy spectrum we can obtain the mean turbulent energy per unit mass of fluid  $MTKE(t)$ , the turbulent energy dissipation rate per unit mass of fluid  $\epsilon(t)$ , and the integral length scale  $A_f(t)$ . That is,  $MTKE(t)$  can be expressed in terms of the energy spectrum as (e.g., [15], p. 48):

$$MTKE(t) = \int_0^{\infty} E(k, t) dk = \frac{1}{2} \overline{v'_i v'_i} \quad (1.337)$$

<sup>33</sup> Kolmogorov [84, 85] introduce the concept of *structure functions* describing processes with stationary—or homogeneous increments. By definition, the second order velocity structure function is the covariance of the difference in velocity between two points in space. A consequence of isotropy is that the structure function can be expressed in terms of a single scalar function. According to the similarity hypotheses of Kolmogorov, the scalar function can be expressed as:  $B_{dd}(x) = \delta v^2 \approx C(\varepsilon x)^{2/3}$ .  $\delta v$  is a derived velocity scale sometimes used in reactor analysis.

Likewise, one can write  $\varepsilon$  in terms of the energy spectrum as (e.g., [15], p. 51):

$$\epsilon(t) = 2\nu \int_0^{\infty} k^2 E(k, t) dk \quad (1.338)$$

and, for the integral length scale one may write (e.g., [15], p. 50; [107]; [122], p. 240):

$$\Lambda_f(t) = \frac{\frac{3\pi}{2} \int_0^{\infty} k^{-1} E(k, t) dk}{E(t)} \quad (1.339)$$

In parallel to the research on the turbulent velocity field, investigations were made concerning the local structure of the fields of passive scalars like chemical species concentrations and temperature. A thorough review of this theory is given by Baldyga and Bourne [5], so this vast theory will not be repeated in this book. Instead, this paragraph is ended by a few comments on the validity of the basic hypotheses of Kolmogorov for chemical reactor flows. It is noted that the physical basis of the Kolmogorov similarity hypotheses was questioned by Landau and Lifshitz ([93], p. 126; i.e., note that the first Russian edition of the book was apparently printed as early as in 1944). Landau's remark was concerned with the effect of fluctuations in the energy dissipation rate on the small scale properties of turbulence. It was argued that these fluctuations must depend on the Reynolds number and other mean flow parameters, thus they cannot be strictly universal. A consequence of this correction is that the two-thirds and five-third laws may retain their form, but the coefficients in these relations are not universal constants as anticipated by Kolmogorov and Obukhov. It was speculated that these factors vary as functions of the probability distribution for  $\varepsilon$  (see also [113], p. 584). Obukhov [118] and Kolmogorov [87] obviously found these remarks valid, thus some refinements of the original hypotheses concerning the local structure of turbulence were discussed. However, these model limitations have apparently not yet attracted wide attention in the chemical engineering research community as many reactor model closures still rely on the preliminary ideas of Kolmogorov.

### 1.3.3 Reynolds Equations and Statistics

In engineering practice only very simple statistics of turbulence is used based on the average (mean), the fluctuation (standard deviation) and the second moment (fluxes) taken at one point in space (i.e., one point time correlation functions). In the following we will thus present some basic statistical methods useful for determining turbulence quantities from experimental data, and show how these measurements of turbulence can be put into the statistical model framework. Usually, *this involves separating the*

*turbulent from the non-turbulent parts of the flow, followed by averaging to provide the statistical descriptor.* We will survey some of the basic methods of statistics, including the mean, variance, standard deviation, covariance, and correlation (e.g., [67], Chap. 1; [155], Chap. 2; [157]). By averaging our velocity measurements over a certain time period, we can eliminate or average out the positive and negative deviations of the turbulent velocities about the mean. Once we have the mean velocity,  $\bar{v}$ , for any time period, we can subtract it from the actual instantaneous velocity,  $v$ , to calculate the turbulent part,  $v'$ :

$$v' = v - \bar{v} \quad (1.340)$$

The velocity fluctuation represents the flow that varies with periods shorter than the averaging time period. Recall that turbulence is a 3D phenomena. Therefore, we expect that fluctuations in the  $x$ -direction might be accompanied by fluctuations in the  $y$ - and  $z$ - directions. Turbulence, by definition, is a type of motion. Yet motions frequently cause variations in the temperature and concentration fields as well, if there is some mean gradient of that variable across the turbulent domain. Hence, it is common practice to portion each of these variables into mean and turbulent parts in the same manner as for the velocity. A *mean quantity* can be defined by time, space, and ensemble averages.

The *time average* applies at one specific point in space, and consists of a sum or integral over a time period  $T$ . For any variable,  $A(t, \mathbf{r})$ , that is a function of time,  $t$ , and space,  $\mathbf{r}$ :

$$\bar{A}(\mathbf{r}) = \frac{1}{N} \sum_{i=0}^{N-1} A(i, \mathbf{r}) \quad (1.341)$$

or

$$\bar{A}(\mathbf{r}) = \frac{1}{T} \int_{t=0}^T A(t, \mathbf{r}) dt \quad (1.342)$$

where  $t = i\Delta t$  for the discrete case.

The *spatial average*, which applies at some instant in time, is given by a sum or integral over the spatial domain. For example, the volume average is given by the sum or integral over the macroscopic volume  $V$ :

$$\langle A \rangle_V(t) = \frac{1}{N} \sum_{j=0}^{N-1} A(t, j) \quad (1.343)$$

or

$$\langle A \rangle_V(t) = \frac{1}{V} \int_{V=0}^V A(t, V) dv \quad (1.344)$$

where  $V = j\Delta V$  for the discrete case.

An *ensemble average* consists of the sum over  $N$  identical experiments:

$$\langle A \rangle_e(t, \mathbf{r}) = \frac{1}{N} \sum_{n=0}^{N-1} A_n(t, \mathbf{r}) \quad (1.345)$$

or

$$\langle A \rangle_e(t, \mathbf{r}) = \int_{\varepsilon} A(t, \mathbf{r}; \mu) p(\mu) d\mu \quad (1.346)$$

In the definitions above,  $\Delta t = T/N$  and  $\Delta V = V/N$ , where  $N$  is the number of data points.  $p(\mu)d\mu$  denotes the probability of observing  $\mu$  in the interval  $d\mu$ , where  $\mu$  is some realization and  $\varepsilon$  is all realizations of the ensemble.

In principle, for laboratory experiments the ensemble average is the most desirable because it allows us to reduce random experimental errors by repeating the basic experiment. However, we often have problems performing repeatable experiments in a operating process equipments and the physical interpretation of the experimental data is complicated. Spatial averages are possible by deploying an array of sensors covering a line, area, or volume. If the turbulence is *homogeneous* (i.e., statistically the same at every point in space) then each of the sensors in the array will be measuring the same phenomenon, making a spatial average meaningful. Most practical flow situations are rarely homogeneous meaning that most spatial means are averaged over a variety of different phenomena. By proper choice of sensor array domain size as well as intra-array spacing, one can sometimes isolate scales of phenomena for study, while averaging out the other scales. Volume averaging is impossible using point measurements such as thermometers because of the difficulty of deploying these sensors at all locations within the grid volumes of finite extent. However, sensors that can scan volumes of the flow making proper volume averages of selected variables are available [157]. On the other hand, such measurements are difficult to perform due to enormous storage requirements. Area averaging is somewhat easier to perform within small area domains, but still proper measurements may be difficult to perform. Line averages are similarly performed by erecting sensors along one direction only. Time averages are frequently used, and are computed from sensors mounted on a single fixed location site. The relative ease of making observations at a fixed point have made this technique the most popular one for practical applications. For turbulence that is both homogeneous and stationary (statistically not changing over time), the time, space and ensemble averages should all be equal. This is called *the ergodic condition*, which is sometimes assumed to make the turbulence problem more tractable.

Using Reynolds decomposition the instantaneous quantities in the instantaneous equation are considered as sums of the mean (averaged) and fluctuating components. Substituting the instantaneous quantities with their decomposed sum and averaging, yields the averaged equations. The resulting time averaged equation will, in addition to proper means, contain unknown non-linear averaged terms which have to be mod-

eled separately. These models are very often of semi-empirical nature and need to be validated. Experimental measurements describing the detailed characteristics of the flow pattern including statistical data analysis is thus of vital importance. On the other hand, statistical descriptors such as the variance, covariance, standard deviation and turbulence intensity are of limited usefulness unless we can physically interpret them.

The *variance*,  $\sigma_A^2$ , is a statistical measure of the dispersion of data about the mean defined by:

$$\sigma_A^2 = \frac{1}{N} \sum_{i=0}^{N-1} (A_i - \bar{A})^2 \quad (1.347)$$

This is known as the biased variance. It is a good measure of the dispersion of a sample of a flow variable, but according to the statistical definition not the best measure of the dispersion of the whole population of possible observations. A better estimate of the variance (an unbiased variance) of the population, given a sample of data, is:

$$\sigma_A^2 = \frac{1}{N-1} \sum_{i=0}^{N-1} (A_i - \bar{A})^2 \quad (1.348)$$

When  $N$  is large  $1/N \approx 1/(N-1)$ , and as a result the biased definition is often used for convenience. Recall that the turbulent part of the turbulent variable is given by  $a' = A - \bar{A}$ . Substituting this into the biased definition of variances and comparing the result with the definition of averages gives:

$$\sigma_A^2 = \frac{1}{N} \sum_{i=0}^{N-1} a_i'^2 = \overline{a'^2} \quad (1.349)$$

Thus, whenever we encounter the average of the square of a turbulent part of a variable, such as  $\overline{v_x'^2}$ ,  $\overline{v_y'^2}$ ,  $\overline{v_z'^2}$ , we can interpret these as variances.

The *standard deviation* is defined as the squared root of the variance:

$$\sigma_A = (\overline{a_i'^2})^{1/2} \quad (1.350)$$

The standard deviation (or root-mean-square, rms, amplitude) always has the same dimensions as the original variable. It can be interpreted as a measure of the magnitude of the spread or dispersion of the original data from its mean. For this reason, it is used as a measure of the intensity of turbulence.

The turbulence intensity is expected to increase as the mean velocity  $\bar{v}_x$  increases, hence a dimensionless measure of the turbulence intensity,  $I$ , is often defined as:

$$I_x = \frac{\sigma_{v_x}}{\bar{v}_x} \quad (1.351)$$

$$I_y = \frac{\sigma_{v_y}}{\overline{v_y}} \quad (1.352)$$

$$I_x = \frac{\sigma_{v_z}}{\overline{v_z}} \quad (1.353)$$

In statistics, *the covariance* between two variables is defined as:

$$\text{covar}(A, B) = \frac{1}{N} \sum_{i=0}^{N-1} (A_i - \bar{A})(B_i - \bar{B}) \quad (1.354)$$

Using the Reynolds averaging methods, we can show that:

$$\text{covar}(A, B) = \frac{1}{N} \sum_{i=0}^{N-1} a'_i b'_i = \overline{a'b'} \quad (1.355)$$

Thus the non-linear turbulence products that were introduced by the averaging process applied to the governing equations have the same meaning as covariances. The covariance indicates the degree of common relationship between the two variables,  $A$  and  $B$ . For example, let  $A$  represent air temperature,  $T$ , and let  $B$  be the vertical velocity,  $v_z$ . In the earth's atmosphere, we might expect the warmer than average air to rise (positive  $T'$  and positive  $v'_z$ ), and the cooler than average air to sink (negative  $T'$  and negative  $v'_z$ ). Thus, the product  $v'_z T'$  will be positive on the average, indicating that  $v_z$  and  $T$  vary together.

Sometimes, one is interested in a normalized covariance. Such a relationship is defined as *the linear correlation coefficient*,  $r_{AB}$ :

$$r_{AB} = \frac{\overline{a'b'}}{\sigma_A \sigma_B} \quad (1.356)$$

This variable ranges between  $-1$  and  $+1$  by definition. Two variables that are perfectly correlated (i.e., vary together) yield  $r = 1$ . Two variables that are perfectly negatively correlated (i.e., vary oppositely) yield  $r = -1$ . Variables with no net variation together yield  $r = 0$ .

The definition of kinetic energy per unit volume is  $\rho \mathbf{v}^2/2$ , whereas the kinetic energy per unit mass is just  $\mathbf{v}^2/2$ . It is common to partition the kinetic energy of the flow into a portion associated with the mean velocity,  $\bar{\mathbf{v}}^2/2$ , and a portion associated with the turbulence,  $\mathbf{v}'^2/2$ . We can thus write the relations:

$$\text{Kinetic Energy of the Mean flow} = \frac{1}{2}(\bar{v}_x^2 + \bar{v}_y^2 + \bar{v}_z^2) \quad (1.357)$$

$$\text{Mean Turbulent Kinetic Energy} = k = \frac{1}{2}(\overline{v_x'^2} + \overline{v_y'^2} + \overline{v_z'^2}) \quad (1.358)$$

### 1.3.4 Semi-Empirical Flow Analysis

In industrial reaction engineering the simplest reactors are designed like tubes or pipes, and even the more complex reactor designs are often idealized as tubes to ease the modeling complexity. Therefore, before we proceed on the CFD related modeling issues the idealized or approximate engineering pipe velocity formulas are given as they are still very useful for simple hand calculations.

#### 1.3.4.1 Engineering Pipe Flow Design Formulas

From the introductory courses in fluid flow one recalls that the simple parabolic profile for laminar flow in a pipe, *the Hagen-Poiseuille law*, is derived by integration of a sufficiently simplified form of the generalized momentum equation (see e.g., [13], Example 3.6.1):

$$\frac{v_z(r)}{v_{z,\max}} = 1 - \left(\frac{r}{R}\right)^2 \quad (1.359)$$

where the maximum velocity at  $r = 0$  can be calculated from the cross-sectional averaged velocity,  $v_{z,\max} = 2\langle v_z \rangle_A$ . Unfortunately, it is not possible to derive an analogue velocity profile for turbulent flow in an analytical manner based on the generalized momentum equations. However, a number of entirely empirical relations of similar simplicity exist for the velocity profile in turbulent pipe flow. One such relation often found in introductory textbooks on engineering fluid flow is the *power law velocity profile*:

$$\frac{\bar{v}_z(r)}{\bar{v}_{z,\max}} = \left(1 - \frac{r}{R}\right)^{1/7} \quad (1.360)$$

where  $\bar{v}_{z,\max}$  is the velocity at the centerline of the pipe (i.e., the centerline velocities are not the same in the two flow regimes).

The latter relation is often used as a reasonable approximation for turbulent pipe flows in engineering practice. That is, for fully developed turbulent flows this relation provides a reasonable approximation to the measured velocity profiles across most of the pipe radius. However, a brief examination of this relation shows that the power-law profile cannot be valid near the wall, since according to this equation the velocity gradient is infinite there. In addition, the simple relation cannot be precisely valid near the centerline because it does not give:  $\frac{d\bar{v}_z}{dr} = 0$  for  $r = 0$ .

The purpose of performing CFD model simulations is to obtain more accurate predictions of the flow fields, thus precise boundary conditions are needed. From the previous discussion it is rather obvious that for CFD reactor simulations the empirical turbulent velocity profile formula for simple pipes is not very useful providing accurate boundary conditions at reactor walls. In the following subsections we thus consider the Prandtl mixing-length model and a more advanced concept for analyzing simple wall shear flows, i.e., exemplified through a fully developed shear flow past

a flat plate, where the mean velocity vector is assumed to be parallel to the wall. This simple flow is of practical importance and has played a prominent role in the historical development of the study of turbulent wall flows. The important step forward using this concept is that the boundary layer approach provides a local description of the flow structure in the vicinity of solid walls. That is, the model is apparently generic and valid on local scales for most turbulent solid wall flows.

### 1.3.4.2 Prandtl's Mixing-Length Model

The mixing-length model of Prandtl [124] for flow near a solid boundary is based on an analogy between the chaotic motion of eddies and the random motion of molecules in dilute gases (kinetic theory). In Cartesian coordinates the Reynolds shear stress  $\rho v'_x v'_y$  represents a flux of  $x$ -momentum in the direction of  $y$ . Prandtl assumed that this momentum was transported by discrete lumps of fluid, which moved in the  $y$  direction over a distance  $l$  without interaction conserving the momentum and then mixed with the existing fluid at the new location. The mixing length,  $l$ , is supposed to be a variable analogous to the mean free path of kinetic theory in this process. Prandtl's model derivation can then be briefly sketched, introducing the Boussinesq [19, 20] approximation for the turbulent viscosity. Starting out with the simple kinetic theory relation that the molecular viscosity equals the molecular velocity times the mean free path, an analogous relation can be formulated for the turbulent viscosity in terms of the turbulent mixing length and a suitable velocity scale,  $\nu_t \approx l v'_x$ . The Prandtl velocity scale yields:

$$v'_x = l \left| \frac{d\bar{v}_x}{dy} \right| \quad (1.361)$$

Supported by experimental observations,  $v'_y$  is assumed to be of the same order of magnitude as  $v'_x$  in the constant stress layer near a solid boundary. Hence, we may define Prandtl's mixing length model as:

$$\overline{\rho v'_x v'_y} \approx -\mu_t \frac{d\bar{v}_x}{dy} \approx -\rho l^2 \left( \frac{d\bar{v}_x}{dy} \right)^2 \quad (1.362)$$

In the inner part of the boundary layer  $l$  is often estimated by  $l = \kappa y$  (e.g., [67]), where  $\kappa$  is known as the von Kàrmàn constant. This relation has been used successfully for many boundary layer flows. However, it is today generally accepted that the physical equivalence between the turbulent mixing length and the molecular mean free path is completely erroneous. The turbulent eddies are not small compared to the width of the mean flow, and they interact continuously rather than collide instantaneously. This model limitation was already recognized by Taylor [158]. The mixing length model of Prandtl [124] is further discussed by McComb ([107], Sect. 1.5.2), Hinze ([67], Sect. 5.2), Sideman and Pinczewski [147], Schlichting and Gersten ([140], Sect. 17.1.4) and Pope ([122], Sect. 7.1.7).

### 1.3.4.3 Velocity Distribution in Turbulent Boundary Layers

Originally, the concept of *fluid boundary layer* was presented by Prandtl [123]. Prandtl's idea was that for flow next to a solid boundary a thin fluid layer (i.e., a boundary layer) develops in which friction is very important, but outside this layer the fluid behaves very much like a frictionless fluid. To define a demarcation line between these two flow regions the thickness of the boundary layer,  $\delta$ , is arbitrarily taken as the distance away from the surface where the velocity reaches 99 % of the free stream velocity (e.g., [55], p. 192; [107], p. 12; [114], p. 545). To proceed giving a thorough description of the equations used for turbulent flows, we need some results from the semi-empirical turbulent boundary layer flow analysis. For a generalized shear flow in the vicinity of a flat horizontal solid wall, the boundary layer flow can be described in Cartesian coordinates. The stress,  $-\bar{\sigma}_{xy,\text{eff}}$ , associated with direction  $y$  normal to the wall is apparently dominant, thus the stream-wise Reynolds averaged momentum equation yields:

$$\rho \frac{D\bar{v}_x}{Dt} \approx -\frac{\partial \bar{p}}{\partial x} - \frac{\bar{\sigma}_{xy,\text{eff}}}{\partial y} \quad (1.363)$$

where

$$\bar{\sigma}_{xy,\text{eff}} = -\mu \frac{\partial \bar{v}_x}{\partial y} + \overline{\rho v'_x v'_y} \quad (1.364)$$

Intuitively one could imagine that the boundary layer as a whole can be characterized in terms of the boundary layer thickness and related dimensionless groups. However, experimental data reveals that the laminar shear is dominant near the wall (i.e., in *the inner wall layer*), and turbulent shear dominates in *the outer wall layer*. There is also an intermediate region, called *the overlap wall region*, where both laminar and turbulent shear are important.

Consequently, Prandtl [124] postulated that, at high Reynolds numbers, close to the wall ( $y/\delta \ll 1$ ) there is an inner layer in which the mean velocity profile is determined by the viscous scales, independent of  $\delta$  and the free stream velocity,  $\bar{v}_x(y = \delta)$ . Since ample experimental analyzes support the Prandtl hypothesis, it is evident that close to the wall the viscosity,  $\nu$ , and the wall shear stress,  $\sigma_W$ , are important parameters. From these quantities one can define viscous scales that are appropriate velocity scales and length scales in the near-wall region. Dimensional analysis confirmed by experiments indicates that the relevant velocity scale for the inner region is *the friction velocity*,<sup>34</sup> given by:

---

<sup>34</sup> In most textbooks the friction velocity is defined as  $v_* = \sqrt{\frac{\bar{\sigma}_W}{\rho}}$ , where  $\bar{\sigma}_W \approx \bar{\sigma}_{xy} + \bar{\sigma}_{xy}^t = \rho \nu \frac{d\bar{v}_x}{dy} - \overline{\rho v'_x v'_y}$ . However, due to the sign convention adopted in this book for the shear stresses, a negative sign has to be introduced in front of the wall stress variable.

$$v_* = \sqrt{\frac{-\bar{\sigma}_W}{\rho}} \quad (1.365)$$

The corresponding length scale characterizing the inner layer, the viscous length scale, is defined as

$$\delta_v = \nu \sqrt{\frac{\rho}{-\bar{\sigma}_W}} = \frac{\nu}{v_*} \quad (1.366)$$

Two local Reynolds numbers can thus be formed based on the characteristic velocity and length scales for the boundary layer. One Reynolds number purely based on the viscous scales of the inner layer,  $v_*\delta_v/\nu$ , is identically unity, and the alternative dimensionless group called *the friction Reynolds number* is defined using scales reflecting both the inner and outer layers,  $\frac{v_*\delta}{\nu} = \frac{\delta}{\delta_v}$ . The distance from the wall measured in viscous lengths, or wall units, can be denoted by:

$$y^+ = \frac{y}{\delta_v} = \frac{yv_*}{\nu} \quad (1.367)$$

Notice that  $y^+$  is very similar to the two local Reynolds numbers just defined for the boundary layer, thus the magnitude of this dimensionless length variable is sometimes interpreted as a kind of Reynolds number.

Subsequent experimental validation lead to additional partitioning of the inner constant stress layer according to the relative magnitude of the viscous and turbulent components of the total shear stress. The total shear stress takes the form:

$$\bar{\sigma}_{xy}^{\text{eff}} = \bar{\sigma}_{xy} + \bar{\sigma}_{xy}^t = -\rho\nu \frac{d\bar{v}_x}{dy} + \overline{\rho v'_x v'_y} \approx \bar{\sigma}_W \quad (1.368)$$

where the viscous part is given by Newton's law applied to the mean rate of strain and the turbulent contribution is just the corresponding component of the Reynolds stress tensor. At the wall, the boundary condition for the instantaneous velocity vector,  $\mathbf{v}(\mathbf{r}, t) = 0$ , dictates that all the Reynolds stresses vanish. Consequently, the wall shear stress is entirely due to the viscous contribution:

$$\bar{\sigma}_W = -\rho\nu \left[ \frac{d\bar{v}_x}{dy} \right]_{y=0} \quad (1.369)$$

The *viscous sub-layer* is defined as the region next to the wall where the first term on the RHS of (1.368) is dominant. For larger values of  $y$ , the second term on the RHS of (1.368) will become dominant, and this region is usually referred to as the the inertial—or *turbulent log-law sub-layer*. Evidently there will be an intermediate region where the two stresses will be of equal magnitude, and this transition sub-layer is called *the buffer layer*. This boundary layer theory is based on the assumption that the effective shear stress is constant throughout the inner layer.

### 1.3.4.4 Viscous Sub-Layer Analysis

In the viscous sub-layer, the total shear stress is determined by the viscous shear contribution:

$$-\frac{\bar{\sigma}_{xy}^{\text{eff}}}{\rho} \approx -\frac{\bar{\sigma}_W}{\rho} = \nu \frac{d\bar{v}_x}{dy} \quad (1.370)$$

for  $y^+ < 5$ .

Since this relation is universal (e.g., [108]), it is convenient to introduce a non-dimensional function,  $\Phi_v(\frac{y}{\delta_v})$ , thus:

$$\frac{d\bar{v}_x}{dy} = \frac{v_*}{y} \frac{y v_*}{\nu} = \frac{v_*}{y} \Phi_v\left(\frac{y}{\delta_v}\right) \quad (1.371)$$

Integrating with respect to  $y$ , we get:

$$\bar{v}_x = \frac{u_*^2 y}{\nu} \quad (1.372)$$

or in the scaled variables  $y^+ = y/\delta_v$  and  $v^+(y^+) = \bar{v}_x/v_*$ , it yields:

$$v^+ = y^+ \quad (1.373)$$

where the constant of integration has been set equal to zero in order to satisfy the boundary condition,  $\bar{v}_x(y=0) = 0$ .

### 1.3.4.5 Turbulent Log-Law Sub-Layer Analysis

At some further distance from the wall, in the turbulent log-law sub-layer, we may neglect the viscous term, and the total stress tensor reduces to:

$$\frac{\bar{\sigma}_{xy}^{\text{eff}}}{\rho} \approx \frac{\bar{\sigma}_W}{\rho} \approx \overline{v'_x v'_y} \quad (1.374)$$

By use of the Prandtl mixing-length model and the relation  $l \approx \kappa y$  [124], yields:

$$\frac{\bar{\sigma}_{xy}^{\text{eff}}}{\rho} \approx \frac{\bar{\sigma}_W}{\rho} \approx \overline{v'_x v'_y} \approx -l^2 \left(\frac{d\bar{v}_x}{dy}\right)^2 \approx -\kappa^2 y^2 \left(\frac{d\bar{v}_x}{dy}\right)^2 \quad (1.375)$$

Hence, by introducing the definition of the friction velocity we obtain:

$$u_*^2 \approx \kappa^2 y^2 \left(\frac{d\bar{v}_x}{dy}\right)^2 \quad (1.376)$$

The velocity gradient can thus be expressed in terms of a non-dimensional function analogous to the one defined for the viscous sub-layer (e.g., [108]),  $\Phi_I(\frac{y}{\delta_v})$ , hence:

$$\frac{d\bar{v}_x}{dy} = \frac{v_*}{y} \frac{1}{\kappa} = \frac{v_*}{y} \Phi_I\left(\frac{y}{\delta_v}\right) \quad (1.377)$$

or in the scaled variables:

$$\frac{dv^+}{dy^+} = \frac{1}{\kappa y^+} \quad (1.378)$$

Finally, integrating with respect to  $y^+$ , we obtain a logarithmic velocity profile:

$$v^+ = \frac{1}{\kappa} \ln y^+ + B \quad (1.379)$$

where  $B$  is a constant of integration. The two parameters in this relation are fitted to experimental velocity data obtained from pipe flow analyzes. However, the values of the constants,  $\kappa$ , and,  $B$ , vary slightly from one literature source to another probably reflecting the experimental accuracy of the analyzes. In most papers on reactor modeling the values  $\kappa = 0.40$  and  $B = 5.5$  are preferred.

A further limitation is that this logarithmic relation is only valid for smooth surfaces. That is, for flow situations where the height of any roughness element on the wall is less than the thickness of the viscous sub-layer. Contrary, if the roughness height is greater than the sub-layer thickness, the roughness height itself determines the inner region length scale. The latter approach is regularly applied in atmospheric weather forecast models (e.g., [22, 41, 76]). For the inner region of the boundary layer, the mean velocity formulas for smooth surfaces can be generalized and expressed in a universal form:

$$v^+ = f(y^+) \quad (1.380)$$

which is known as *the law of the wall*, sketched in Fig 1.7.

### 1.3.4.6 Outer Layer Analysis

von Kàrmàn [176] deduced that in the outer layer the velocity gradient actually depends on the thickness of the boundary layer as a whole. Hence, based on dimensional arguments this implies that the velocity gradient can be expressed in terms of a non-dimensional function similar to those used for the viscous sub-layers [108]:

$$\frac{d\bar{v}_x}{dy} = \frac{v_*}{y} \Phi_o\left(\frac{y}{\delta}\right) \quad (1.381)$$

where the appropriate lengthscale has been introduced.

**Fig. 1.7** The law of the wall, taken from Tennekes and Lumley ([168], p. 160). In this figure the  $U$  and  $u_*$  variables correspond to the  $\bar{v}_x$  and  $v_*$  variables used in the present text. Reprinted with permission of the MIT Press

Integrating this equation between  $y$  and  $\delta$  yields the *velocity-defect law* for the outer layer. This, of course, requires that the non-universal non-dimensional function,  $\Phi_o$ , is known.

This function, at present being unknown, can be determined as we notice that the semi-empirical relations for the inner- and outer layers are different in form, but they must overlap smoothly in the intermediate layer. Mathematically, this implies that the dimensionless functions, i.e.,  $\Phi_I(\frac{y}{\delta_v})$  and  $\Phi_o(\frac{y}{\delta})$ , should approach the same asymptotic value in the overlap region (e.g., [108]; [122], p. 275). The velocity gradient can thus be expressed in both sets of scales:

$$\frac{y}{v_*} \frac{d\bar{v}_x}{dy} = \Phi_I\left(\frac{y}{\delta_v}\right) = \Phi_o\left(\frac{y}{\delta}\right) = \frac{1}{\kappa} \approx 2.4 \quad (1.382)$$

This relation establishes the form of the velocity-defect law for small  $y/\delta$ , and indicates that the log-law can give reasonable predictions also for relatively large values of  $y^+$  provided that the overlap region has a significant width.

In summary, experimental data indicates that the turbulent boundary layer can be subdivided into an inner constant wall stress layer for the approximate range

$0 \leq y \leq 0.1\delta$ , and an outer non-constant stress layer bounded by  $0.1\delta < y \leq \delta$  [122, 138].

The inner layer is further classified as:

1. Viscous sub-layer:  $0 \leq y^+ \leq 5$
2. Transition sub-layer:  $5 < y^+ \leq 30$
3. Turbulent constant stress layer:  $30 < y^+ \leq 400$

The values used for  $\delta$  and  $y^+$  to classify the various layers may vary from one literature source to another. These discrepancies reflect the experimental accuracy obtained determining the boundaries between the various layers. A common simplification adopted in many engineering CFD calculations is to neglect the influence of the deviating physics occurring in the buffer-layer. The inner part of the boundary layer is thus roughly subdivided into two more approximate sub-layers only, those are a viscous—and a turbulent sub-layer. The two sub-layers are separated at a certain distance from the wall  $y^+ = 11.63$  where the linear velocity profile in the viscous sub-layer meets the logarithmic velocity profile in the turbulent constant stress layer. For shorter distances from the wall ( $y^+ < 11.63$ ) the flow is assumed to be purely viscous and at larger distances from the wall ( $y^+ \geq 11.63$ ) the flow is purely turbulent. The semi-empirical boundary layer analyzes of Prandtl [124] and von Kàrmàn [176] are further discussed by [67], Sect. 7.5; [107], Sect. 1.4.2; [108]; [122], Sect. 7; [140], Sect. 17.

### 1.3.5 Reynolds Averaged Models

Reynolds [128] postulated that the Navier-Stokes equations are still valid for turbulent flows, but recognized that these equations could not be applied directly due to the complexity and irregularity of the fluid dynamic variables. A true description of these flows at all points in time and space was not feasible, and probably not very useful at the time. Instead, Reynolds proposed to develop equations governing the mean quantities that were actually measurable. To reformulate the governing equations in terms of mean flow quantities rather than instantaneous quantities, Reynolds postulated the fundamental ideas of averaging.

In the averaging procedure devised by Reynolds [128] the instantaneous quantities are decomposed<sup>35</sup> into the sum of mean and fluctuating quantities. The mean quantities were defined by time-averaging the instantaneous quantities over a sufficient

---

<sup>35</sup> Note that the turbulent viscosity parameter has an empirical origin. In connection with a qualitative analysis of pressure drop measurements Boussinesq [19] introduced some apparent internal friction forces, which were assumed to be proportional to the strain rate ([20], p. 8), to fit the data. To explain these observations Boussinesq proceeded to derive the same basic equations of motion as had others before him, but he specifically considered the molecular viscosity coefficient to be a function of the state of flow and not only on the system properties [136]. It follows that the turbulent viscosity concept (frequently referred to as the Boussinesq hypothesis in the CFD literature) represents an empirical first attempt to account for turbulence effects by increasing the viscosity coefficient in

time period ( $\Delta t$ ), i.e., being long enough to smooth out the turbulent fluctuations, separating the turbulent parts from the non-turbulent parts. Introducing a generalized instantaneous quantity,  $\psi$ , the corresponding time average quantity is defined by:

$$\bar{\psi} = \frac{1}{\Delta t} \int_t^{t+\Delta t} \psi(t) dt \quad (1.383)$$

It has been shown that the averaging procedure is valid for statistically stationary variables only, thus the time average should be independent of the origin  $t$ . Apparently, the conventional Reynolds averaging procedure requires that the transients in the governing equations should be negligibly small (e.g., [67], p. 6; [168], p. 28).

After the mean quantities have been obtained, the fluctuations can be obtained by subtracting the mean values from the corresponding instantaneous ones. The mean of a fluctuating quantity is zero by definition:

$$\overline{\psi'} = \frac{1}{\Delta t} \int_t^{t+\Delta t} (\psi(t) - \bar{\psi}) dt \equiv 0 \quad (1.384)$$

In the averaging procedure devised by Reynolds not only single quantities are considered, but also products of quantities constituting the governing equations.

Let  $A = \bar{A} + a'$  and  $B = \bar{B} + b'$  be two instantaneous variables, and let  $c$  represent a constant. Accordingly, the Reynolds [128] axioms or mathematical rules of averaging can be expressed as:

$$\begin{aligned} \bar{c} &= c \\ \overline{\bar{A}} &= \bar{A} \\ \overline{\bar{A}\bar{B}} &= \bar{A}\bar{B} \\ \overline{a'} &= 0 \\ \overline{\bar{A} + a'} &= \bar{\bar{A}} + \overline{a'} = \bar{A} \\ \overline{cA} &= \overline{c\bar{A} + a'} = c\bar{A} \\ \overline{b'} &= 0 \\ \overline{\bar{A}B} &= \overline{\bar{A}(\bar{B} + b')} = \bar{A}\bar{B} \\ \overline{A + B} &= \overline{\bar{A} + a' + \bar{B} + b'} = \bar{A} + \bar{B} \end{aligned} \quad (1.385)$$

---

(Footnote 35 continued)

an empirical manner fitting experimental data. Moreover, at the time Boussinesq [19, 20] was apparently not aware of the Reynolds averaging procedure that was published 18 years after the first report by Boussinesq [19] on the apparent viscosity parameter.

$$\frac{d\overline{A}}{dt} = \frac{d\overline{A}}{dt}$$

$$\overline{AB} = \overline{(\overline{A} + a')(\overline{B} + b')} = \overline{\overline{A}\overline{B}} + \overline{\overline{A}b'} + \overline{\overline{B}a'} + \overline{a'b'} = \overline{\overline{A}\overline{B}} + \overline{a'b'}$$

Turbulence is a 3D phenomenon, thus it is expected that turbulence in one dimension might be accompanied by similar effects in the other two directions. In addition, as mentioned above, the turbulent motions frequently cause variations in the other quantities too. Hence, all the dependent variables defining the system can be partitioned into mean and turbulent parts. Lately, a few alternative interpretations and extensions of the conventional Reynolds averaging procedure are given in the literature. A least two of these deviants deserve to be mentioned, as they are used frequently although not necessarily in reactor modeling. The desire to make practical calculations of statistically non-stationary flows has led engineers to formulate semi-empirical extensions of the conventional method. In this case the instantaneous variables are said to be time averaged over a time interval which is large compared to the turbulent time scales, but still small compared to the time dependency of the mean component. Using this averaging procedure one should be aware of the problem of interpreting the simulated results, as the spectral split between the mean and turbulent contributions becomes rather vague and apparently related to both the time interval of averaging and the resolution of the numerical solution method.

An alternative interpretation of the Reynolds averaging procedure is regularly used in meteorology developing weather forecast models. The physical basis for this approach is neat and intuitive [155]. In boundary layer meteorology experimental analyzes show that a spectral energy gap is evident. This spectral gap provides a means to separate the turbulent from the non-turbulent scales of motion. By time-averaging the instantaneous quantities over a time period that corresponds to the spectral gap scales, the turbulent effects are eliminated from the mean. The turbulent part of the flow varies with periods shorter than the ones corresponding to the spectral gap scales, whereas the mean represents the part that varies with longer periods. These turbulence analyzes thus rely on the separation of scales enabling proper partitioning of the flow into the mean and turbulent parts. On physical reasons many of the operational numerical weather forecast models use grid resolutions or wavelength cutoffs that fall within the spectral gap. This means that larger scale motions can be explicitly resolved, whereas the smaller scale turbulent motions are modeled directly. That is, the effects of the sub-grid scale motions on the larger scales are parameterized by sub-grid scale statistical models. In one interpretation this averaging procedure is analogous to the filtering procedure used in the LES method as the averaging operator used is generic for time-, space- and ensemble averages. Unfortunately, for many practical flows one might not be able to obtain any vivid separation of scales, averaging the variables over a finite time period. Then the decomposition procedure may break down, and the simulated results may become inaccurate and difficult to interpret. Stull ([155], Sect. 2.4) and McComb ([107], app B) discuss the statistical basis of the averaging procedures in further details. However, while the convectional process of averaging the equations can be considered an exact proce-

ture, the resulting averaged equations do not contain enough information about the turbulence to form a solvable set of equations. The statistical studies of the equations always lead to a situation in which there are more unknowns than equations. This is called *the closure problem* of turbulence theory. One has to make ad hoc assumptions to make the number of equations equal to the number of unknowns. The process of replacing the unknown averages or covariances, occurring in the governing equations after the equations have been averaged, with equations for variables which can be considered as dependent variables in the problem is called *turbulence modeling*. The resulting equations are termed a turbulence model. The turbulence model can be either an algebraic relation or a set of transport equations for some characteristic turbulent quantities. The various models are often classified according to the number of extra partial differential equations which are considered in addition to the Reynolds-averaged Navier-Stokes equations. That is, the zero-, one-, and two-equation models, as well as Reynolds Stress Models.

All the average model formulations, except the Reynolds Stress Model, are based on the eddy viscosity hypothesis in what is often known as *the generalized Boussinesq hypothesis* [19, 20]:

$$\overline{v'_i v'_j} = \frac{2}{3} k \delta_{ij} - \nu_t \left( \frac{\partial \bar{v}_i}{\partial x_j} + \frac{\partial \bar{v}_j}{\partial x_i} \right) \quad (1.386)$$

where  $\delta_{ij}$  is the Kronecker delta and  $\nu_t$  is the eddy viscosity variable. The first term on the RHS is required as the sum of the normal stresses has to be consistent with the definition of  $k$ .

By formulating a proper turbulence model, the total number of equations involved equals the number of unknown variables, and a closed set of model equations is obtained. That is, adopting the eddy viscosity hypothesis we basically need to find proper expressions estimating the eddy viscosity variable. If the term containing the turbulent normal stresses is not neglected in Eq. (1.386), we need to determine the  $k$  variable too. The complexity of such model formulations may vary a lot, thus only a few of the most popular ones will be described below. In multiphase reactor simulations the zero- and two equation models are very popular, only a few attempts have been made to implement Reynolds Stress Models, and LES models are still really rare.

### 1.3.5.1 Zero-Equation Models

Turbulence models containing the partial differential equations for the mean variable fields, and no differential equations for the turbulence are classified as *the zero-equation models*. All models belonging to this class is based on the eddy-viscosity concept. The eddy-viscosity is furthermore related to the mean flow field via an algebraic relation. Therefore, these models are also called algebraic models. Because of their simplicity, zero-equation models have received considerable interest over the years, and have been in common use for sophisticated engineering applications during the last decades. The very simplest approximation of the turbulent effects on

the mean flow can be achieved by assuming that the eddy-viscosity is proportional to the molecular viscosity:

$$\nu_t = f\nu \quad (1.387)$$

throughout the flow field. The dimensionless constant  $f$  is typically of the order 1000.

The mixing-length model of Prandtl [124] for flow near a solid boundary, i.e., that have been referred several times already, is perhaps the most popular zero-equation model.

### 1.3.5.2 Reynolds Stress Models

Stull [155] presents an excellent review of the procedures for formulating transport equations for the turbulent fluxes and variances applied to boundary layer meteorology. Wilcox [185], Pope [122] and Biswas and Eswaran [15] provide alternative texts intended for the engineering community, the latter textbook also considers experimental aspects of the field. Chou [23] was the first to derive and publish the generalized transport equation for the Reynolds stresses. The exact transport equation for the Reynolds stresses was established by use of the momentum equation, the continuity equation and a moderate amount of algebra.

Because the upcoming derivations are sometimes long and involved, it is easy *to lose sight of the forest for the trees*. The following summary gives the steps that will be taken in the subsequent subjects. to develop the governing equations in a form suitable for describing turbulent flows:

1. Apply the Reynolds decomposition procedure and expand the dependent variables within the instantaneous equations into mean and fluctuating parts.
2. Apply the time- or ensemble averaging procedure to get the equations for the mean variables describing turbulent flows.
3. Subtract the equations of step 2 from the corresponding ones of step 1 to get equations for the turbulent fluctuations.
4. Multiply the result of step 3 by other turbulent quantities and time- or ensemble average to yield the transport equations for turbulence statistics such as the Reynolds stresses and the turbulent kinetic energy.
5. Finally, formulate the transport equations for the other turbulent fluxes and variances (i.e., sometimes called turbulent correlations).

The conventional Reynolds averaging procedure is deduced from the governing equations for incompressible fluid systems. In Cartesian coordinates the corresponding instantaneous equation of continuity takes the following form (i.e., written in a compact form by use Einstein's summation notation):

$$\frac{\partial v_i(t, \mathbf{r})}{\partial x_i} = 0 \quad (1.388)$$

where  $v_i(t, \mathbf{r})$  is the fluid velocity at space position  $\mathbf{r}$  and time  $t$ .

For an incompressible fluid, the instantaneous equation expressing conservation of momentum is:

$$\frac{\partial v_i}{\partial t} + \frac{\partial v_j v_i}{\partial x_j} = -\frac{1}{\rho} \frac{\partial p}{\partial x_i} - \frac{1}{\rho} \frac{\partial \sigma_{ij}}{\partial x_j} \quad (1.389)$$

where  $\sigma_{ij}$  is the deviatoric stress tensor.

For an incompressible Newtonian fluid,  $\sigma_{ij}$  is given by:

$$\sigma_{ij} = -\rho\nu \left( \frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i} \right) \quad (1.390)$$

where  $\nu$  is the kinematic viscosity of the fluid.

With the substitution of  $\sigma_{ij}$  from (1.390) and the use of (1.388), the resulting instantaneous equation of motion is known as the Navier-Stokes equation:

$$\frac{\partial v_i}{\partial t} + v_j \frac{\partial v_i}{\partial x_j} = -\frac{1}{\rho} \frac{\partial p}{\partial x_i} + \nu \frac{\partial^2 v_i}{\partial x_j \partial x_j} \quad (1.391)$$

By use of Reynolds averaging rules (1.385), the instantaneous continuity (1.388) can be averaged and we obtain:

$$\frac{\partial \bar{v}_i(\mathbf{r})}{\partial x_i} = 0 \quad (1.392)$$

Subtracting this result from (1.388) yields a similar equation for  $v'_i$ , thus the mean and fluctuating velocities separately satisfy the continuity equation. This is a trivial consequence of the linearity of (1.388). In order to treat the equation of motion in the same way, we apply the Reynolds decomposition procedure on the instantaneous velocity and pressure variables in (1.391) and average term by term. It can be shown by use of Leibnitz' theorem that the operation of time averaging commutes with the operation of differentiating with respect to time when the limits of integration are constant [15, 107, 122, 155].

The result is:

$$\frac{\partial \bar{v}_i}{\partial t} + \bar{v}_j \frac{\partial \bar{v}_i}{\partial x_j} + \frac{\partial \overline{v'_i v'_j}}{\partial x_j} = -\frac{1}{\rho} \frac{\partial \bar{p}}{\partial x_i} + \nu \frac{\partial^2 \bar{v}_i}{\partial x_j \partial x_j} \quad (1.393)$$

Comparison with (1.391) shows that the equation for the mean velocity is just the Navier-Stokes equation written in terms of the mean variables, but with the addition of the term involving  $\overline{v'_i v'_j}$ . Thus, the equations of mean motion involve three independent unknowns  $\bar{v}_i$ ,  $\bar{p}$  and  $\overline{v'_i v'_j}$ . This is perhaps the best known version of the closure problem. Equation (1.393) is the Reynolds equation and the term  $\overline{v'_i v'_j}$  is the Reynolds stress. This term represents the transport of momentum due to turbulent fluctuations.

Equation (1.393) for the mean velocity is formally identical to the original Navier-Stokes equation, provided that we absorb the Reynolds stress into a more general stress tensor. An effective stress tensor is thus defined by:

$$\overline{\sigma_{ij,\text{eff}}} = -\rho\nu\left(\frac{\partial\bar{v}_i}{\partial x_j} + \frac{\partial\bar{v}_j}{\partial x_i}\right) + \rho\overline{v'_i v'_j} \quad (1.394)$$

With a proper turbulence model the mean velocity is expected to be a fairly smooth function of time and position, and hence the problem of solving (1.393) should be very much simpler than the alternative direct numerical simulation task based on the primitive Navier-Stokes equation. The simplest prescription for the Reynolds stress is apparently obtained from an algebraic turbulence model like the Prandtl [124] mixing-length model. The Prandtl model is, as explained in the foregoing analysis, based on the eddy viscosity concept and thus possesses the defects of this hypothesis. In addition, it lacks universality mainly because the prescription of the mixing length varies from one type of flow to another, and thus in complicated flows it may be impossible to specify any reliable parameterization for the mixing length. The next category of turbulence closures, i.e., implying to be more accurate than the very simple algebraic models, is a hierarchy of turbulent models based on the transport equation for the fluctuating momentum field. These are the first-order closure models, i.e., those that require parameterizations for the second moments  $\overline{v'_i v'_k}$ , and the second-order closure models, i.e., those that require parameterizations for representing the third moments  $\overline{v'_i v'_j v'_k}$ . Since the Reynolds stress transport equation constitutes the basis for both the first- and second-order closure models, its derivation is presented next.

The equation of motion for the fluctuating velocity is obtained by subtracting (1.393) from (1.391):

$$\frac{\partial v'_i}{\partial t} + \bar{v}_j \frac{\partial v'_i}{\partial x_j} + v'_j \frac{\partial \bar{v}_i}{\partial x_j} + v'_j \frac{\partial v'_i}{\partial x_j} - \frac{\partial \overline{v'_i v'_j}}{\partial x_j} = -\frac{1}{\rho} \frac{\partial p'}{\partial x_i} + \nu \frac{\partial^2 v'_i}{\partial x_j \partial x_j} \quad (1.395)$$

In accordance with the equation for the fluctuating component  $v'_i$ , (1.395), a corresponding equation for the fluctuating component  $v'_k$  can be formulated simply by changing the index from  $i$  ( $x_i$ —momentum) to  $k$  ( $x_k$ —momentum) keeping all other indices and variables the same as before. The result is:

$$\frac{\partial v'_k}{\partial t} + \bar{v}_j \frac{\partial v'_k}{\partial x_j} + v'_j \frac{\partial \bar{v}_k}{\partial x_j} + v'_j \frac{\partial v'_k}{\partial x_j} - \frac{\partial \overline{v'_k v'_j}}{\partial x_j} = -\frac{1}{\rho} \frac{\partial p'}{\partial x_k} + \nu \frac{\partial^2 v'_k}{\partial x_j \partial x_j} \quad (1.396)$$

Multiply (1.395) for the component  $i$  through with the fluctuating velocity  $v'_k$ , and time average yields:

$$\overline{v'_k \frac{\partial v'_i}{\partial t}} + \bar{v}_j \overline{v'_k \frac{\partial v'_i}{\partial x_j}} + \overline{v'_k v'_j \frac{\partial \bar{v}_i}{\partial x_j}} + \overline{v'_k v'_j \frac{\partial v'_i}{\partial x_j}} = -\frac{1}{\rho} \overline{v'_k \frac{\partial p'}{\partial x_i}} + \nu \overline{v'_k \frac{\partial^2 v'_i}{\partial x_j \partial x_j}} \quad (1.397)$$

It is recognized that (1.397) doesn't completely constitute a transport equation for the second moments. However, combined with the corresponding transport equation, i.e.,

the one having the inverse  $i$  and  $k$  indexes, and with some mathematical manipulation the exact transport equations for the Reynolds stresses are achieved.

For deriving the second equation, we multiply (1.396) for the component  $k$  through with the fluctuating velocity  $v'_i$ , and time average. The resulting equation can also be formulated by interchanging the  $i$  and  $k$  indices (i.e., replace each occurrence of  $i$  with  $k$ , and each occurrence of  $k$  with  $i$ ) in the above equation. The result is:

$$\overline{v'_i \frac{\partial v'_k}{\partial t}} + \overline{\bar{v}_j v'_i \frac{\partial v'_k}{\partial x_j}} + \overline{v'_i v'_j \frac{\partial \bar{v}_k}{\partial x_j}} + \overline{v'_i v'_j \frac{\partial v'_k}{\partial x_j}} = -\frac{1}{\rho} \overline{v'_i \frac{\partial p'}{\partial x_k}} + \overline{\nu v'_i \frac{\partial^2 v'_k}{\partial x_j \partial x_j}} \quad (1.398)$$

Summation of these two equations, and by use of the product rule of calculus to produce combinations like,  $\overline{v'_i \frac{\partial v'_k}{\partial t}} + \overline{v'_k \frac{\partial v'_i}{\partial t}} = \overline{\frac{\partial v'_i v'_k}{\partial t}}$ , yields:

$$\begin{aligned} & \overline{\frac{\partial v'_i v'_k}{\partial t}} + \overline{\bar{v}_j \frac{\partial v'_i v'_k}{\partial x_j}} + \overline{v'_i v'_j \frac{\partial \bar{v}_k}{\partial x_j}} + \overline{v'_k v'_j \frac{\partial \bar{v}_i}{\partial x_j}} + \overline{v'_j \frac{\partial v'_i v'_k}{\partial x_j}} \\ & = -\frac{1}{\rho} \overline{\left( v'_i \frac{\partial p'}{\partial x_k} + v'_k \frac{\partial p'}{\partial x_i} \right)} + \nu \overline{\left( v'_i \frac{\partial^2 v'_k}{\partial x_j \partial x_j} + v'_k \frac{\partial^2 v'_i}{\partial x_j \partial x_j} \right)} \end{aligned} \quad (1.399)$$

The last term before the equal sign in (1.399) can be put into flux form by use of the continuity equation for the fluctuating components:

$$\frac{\partial}{\partial x_j} \overline{v'_i v'_j v'_k} = \overline{v'_j \frac{\partial v'_i v'_k}{\partial x_j}} + \overline{v'_i v'_k \frac{\partial v'_j}{\partial x_j}} = \overline{v'_i v'_j \frac{\partial v'_k}{\partial x_j}} + \overline{v'_j v'_k \frac{\partial v'_i}{\partial x_j}}$$

Each pressure term can be rewritten using the product rule of calculus, as illustrated

in the following example:  $\overline{v'_k \frac{\partial p'}{\partial x_i}} = \overline{\frac{\partial p' v'_k}{\partial x_i}} - \overline{p' \frac{\partial v'_k}{\partial x_i}}$ .

The viscous terms can also be rearranged using the product rule in a similar manner.

Consider a term of the form  $\overline{\frac{\partial^2 v'_i v'_k}{\partial x_j^2}}$ , using simple rules of calculus we can rewrite it as:

$$\begin{aligned} \overline{\frac{\partial^2 v'_i v'_k}{\partial x_j^2}} &= \frac{\partial}{\partial x_j} \left[ \overline{\frac{\partial v'_i v'_k}{\partial x_j}} \right] = \frac{\partial}{\partial x_j} \left[ \overline{v'_i \frac{\partial v'_k}{\partial x_j}} + \overline{v'_k \frac{\partial v'_i}{\partial x_j}} \right] \\ &= \overline{\frac{\partial v'_i}{\partial x_j} \frac{\partial v'_k}{\partial x_j}} + \overline{v'_i \frac{\partial^2 v'_k}{\partial x_j^2}} + \overline{\frac{\partial v'_k}{\partial x_j} \frac{\partial v'_i}{\partial x_j}} + \overline{v'_k \frac{\partial^2 v'_i}{\partial x_j^2}} \\ &= 2 \overline{\frac{\partial v'_i}{\partial x_j} \frac{\partial v'_k}{\partial x_j}} + \overline{v'_i \frac{\partial^2 v'_k}{\partial x_j^2}} + \overline{v'_k \frac{\partial^2 v'_i}{\partial x_j^2}} \end{aligned}$$

If we multiply these terms by  $\nu$ , then the last two terms above will be identical to the last two terms in the transport equation. Thus, we can write the last two terms in the transport equation as:

$$\overline{\nu v'_i \frac{\partial^2 v'_k}{\partial x_j^2}} + \overline{\nu v'_k \frac{\partial^2 v'_i}{\partial x_j^2}} = \nu \frac{\partial^2 \overline{v'_i v'_k}}{\partial x_j^2} - 2\nu \frac{\partial \overline{v'_i}}{\partial x_j} \frac{\partial \overline{v'_k}}{\partial x_j}$$

The final form of the Reynolds stress transport equation (i.e., the transport equation for the turbulent momentum flux<sup>36</sup>) is:

$$\begin{aligned} \frac{\partial \overline{v'_i v'_k}}{\partial t} + \overline{v_j} \frac{\partial \overline{v'_i v'_k}}{\partial x_j} = & - \overline{v'_i v'_j} \frac{\partial \overline{v_k}}{\partial x_j} - \overline{v'_k v'_j} \frac{\partial \overline{v_i}}{\partial x_j} - \frac{\partial \overline{v'_i v'_j v'_k}}{\partial x_j} \\ & - \frac{1}{\rho} \left[ \frac{\partial \overline{p' v'_i}}{\partial x_k} + \frac{\partial \overline{p' v'_k}}{\partial x_i} - p' \left( \frac{\partial \overline{v'_i}}{\partial x_k} + \frac{\partial \overline{v'_k}}{\partial x_i} \right) \right] \\ & + \nu \frac{\partial^2 \overline{v'_i v'_k}}{\partial x_j^2} - 2\nu \frac{\partial \overline{v'_i}}{\partial x_j} \frac{\partial \overline{v'_k}}{\partial x_j} \end{aligned} \quad (1.400)$$

The physical interpretation of the terms in the equation is not necessary obvious. *The first term on the LHS* denotes the rate of accumulation of the kinematic turbulent momentum flux  $\overline{v'_i v'_k}$  within the control volume. *The second term on the LHS* denotes the advection of the kinematic turbulent momentum flux by the mean velocity. In other words, the left hand side of the equation constitutes the substantial time derivative of the Reynolds stress tensor  $\overline{v'_i v'_k}$ . *The first and second terms on the RHS* denote the production of the kinematic turbulent momentum flux by the mean velocity shears. *The third term on the RHS* denotes the transport of the kinematic momentum flux by turbulent motions (turbulent diffusion). This latter term is unknown and constitutes the well known moment closure problem in turbulence modeling. *The fourth and fifth terms on the RHS* denote the turbulent transport by the velocity-pressure-gradient correlation terms (pressure diffusion). *The sixth term on the RHS* denotes the redistribution by the return to isotropy term. In the engineering literature this term is called the pressure-strain correlation, but is nevertheless characterized by its redistributive nature (e.g., [132]). *The seventh term on the RHS* denotes the molecular diffusion of the turbulent momentum flux. *The eighth term on the RHS* denotes the viscous dissipation term. This term is often abbreviated by the symbol  $2\epsilon_{ik}$ .

For practical applications, second-order closure models are required for the third-order diffusion correlations, the pressure-strain correlation and the dissipation rate correlation as described by Launder and Spalding [95] and Wilcox ([185], Sect. 6.3). Launder and Spalding [95] argued that the pressure diffusion terms and the molecular diffusion of turbulent momentum fluxes are smaller than the rest of the terms in the equation. These terms can thus be sufficiently approximated by a gradient

<sup>36</sup> Momentum is by definition mass times velocity with units (kg m/s). A momentum flux is thus a quantity with units (kg m/s / m<sup>2</sup> s). These units are identical to (N/m<sup>2</sup>), which are the units for stress. For convenience, as we are usually measuring velocities and not fluxes, the fluxes are redefined in kinematic form by dividing by the mixture density. A kinematic momentum flux thus has units (m<sup>2</sup>/s<sup>2</sup>).

type diffusion hypothesis. The third-order closure based on transport equations for the third moments are not considered worthwhile, as these correlations are considered small in engineering flows. The most common approach used in modeling the third moments is to adopt a gradient transport hypothesis for this term too. Because the turbulent energy dissipation occurs at the smallest scales, most modelers use the Kolmogorov [84] hypothesis of local isotropy to model the dissipation tensor ( $\varepsilon_{ik} = \frac{2}{3}\rho\varepsilon\delta_{ik}$ ). A common feature of the full Reynolds stress models and the two-equation models is thus the limited accuracy reflected by the transport equation used for the turbulent length-scale (e.g., the  $\varepsilon$ -equation). Naturally, in conjunction with the Reynolds stress model second-order closures are used for the inherent terms in the length scale equation, whereas first-order closures are adopted in the corresponding two equation model equation. The pressure-strain correlation tensor, i.e., apparently being of the same order of magnitude as the production term [185], is also very difficult to parameterize further limiting the accuracy reflected by the Reynolds stress models. Considerable attention has been paid to this term by turbulence modelers, since there is no direct experimental information available for this correlation [185]. The recent LES and direct numerical simulations (DNS) have yet provided computer generated estimates for this term. Substantial improvements are also needed modeling near wall regions. Finally, in practice, each additional turbulence model equation increases both the computing time and the task of optimizing model parameters. It is easily seen that the Reynolds stress model basically includes 9 unknown terms for 3D simulations, since each term in Eq. (1.400) contains unrepeated  $i$  and  $k$  indices. Fortunately, the number of independent terms is reduced to 6 by symmetries. The computation of the nine terms in the Reynolds stress tensor thus requires that 7 additional transport equations are solved (i.e., including one transport equation for the turbulent energy dissipation rate). In addition, the Reynolds stress simulations are not as robust as the simpler two-equation model solution behavior. Consequently, although the second-order closure models is considered a standard model in most commercial CFD codes, the Reynolds stress model is usually not considered worthwhile for complex reactor simulations. Actually, for dynamic simulations the interpretation problems, mentioned earlier in this paragraph, have shifted the attention towards the VLES simulations to be described shortly. In this book the second-order closure models are thus not considered in further details, the interested reader is referred to standard textbooks on turbulence modeling for CFD applications (e.g., [122, 185]).

### 1.3.5.3 Two-Equation Models

Due to their robustness and reasonable accuracy, the first-order two-equation models, such as the  $k$ - $\varepsilon$  closure originally proposed by Harlow and Nakayama [62, 63], have become very popular for reactor simulations. In this section the formal derivation of the  $k$ - $\varepsilon$  model equations are given and discussed. A transport equation for the *turbulent kinetic energy*, or actually the momentum variance, can be derived by multiplying the equation for the fluctuating component  $v'_i$ , (1.395), by  $2v'_i$ , there-

after use the product rule of calculus to convert some of the terms in the provisional equation, and finally time average the resulting equation [155]. An alternative procedure is to simplify the transport equation for the kinematic momentum fluxes or Reynolds stresses. The contraction of the Reynolds stress transport equation (1.400) (that is, when the 3 equations for the 3 normal stresses,  $(i = k = 1, 2, 3)$  are summed up) gives an exact transport equation for the turbulent kinetic energy (e.g., [107, 132, 168]). Applying the latter procedure we set  $i = k$  in the Reynold stress equation (1.400), and we obtain the equation for the mean square of each component of the fluctuating velocity:

$$\begin{aligned} \frac{\partial \overline{v_i'^2}}{\partial t} + \bar{v}_j \frac{\partial \overline{v_i'^2}}{\partial x_j} = & -2\overline{v_i'v_j'} \frac{\partial \bar{v}_i}{\partial x_j} - \frac{\partial \overline{v_j'v_i'^2}}{\partial x_j} - \frac{2}{\rho} \left[ \frac{\partial \overline{p'v_i'}}{\partial x_i} - \overline{p' \left( \frac{\partial v_i'}{\partial x_i} \right)} \right] \\ & + \nu \frac{\partial^2 \overline{v_i'^2}}{\partial x_j^2} - 2\nu \overline{\left( \frac{\partial v_i'}{\partial x_j} \right)^2} \end{aligned} \quad (1.401)$$

The *first term on the LHS* denotes the rate of accumulation of the velocity variance  $\overline{v_i'^2}$  within the control volume. The *second term on the LHS* denotes the advection of the velocity variance by the mean velocity. The *first term on the RHS* denotes the production of velocity variance by the mean velocity shears. The momentum flux  $\overline{v_i'v_j'}$  is usually negative, thus it results in a positive contribution to variance when multiplied by a negative sign. The *second term on the RHS* denotes a turbulent transport term. It describes how variance  $\overline{v_i'^2}$  is moved around by the turbulent eddies  $v_j'$ . The *third term on the RHS* describes how variance is redistributed by pressure perturbations. This term is often associated with oscillations in the fluid (e.g., like buoyancy or gravity waves.) The *fourth term on the RHS* is called the pressure redistribution term. The factor in square brackets consists of the sum of three terms (i.e., here given in Cartesian coordinates):  $\frac{\partial v_x'}{\partial x}$ ,  $\frac{\partial v_y'}{\partial y}$ , and  $\frac{\partial v_z'}{\partial z}$ . These terms sum to zero because of the turbulence continuity equation. Hence, this term does not change the total variance (i.e., the sum of all three variance components). But it does tend to take energy out of the components having the most energy and put it into components with less energy. Thus, it makes the turbulence more isotropic, and is also known as *the return to isotropy term*. The *fifth term on the RHS* denotes molecular diffusion of the turbulent velocity variance. The *sixth term on the RHS* denotes the rate of viscous dissipation of velocity variance. It is noted that this formulation of the dissipation rate tensor term is not strictly correct [107]. The viscous energy dissipation rate for Newtonian fluids is generally defined by (1.134) in Sect. 1.2.4.3. For incompressible fluids it can be slightly simplified and written as:

$$\epsilon = \frac{\nu}{2} \sum_i \sum_j \left( \frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i} \right)^2 \quad (1.402)$$

Consider the extension of this definition for the dissipation rate to the case of turbulence. We can introduce the mean dissipation rate by averaging both sides of (1.402), and introducing the decomposition of the velocity field into mean and fluctuating variables. The result is:

$$\bar{\epsilon} = \frac{\nu}{2} \sum_i \sum_j \left( \frac{\partial \bar{v}_i}{\partial x_j} + \frac{\partial \bar{v}_j}{\partial x_i} \right)^2 + \frac{\nu}{2} \sum_i \sum_j \overline{\left( \frac{\partial v'_i}{\partial x_j} + \frac{\partial v'_j}{\partial x_i} \right)^2} \quad (1.403)$$

For the particular case of homogeneous turbulence, we can set the mean velocity gradient to zero and consider only the dissipation of the kinetic energy of the fluctuating motions. That is, (1.403) becomes:

$$\bar{\epsilon} = \frac{\nu}{2} \sum_i \sum_j \overline{\left( \frac{\partial v'_i}{\partial x_j} + \frac{\partial v'_j}{\partial x_i} \right)^2} \approx \nu \sum_i \sum_j \overline{\left( \frac{\partial v'_i}{\partial x_j} \right)^2} \quad (1.404)$$

where it can be shown that the last step follows from the particular properties of homogeneous turbulence [160]. Therefore, the last term in the transport equation is not strictly the dissipation, unless the turbulence is homogeneous. However, it is usual to argue that the small scales responsible for the dissipation are homogeneous and hence this is probably quite a good approximation, except possibly near a solid surface. It is obvious that this term is always positive, because it is a squared quantity. Therefore, when this term appears in the transport equation with the negative sign, it is always causing a decrease in the variance with time. In addition, it becomes larger in magnitude as the eddy size become smaller (i.e., using the hypothesis of Kolmogorov [84]). For these small eddies, the eddy motions are rapidly damped by viscous mechanisms and irreversibly converted into heat. This heating rate is so small, however, that it is often neglected in the energy conservation equation for turbulent flows.

By definition the turbulent kinetic energy per unit mass is one half of the variance  $\overline{v_i'^2}$ . Therefore, if we sum over  $i$ , then (1.401) gives us the balance equation for the turbulent kinetic energy,  $k$ , per unit fluid mass, which is defined by:

$$2k = \sum_i \overline{v_i'^2} \quad (1.405)$$

The only manipulation required is to divide all the terms in the equation by 2 and replace  $\frac{1}{2} \sum_i \overline{v_i'^2}$  on the left hand side by  $k$ . The turbulent kinetic energy equation then is given by [79, 96, 132]:

$$\frac{\partial k}{\partial t} + \bar{v}_j \frac{\partial k}{\partial x_j} = -\overline{v'_i v'_j} \frac{\partial \bar{v}_i}{\partial x_j} + \frac{\partial}{\partial x_j} \left( \frac{\overline{v_i'^2 v'_j}}{2} + \frac{1}{\rho} \overline{v'_j p'} \right) + \nu \frac{\partial^2 k}{\partial x_j^2} - \nu \overline{\left( \frac{\partial v'_i}{\partial x_j} \right)^2} \quad (1.406)$$

In (1.406), *the first term on the LHS* denotes the rate of accumulation of turbulent kinetic energy,  $k$ , within the control volume; *the second term on the LHS* denotes the advection of turbulent kinetic energy,  $k$ , by the mean velocity; *the first term on the RHS* denotes the production of turbulent kinetic energy by the mean velocity shear, and represents the rate at which kinetic energy is transferred from the mean flow to the turbulence; *the second and third terms on the RHS* denote turbulent transport of  $k$ . The triple velocity correlation is usually interpreted as the rate at which turbulent energy is transported through the fluid by turbulent fluctuations. The pressure-velocity correlation is interpreted as turbulent transport resulting from pressure and velocity fluctuations; *the fourth term on the RHS* denotes the molecular diffusion of turbulent energy,  $k$ ; *the fifth term on the RHS* represents the irreversible dissipation of turbulent kinetic energy to heat for homogeneous turbulence.

Closing the  $k$ - $\varepsilon$  model by turbulence modeling we relate the unknown Reynolds stress tensor and the turbulent transport terms to the fundamental mean flow variables, or the scaled variables in turbulent boundary layers, introducing additional approximations. The second, third and fourth terms on the RHS of (1.406) (i.e., the triple moment, the pressure-velocity correlation, and the viscous diffusion term) are normally lumped together and modeled as diffusive transport processes being proportional to the gradient of the kinetic energy,  $k$ , (i.e., thus sometimes called the turbulent diffusion terms). That is, the triple moment is modeled as a turbulent diffusion process and approximated in accordance with the standard gradient hypothesis for scalar quantities. The pressure-velocity correlation is assumed to be small and approximated as a gradient-transport process too, apparently due to the lack of any better guess. The viscous diffusion term is negligible except near the wall (i.e., where the turbulence theory model is actually not valid since the flow is not fully turbulent).

The first-order closure models are all based on the Boussinesq hypothesis [19, 20] parameterizing the Reynolds stresses. Therefore, for fully developed turbulent bulk flow, i.e., flows far away from any solid boundaries, the turbulent kinetic energy production term is modeled based on the generalized eddy viscosity hypothesis,<sup>37</sup> defined by (1.386). The modeled  $k$ -equation<sup>38</sup> is written as:

$$\frac{\partial k}{\partial t} + \bar{v}_j \frac{\partial k}{\partial x_j} = \nu_t \left( \frac{\partial \bar{v}_i}{\partial x_j} + \frac{\partial \bar{v}_j}{\partial x_i} \right) \frac{\partial \bar{v}_i}{\partial x_j} + \frac{\partial}{\partial x_j} \left[ \left( \nu + \frac{\nu_t}{\sigma_k} \right) \frac{\partial k}{\partial x_j} \right] - \varepsilon \quad (1.408)$$

where  $\nu_t$  is the turbulent eddy kinematic viscosity and  $\sigma_k$  is an empirical constant.

<sup>37</sup> Equation (1.386) is based on the assumption that all the normal stresses are equal thus representing an *isotropic* model for the Reynolds stresses.

<sup>38</sup> For the turbulent part of the inner boundary layer close to solid walls we usually adopt another closure for the Reynolds stresses and neglect the molecular diffusion term. The starting point for the boundary layer analysis, to be discussed shortly, is thus the  $k$ -equation in the following form:

$$\frac{\partial k}{\partial t} + \bar{v}_j \frac{\partial k}{\partial x_j} = -\overline{v'_i v'_j} \frac{\partial \bar{v}_i}{\partial x_j} + \frac{\partial}{\partial x_j} \left[ \left( \frac{\nu_t}{\sigma_k} \right) \frac{\partial k}{\partial x_j} \right] - \epsilon \quad (1.407)$$

The turbulent viscosity is modeled by analogy with kinetic gas theory (i.e.,  $\nu_t \propto v_{\text{rms}}L$ , and  $v_{\text{rms}} \approx k^{1/2}$ ), thus:

$$\nu_t = C'_\mu k^{1/2} L \quad (1.409)$$

where  $C'_\mu$  is an empirical parameter and  $L$  is an integral length scale. This is analogous to the relationship in kinetic theory between the viscosity, the particle energy, and the mean free path, and is often referred to as the *Kolmogorov-Prandtl relationship* (e.g., [86, 125]).

At first sight, though, this model seems to represent only marginal advance on the mixing length theory, if the length  $L$  still has to be fixed by simple empirical arguments. The turbulent energy dissipation rate,  $\epsilon$ , is also unknown and needs to be parametrized. To proceed it is apparently anticipated that the turbulence model will give more realistic predictions if the length scale,  $L$ , is calculated from a transport equation rather than from some local algebraic expression even though these models are not rigorously derived. In this way a second transport equation is introduced, from which the length scale can be derived. Models at this level are accordingly known as two equation models and there are many of them. In fact we do not formulate a transport equation for the length scale,  $L$ , itself, rather a transport equation for the product  $k^m L^n$  has been considered, where  $k$  is the kinetic energy of turbulence [95]. In order to obtain a dependent variable which really reflects the physics of the turbulence, several combinations of  $k$  and  $L$  have been considered over the years. Some of the combinations have an obvious physical interpretation. For example, the combination  $m = 1/2$  and  $n = -1$  represents a turbulent or eddy frequency, the combination  $m = 1$  and  $n = -2$  represents turbulent vorticity. The far most popular combination is  $m = 3/2$  and  $n = -1$ , by which the dependent variable is identified as the dissipation rate of turbulent energy. For this variable, in principle a rigorous equation can be derived from the transport equation for the fluctuating velocity, but in practice many empirical steps are needed to make it tractable (e.g., [15], Chap. 10.5). Instead, a simple semi-empirical procedure (i.e., apparently based on an analogy with the  $k$ -equation) is often used in engineering practice to draw up a transport equation for the dissipation rate,  $\epsilon$ . An approximate transport equation can be expressed as:

$$\frac{\partial \epsilon}{\partial t} + \bar{v}_j \frac{\partial \epsilon}{\partial x_j} = -C_{\epsilon 1} \frac{\epsilon}{k} \overline{v'_i v'_j} \frac{\partial \bar{v}_i}{\partial x_j} + \frac{\partial}{\partial x_j} \left[ \left( \frac{\nu_t}{\sigma_\epsilon} \right) \frac{\partial \epsilon}{\partial x_j} \right] - \frac{C_{\epsilon 2} \epsilon^2}{k} \quad (1.410)$$

where  $C_{\epsilon 1}$  and  $C_{\epsilon 2}$  are additional empirical constants. This equation possesses production and dissipation terms that are similar to those in the kinetic energy transport equation, except that they are divided by the turbulence time scale of the energy containing eddies,  $\tau_t = \frac{k}{\epsilon}$ . As for the  $k$ -equation, the Reynolds stresses are parameterized based on the eddy viscosity hypothesis.

To close the  $k$ - $\epsilon$  model we need to eliminate the length scale variable,  $L$ , from the model relation (1.409). This has been achieved by relating the length scale to the dissipation rate and  $k$  through a semi-empirical relationship:

$$\epsilon = C_D \frac{k^{3/2}}{L} \quad (1.411)$$

This relation has been put up by Taylor [160] based on dimensional analysis (i.e.,  $\epsilon \propto \frac{v_{\text{rms}}^3}{L}$ , and one assumes  $v_{\text{rms}} \approx k^{1/2}$ ).  $C_D$  is an empirical parameter which in most instances is set to unity as it is very difficult to design experiments for direct validation of this parameter value.

By combining (1.409) and (1.411) we obtain a relation for the turbulent viscosity in terms of  $k$ , the obscure length scale variable  $\epsilon$ , and one empirical parameter:

$$\nu_t = \frac{C_\mu k^2}{\epsilon} \quad (1.412)$$

where  $C_\mu = C'_\mu C_D$ .

Examination of several two-equation models reveals that there is only very small differences between the various models of this type [107]. This may be expected since all proposals for formulating the 2nd equation are closely related, though they differ in the forms of diffusion and near wall terms employed [96]. However, as mentioned above, the  $k$ - $\epsilon$  model of Jones and Launder [79] has been predominant in the literature, and this model also determine the basis for most multi-phase turbulence models adopted in the more fundamental (CFD) reactor modeling approaches.

#### 1.3.5.4 Standard Model Parameter Values

The model parameter values have to be determined before the turbulence closure can be used in practice. The pioneering Imperial College group [59–61, 79, 95, 97] performed a few simple laboratory experiments and, combined with model analysis of these data, determined a set of parameter values which have later been referred to as the ‘standard’ parameter values. The specific flow situations investigated by the Imperial College group and the corresponding  $k$ - $\epsilon$  model simplifications used fixing this set of parameter values have been further discussed by Rodi [133] and Pope ([122], Sect. 10). Basically, the parameter values are assumed to be universal and considered individually, as the problem specific  $k$ - $\epsilon$  model equations contain only one single unknown parameter for each flow situation studied. Accordingly, the parameter values are fitted one by one to experimental data analyzing a few simple turbulent single phase flows only.

- In this manner, to determine the  $C_{\epsilon 2}$  parameter, the  $k$ - $\epsilon$  model is applied to describe homogeneous decay of turbulence behind a grid. In this flow there are no velocity gradients so there are no diffusion terms and no production terms, only dissipation. The  $k$  and  $\epsilon$  equations (1.407) and (1.410) become:

$$\bar{v}_x \frac{dk}{dx} = -\epsilon \quad (1.413)$$

$$\bar{v}_x \frac{d\epsilon}{dx} = -C_{\epsilon 2} \left( \frac{\epsilon^2}{k} \right) \quad (1.414)$$

$C_{\epsilon 2}$  is then the only parameter appearing in the equations, and it can therefore be determined directly from the measured rate of decay of  $k$  behind a grid (e.g., [61]). The experimental data indicates that  $C_{\epsilon 2} = 1.92$ .

- Correspondingly, the  $C_\mu$  parameter has been found analyzing simple turbulent shear flows where  $\frac{d\bar{v}_x}{dy}$  is the only non-zero mean velocity gradient. Applying the  $k$ -equation (1.407) to this flow situation we recognize that the dissipation and production terms are approximately equal. In statistical turbulence analysis (e.g., [67]), this property is said to be denoting an equilibrium shear flow. The simplified  $k$ -equation yields:

$$\overline{v'_x v'_y} \frac{d\bar{v}_x}{dy} \approx -\epsilon \quad (1.415)$$

By use of (1.412) the  $k$ -equation can be written as:

$$\overline{v'_x v'_y} \frac{d\bar{v}_x}{dy} \approx -C_\mu \frac{k^2}{\nu_t} \quad (1.416)$$

Alternatively, after minor reformulation, an expression for the unknown model parameter is given by:

$$C_\mu \approx \frac{\overline{v'_x v'_y}}{k^2} (-\nu_t \frac{d\bar{v}_x}{dy}) \quad (1.417)$$

The unknown Reynolds stress term can be calculated using the eddy viscosity hypothesis (1.386), or, alternatively, the term in the bracket on the RHS of this relation can be recognized as being approximately equal to the Reynolds stress:

$$\overline{v'_x v'_y} \approx -\nu_t \frac{d\bar{v}_x}{dy} \quad (1.418)$$

The  $C_\mu$  parameter can thus be determined experimentally based on the following model:

$$C_\mu \approx \frac{1}{k^2} [\nu_t \frac{d\bar{v}_x}{dy}]^2 \approx \left[ \frac{\overline{v'_x v'_y}}{k} \right]^2 \quad (1.419)$$

Measurements reported by Hanjalic and Launder [61] show that  $\left[ \frac{\overline{v'_x v'_y}}{k} \right] \approx 0.3$ , giving  $C_\mu \approx 0.09$ .

- $\sigma_k$  is set to unity in accordance with the standard Reynolds analogy for turbulent flows.

- Likewise,  $\sigma_\varepsilon$  is preliminarily set to unity in accordance with the standard Reynolds analogy for turbulent flows (i.e., later fixed at  $\sigma_\varepsilon = 1.3$  representing an optimization to experimental data for a number of 2D Couette flows. See next item.).
- The last parameter,  $C_{\varepsilon 1}$ , is determined investigating inhomogeneous high Reynolds number, fully developed channel flows (i.e., these flows are sometimes referred to as 2D Couette flows). Actually, the turbulence model is applied describing the flow in regions near walls, where the logarithmic velocity profile applies. Starting out with fully developed channel flows the quantities of interest (i.e.,  $\bar{v}_x$ ,  $k$  and  $\varepsilon$ ) depend only on  $y$ , so the  $k$ - $\varepsilon$  model equations (1.407) and (1.410) reduce to:

$$0 = \frac{d}{dy} \left( \frac{\nu_t}{\sigma_k} \frac{dk}{dy} \right) - \overline{v'_x v'_y} \frac{d\bar{v}_x}{dy} - \varepsilon \quad (1.420)$$

$$0 = \frac{d}{dy} \left( \frac{\nu_t}{\sigma_\varepsilon} \frac{d\varepsilon}{dy} \right) - C_{\varepsilon 1} \frac{\varepsilon}{k} \overline{v'_x v'_y} \frac{d\bar{v}_x}{dy} - C_{\varepsilon 2} \frac{\varepsilon^2}{k} \quad (1.421)$$

This result shows that for the  $\varepsilon$ -equation (1.421), only the advective term is negligible. The transport equation for the dissipation rate cannot be further reduced, and we recognize that the diffusion term in the  $\varepsilon$ -equation may play an important role in near wall flows.

However, further simplifications can be achieved focusing on the log-law region. Considering the  $k$ -equation (1.420) experimental observations indicate that the production and dissipation terms balance (i.e., thus the dissipation and production terms are in local equilibrium), hence in the  $k$ -equation the diffusion term vanishes. This implies that  $k$  is approximately uniform.

Introducing the result that the dissipation- and production terms in the  $k$ -equation are in approximate local equilibrium, the  $\varepsilon$ -equation (1.421) yields:

$$\frac{d \left[ \left( \frac{\nu_t}{\sigma_\varepsilon} \right) \frac{d\varepsilon}{dy} \right]}{dy} + \frac{\varepsilon^2}{k} (C_{\varepsilon 1} - C_{\varepsilon 2}) \approx 0 \quad (1.422)$$

or

$$\frac{1}{\sigma_\varepsilon} \left( \frac{d\nu_t}{dy} \frac{d\varepsilon}{dy} + \nu_t \frac{d^2\varepsilon}{dy^2} \right) + \frac{\varepsilon^2}{k} (C_{\varepsilon 1} - C_{\varepsilon 2}) \approx 0 \quad (1.423)$$

This ordinary differential equation (ODE) indicates that there is a net source in the  $\varepsilon$ -equation that is balanced by the diffusion of  $\varepsilon$  away from the wall. The last parameter in the  $\varepsilon$ -equation that still remains undetermined,  $C_{\varepsilon 1}$ , has been estimated recognizing that for the log-law region the given ODE reduces to a very simple algebraic relationship between the parameters in the  $\varepsilon$ -equation. So, by fixing the values for the other model parameters just determined above,  $C_{\varepsilon 1}$  can be calculated directly from this relationship.<sup>39</sup>

To reduce the  $\varepsilon$ -equation sufficiently deriving the afore mentioned algebraic

<sup>39</sup> Alternatively, as the Reynolds analogy for turbulent flows is rather rough, it has also been speculated that by fixing  $C_{\varepsilon 1}$ ,  $\sigma_{\varepsilon 1}$  can be calculated directly from the given relationship instead. Of

relation between the model parameters only, all the physical variables have to be eliminated. This variable elimination is achieved by adopting a few hypotheses established in statistical turbulence theory and in the semi-empirical boundary layer flow analysis discussed in the foregoing sects, and by further analysis of the  $k$ - $\varepsilon$  model equations. In this manner, the  $\varepsilon$  and  $\nu_t$  variables can be expressed in terms of  $v_*$ ,  $y$  and the empirical model parameters only. After that,  $\frac{d\varepsilon}{dy}$ ,  $\frac{d^2\varepsilon}{dy^2}$  and  $\frac{d\nu_t}{dy}$  are easily deduced from the resulting expressions for  $\varepsilon$  and  $\nu_t$  since  $v_*$  is considered independent of  $y$ .

Considering the  $\varepsilon$  variable first, the starting point is the semi-empirical relation (1.411) stating that  $\varepsilon$  can be estimated from  $L$  and  $k$ . Therefore, the unknown variables  $L$  and  $k$  are then expressed in terms of  $v_*$ ,  $y$  and the empirical model parameters, and thereafter eliminated from (1.411). So, the purpose of the forthcoming task is to derive an expression for the integral lengthscale,  $L$ , in terms of  $y$  and two empirical parameters only. Initially, the mathematical operations involved are outlined briefly in an easy to follow manner, thereafter the detailed model derivation is given. A relationship between the integral lengthscale,  $L$ , and eddy viscosity parameter,  $\nu_t$ , is found by introducing appropriate simplifications of the  $k$  equation (1.407), approximating the production term in accordance with the eddy viscosity hypothesis (1.386), and applying the Prandtl-Kolmogorov relation (1.409) to eliminate the turbulent kinetic energy variable from the equation. Thereafter, a relationship between the integral length scale,  $L$ , and the mixing length,  $l$ , is found by comparing the resulting expression for the viscosity parameter with the corresponding one deduced from the Prandtl mixing length model (1.362). Thus, in the inner part of the boundary layer  $L$  is determined by the mixing length and three model parameters. Finally, the mixing length is approximated in terms of  $y$  and an empirical parameter [173]. Accordingly, in mathematical terms, recognizing that the production and dissipation terms are approximately equal constituting an equilibrium flow, the  $k$ -equation is written as:

$$\overline{v'_x v'_y} \frac{\partial \overline{v_x}}{\partial y} \approx -\epsilon \approx -C_D \frac{k^{3/2}}{L} \quad (1.424)$$

where the turbulent energy dissipation rate has been substituted by (1.411).

On the LHS, the production term is modeled in accordance with the eddy viscosity hypothesis (1.386), hence:

$$\nu_t \left( \frac{\partial \overline{v_x}}{\partial y} \right)^2 \approx C_D \frac{k^{3/2}}{L} \quad (1.425)$$

---

(Footnote 39 continued)

course, anyhow, it remains to find a plausible way of fixing one of the two parameters. Actually, the preliminary parameter values adjusted using the Reynolds analogy has later been optimized representing a best fit to a larger number of experimental data and flow situations.

Next, the Prandtl-Kolmogorov relation (1.409) is used to eliminate  $k$  from the relation:

$$\nu_t \left( \frac{\partial \bar{v}_x}{\partial y} \right)^2 \approx C_D \frac{(\frac{\nu_t}{C'_\mu L})^3}{L} = C_D \frac{\nu_t^3}{C'^3_\mu L^4} \quad (1.426)$$

After some manipulation, yields:

$$\nu_t \approx \left( \frac{C'_\mu}{C_D} \right)^{\frac{1}{2}} L^2 \left( \frac{\partial \bar{v}_x}{\partial y} \right) \quad (1.427)$$

By use of the eddy viscosity hypothesis (1.386) and the Prandtl mixing length model (1.362), a similar expression for the turbulent viscosity can be deduced, and given by:

$$\nu_t \approx l^2 \left| \frac{d\bar{v}_x}{dy} \right| \quad (1.428)$$

Comparing the resulting relations (1.427) and (1.428), one may suggest that:

$$L \approx l \left( \frac{C_D}{C'^3_\mu} \right)^{\frac{1}{4}} \approx \kappa y \left( \frac{C_D}{C'^3_\mu} \right)^{\frac{1}{4}} \quad (1.429)$$

This expression is used eliminating  $L$  from the relation for  $\varepsilon$  (1.411).

The purpose of the next task is thus to derive an expression for the turbulent energy,  $k$ , in terms of  $v_*$  and one empirical parameter only. Again, the mathematical operations involved are outlined briefly in an easy to understand manner, thereafter the detailed model derivation is given. An expression for  $k$  in terms of the integral lengthscale,  $L$ , the mixing length,  $l$ , the average velocity gradient and one empirical parameter is derived using the Prandtl mixing length model (1.362), the eddy viscosity hypothesis (1.386), and the Prandtl-Kolmogorov relation (1.409). The integral length scale,  $L$ , is eliminated from the resulting expression using the relationship between the integral lengthscale,  $L$ , and the mixing length,  $l$  (1.429) just derived in the previous paragraph. Then, the velocity gradient near the wall is eliminated by use of the law of the wall (1.379). Accordingly, in mathematical terms, the Prandtl mixing length model (1.362) is combined with the eddy viscosity hypothesis (1.386) to form an expression for the eddy viscosity parameter close to the wall. The result is given by:

$$\nu_t \approx l^2 \frac{d\bar{v}_x}{dy} \quad (1.430)$$

Eliminating the eddy viscosity parameter by use of the Prandtl-Kolmogorov relation (1.409) one obtains an expression for  $k$  near the wall:

$$C'_\mu k^{1/2} L \approx l^2 \frac{d\bar{v}_x}{dy} \quad (1.431)$$

After some manipulation:

$$k \approx \frac{l^2}{C_\mu'^{\frac{1}{2}}} \left( \frac{d\bar{v}_x}{dy} \right)^2 \quad (1.432)$$

The velocity gradient near a wall can be estimated from the logarithmic velocity profile (1.379):

$$\frac{d\bar{v}_x}{dy} \approx \frac{v_*}{\kappa y} \quad (1.433)$$

Eliminating the velocity gradient in (1.432) by use of (1.433), one can estimate  $k$  as:

$$k \approx \frac{l^2}{C_\mu'^{\frac{1}{2}}} \left( \frac{v_*}{\kappa y} \right)^2 \approx \frac{(\kappa y)^2}{C_\mu'^{\frac{1}{2}}} \left( \frac{v_*}{\kappa y} \right)^2 \approx \frac{v_*^2}{C_\mu'^{\frac{1}{2}}} \quad (1.434)$$

Inserting the resulting expressions for  $L$  (1.429) and  $k$  (1.434) into the relation for  $\epsilon$  (1.411), yields:

$$\begin{aligned} \epsilon &\approx C_D \frac{k^{3/2}}{L} \approx C_D \frac{k^{3/2}}{l \left( \frac{C_D}{C_\mu^3} \right)^{\frac{1}{4}}} \approx (C_D C_\mu')^{\frac{3}{4}} \frac{k^{3/2}}{\kappa y} \approx (C_D C_\mu')^{\frac{3}{4}} \frac{\left( \frac{v_*^2}{C_\mu'^{\frac{1}{2}}} \right)^{3/2}}{\kappa y} \\ &\approx \frac{v_*^3}{\kappa y} C_D^{3/4} \end{aligned} \quad (1.435)$$

From this expression two of the unknown derivatives in the ODE (1.423) can be deduced by simple rules of calculus:

$$\frac{d\epsilon}{dy} \approx -C_D^{3/4} \frac{v_*^3}{\kappa y^2} \quad (1.436)$$

and

$$\frac{d^2\epsilon}{dy^2} \approx 2C_D^{3/4} \frac{v_*^3}{\kappa y^3} \quad (1.437)$$

The last unknown variable in the ODE (1.423), the turbulent or eddy viscosity,  $\nu_t$ , is estimated from the Prandtl-Kolmogorov relation (1.409). In this context the integral lengthscale,  $L$ , is eliminated by use of the Taylor [160] expression (1.411), where the  $k$  and  $\epsilon$  variables therein have been substituted by use of (1.434) and (1.435), respectively. The result is:

$$\nu_t \approx C_\mu' k^{\frac{1}{2}} L \approx C_D C_\mu' \frac{k^2}{\epsilon} \approx C_D C_\mu' \frac{\left( \frac{v_*^2}{C_\mu'^{\frac{1}{2}}} \right)^2}{\frac{C_D^{3/4} v_*^3}{\kappa y}} \approx v_* \kappa y C_D^{1/4} \quad (1.438)$$

The derivative of the eddy viscosity parameter,  $\nu_t$ , with respect to  $y$  is expressed by:

$$\frac{d\nu_t}{dy} \approx C_D^{1/4} v_* \kappa \quad (1.439)$$

To conclude, by insertion of (1.434) to (1.439) into the  $\epsilon$ -equation (1.423), the relationship between the model parameters yields:

$$C_{\epsilon 1} - C_{\epsilon 2} \approx -\frac{\kappa^2}{C_\mu^{1/2} \sigma_\epsilon} \quad (1.440)$$

where  $\kappa$  is the von Kàrmàn constant and takes the value  $\kappa = 0.4$ .

This relationship (1.440) was, as a first approach, used to fix  $C_{\epsilon 1}$  when  $\sigma_\epsilon$  was fixed at unity in accordance with the well known Reynolds analogy. However, computer optimization fitting the parameters to experimental data gathered from several flow situations gives the values  $C_{\epsilon 1} = 1.44$  and  $\sigma_\epsilon = 1.3$ .

The two-equation turbulence closure with the prescribed parameters given above is called *the standard  $k$ - $\epsilon$  model*. With these parameters the model is able to predict several types of turbulent flow, in particular the flows used to determine the parameters.

Numerous papers have been published regarding the influence of the standard  $k$ - $\epsilon$  model parameters on the simulated results, both for single and multiphase flows, as outlined by Jakobsen [77]. Andersson [1] summarized the current experience applying the standard  $k$ - $\epsilon$  model to various single phase flow simulations. It was stated that the standard parameters by no means can be regarded as universal constants. Ad hoc correlations must often be made to the parameters in order to obtain good correspondence with experimental data. Experience has shown that even in certain fairly simple single phase flow situations some of the constants require other values. Furthermore, no direct method for establishing adequate parameters for a given flow situation has been proposed yet. These parameters are thus fixed only in the sense that they are not changed during a calculation. Of course this must also be an approximation, as flow condition may well vary considerably from one part of an apparatus to the other during a calculation. Therefore, despite the great success of the  $k$ - $\epsilon$  model in engineering applications, caution is needed especially when high accuracy is required. Biswas and Eswaran [15], Pope [122], among others, list some of the major problems encountered in the application of the  $k$ - $\epsilon$  model. In the context of reactor modeling, it is important to notice that this model rely on the Boussinesq eddy-viscosity concept which is based on the assumption that turbulence is isotropic. This means that the normal Reynolds stresses are considered equal and that the eddy viscosity is approximately isotropic. Therefore, the  $k$ - $\epsilon$  model cannot reproduce secondary flows which arise due to unequal normal Reynolds stresses. Unfortunately, the non-isotropic effects are important in many chemical reactors like bubble columns, fluidized beds and stirred tanks. In addition, the standard  $k$ - $\epsilon$  model also requires modifications when applied to swirling flows, thus making

this closure usability rather limited for stirred tank simulations. Furthermore, the values of the empirical parameters need modifications when the model is applied to flows where the molecular viscosity plays an important role. Basically, the  $k$ - $\varepsilon$  model cannot be used near solid walls.

### 1.3.5.5 Wall Functions

In this paragraph the wall function concept is outlined. The wall functions are empirical parameterizations of the mean flow variable profiles within the inner part of the wall boundary layers, bridging the fully developed turbulent log-law flow quantities with the wall through the viscous and buffer sub-layers where the two-equation turbulence model is strictly not valid. These empirical parameterizations thus allow the numerical flow simulation to be carried out with a finite resolution within the wall boundary layers, and one avoids accounting for viscous effects in the model equations. Therefore, in the numerical implementation of the  $k$ - $\varepsilon$  model one anticipates that the boundary layer flow is not fully resolved by the model resolution. The first grid point or node used at a wall boundary is thus placed within the fully turbulent log-law sub-layer, rather than on the wall itself [96]. In effect, the wall functions amount to a synthetic boundary condition for the  $k$ - $\varepsilon$  model. In addition, the limited boundary layer resolution required also provides savings on computer time and storage. Both equilibrium and non-equilibrium wall boundary implementations are considered. For equilibrium flows the local production rate of turbulence equals the dissipation rate in the near wall grid node. The first set of wall function boundary conditions reported was apparently used for equilibrium flows by Gosman et al. [59]. Denoting the dependent variables in the first point near the wall by a subscript  $P$ , an approximate sketch of their approach is given next.

- The velocity components parallel to the wall are estimated from the logarithmic velocity profile relation (1.379). For example, using Cartesian coordinates, the x-component of the velocity vector is given as:

$$\bar{v}_{x,P} \approx \frac{v_*}{\kappa} \ln\left(E \frac{v_* y_P}{\nu}\right) = \frac{v_*}{\kappa} \ln(E y_P^+) \quad (1.441)$$

where the parameter value (i.e., the constant of integration) is considered a function of surface roughness and shear stress variations (e.g., [59, 60, 107, 155]). In accordance with the practice of Gosman et al. [59] and Gosman et al. [60], we suggest  $E = 9.793$  to be applied to chemical reactor models.

- Using a staggered grid arrangement the normal velocity component, say, the y-component, is set equal to zero at the wall (i.e., valid for impermeable walls only):

$$\bar{v}_{y,\text{wall}} = 0 \quad (1.442)$$

- The wall boundary condition for  $k_p$  is specified in accordance with (1.434):

$$k_P \approx \frac{v_*^2}{C_\mu^{\frac{1}{2}}}$$

Accordingly, the wall boundary condition for the turbulent energy dissipation rate,  $\epsilon$ , is given by (1.435):

$$\epsilon_P \approx \frac{v_*^3}{\kappa y_P}$$

In the early FVM program codes, all the equilibrium variable values at the grid point, P, were simply calculated from the given parameterizations. However, in these steady state program codes the friction velocity is not known a priori but is an outcome of the iterative solution algorithm where the boundary values are coupled through the governing transport equations. In addition, the logarithmic law is strictly valid for high-Reynolds number zero pressure gradient boundary layers only. Therefore, under practical flow conditions the physical basis is uncertain and the accuracy reflected by these relations becomes poor [185]. In consequence, the given wall function concept is not robust as severe numerical convergence- and stability problems often arise, thus more advanced implementations evolved. The wall functions and their implementations were subsequently extended to enable more robust boundary conditions providing solutions under almost any circumstances. One outcome of the subsequent model development is that in the modern FVM codes the transport equations for the velocity components being parallel to the wall and  $k$  are solved for the first grid node, P, within the calculation domain close to the wall boundary. For the velocity components being parallel to the wall there are no values stored at the solid surface in a staggered grid arrangement, so the wall friction force at the cell surface is replaced by an apparent source at the node point, P. The physical observation that the shear stress is approximately constant over the inner part of the boundary layer allows the modeler to relocate the point where the shear stress is actually calculated without further considerations. Since the physical value of  $k$  approaches zero at the wall, there is no  $k$ -flux contribution from the wall in the  $k$ -equation. Furthermore, at the node, P, close to the wall the turbulence production term reduces to a simple form expressed in terms of the wall shear stress. In this way the value of  $k$  at the wall node, P, is determined by the turbulence level in the mean flow and a modified turbulence generation term.

- For the velocity components parallel to the wall the calculation of the wall boundary conditions, i.e., the apparent bulk source term, for turbulent flows starts with the estimation of  $y_P^+$ , the dimensionless distance of the near wall node, P, to the solid surface. For turbulent flows where  $y_P^+ \leq 11.63$ , the value of the laminar wall shear stress is determined from:

$$-\overline{\sigma}_W = \mu \frac{\bar{v}_{x,P}}{y_P} \quad (1.443)$$

where  $\bar{v}_{x,P}$  is the velocity component parallel to the wall calculated at the first grid node inside the calculation domain. The resulting shear force,  $F_w$ , is defined by:

$$F_w = \overline{\sigma}_w A_{\text{Cell}} = -\mu \frac{\overline{v}_{x,P}}{y_P} A_{\text{Cell}} \quad (1.444)$$

where  $A_{\text{Cell}}$  is the wall area of the cell volume.

However, the friction force estimate calculated in this way is only valid in the laminar layer very close to the wall and rapidly becomes inaccurate as the node point enters the buffer layer. More important, nevertheless, the  $k$ - $\varepsilon$  model is strictly not valid in the viscous sub-layer. In practice the first node is often incidentally placed within the laminar layer intending to make sure that the numerical grid resolution is sufficiently fine, with the unfortunate consequence that the simulated results are in poor agreement with the physical flow situation. Therefore, in such situations, it is recommended to choose a coarser grid resolution ensuring that the first grid node, P, is located in the log-law layer. For boundary layer flows for which the log-law relations are accurate, the overall solution is then insensitive to the choice of  $y_P$ . However, in other flows it is found that the solution is sensitive to the choice of  $y_P$  even within the log-law region. Unfortunately, it might not be possible to obtain numerically accurate, grid-independent solutions in these cases. If  $y_P^+ > 11.63$ , node, P, is considered to be in the log-law region of the inner part of the turbulent boundary layer. In this region the law of the wall (1.379) (i.e., in the form  $v^+ = \frac{1}{\kappa} \ln(Ey^+)$ ) is used to calculate the shear stress variable. Actually, several possibilities exist formulating the wall friction force. The natural boundary layer shear stress definition to use is the one deduced from the fundamental equilibrium boundary layer analysis. The wall shear stress is thus defined as  $-\overline{\sigma}_w = \rho v_* v_*$ . Calculating the friction velocity from the log-law (1.379), yields:

$$-\overline{\sigma}_w = \rho \frac{\kappa^2 \overline{v}_{x,P}^2}{(\ln(Ey_P^+))^2} \quad (1.445)$$

In this approach the shear force,  $F_w$ , is defined by:

$$F_w = \overline{\sigma}_w A_{\text{Cell}} = -\rho \frac{\kappa^2 \overline{v}_{x,P}^2}{(\ln(Ey_P^+))^2} A_{\text{Cell}} \quad (1.446)$$

In other flow situations where the turbulent energy diffusion towards the wall is significant, appreciable departures from local equilibrium occur. There are a variety of non-equilibrium boundary conditions suggested in the literature. Launder and Spalding [96] recognized that the relation obtained for  $k$  in the log-law layer (1.434) permits us to redefine the friction velocity, when the  $k$  value is considered known from the previous iteration or time level. Hence, a non-equilibrium boundary layer shear stress approximation is given by  $-\overline{\sigma}_w = \rho v_* v_k$ . Calculating the friction velocity from the log-law (1.379), and the non-equilibrium velocity scale from (1.434), yields:

$$-\overline{\sigma}_W \approx \rho C_\mu'^{1/4} k_P^{1/2} \frac{\kappa \bar{v}_{x,P}}{\ln(Ey_P^+)} \approx \rho C_\mu'^{1/4} k_P^{1/2} \frac{\bar{v}_{x,P}}{v^+} \quad (1.447)$$

In this approach the shear force,  $F_w$ , is given by:

$$F_w = \overline{\sigma}_W A_{\text{Cell}} = -\rho C_\mu'^{1/4} k_P^{1/2} \frac{\bar{v}_{x,P}}{v^+} A_{\text{Cell}} \quad (1.448)$$

For quite a few flow situations this relation provides results being in better agreement with experimental data, compared to the corresponding predictions obtained using the equilibrium formulation. Versteeg and Malalasekera [174] state that this approach represents the optimum near wall relationships from extensive computing trails. To further minimize the numerical convergence- and stability problems related to the friction force calculations, yet another relation has been suggested based on the friction coefficient concept. In this approach the shear stress is defined by:

$$-\overline{\sigma}_W = \rho C_f |\bar{\mathbf{v}}_P| (\bar{v}_{x,P} - \bar{v}_{x,W}) \quad (1.449)$$

where  $\bar{v}_{x,w}$  is a moving wall velocity set to zero for stationary walls.

The skin friction coefficient is calculated from the log-law relation in an implicit iteration loop:

$$\frac{1}{\sqrt{C_f}} = \frac{1}{\kappa} \ln(E \sqrt{C_f} \frac{\bar{v}_{x,P} y_P}{\nu}) = \frac{1}{\kappa} \ln(E \sqrt{C_f} Re_y) \quad (1.450)$$

where  $-\overline{\sigma}_W = C_f \rho \bar{v}_{x,P}^2$  defines the friction factor.

Normally, simulating chemical reactor flows non-equilibrium wall boundary conditions are used. Basically, the solutions obtained based on the two non-equilibrium wall shear stress formulations given above do not diverge significantly, but the last one may have slightly better inherent numerical properties as the iteration process is sometimes converging a little faster.

- Assuming that  $v'_x v'_y = \sigma_{xy,t} \approx \sigma_W$ , the  $k$ -equation (1.407) production term yields:

$$P_k \approx -\overline{x'_x v'_y} \frac{d\bar{v}_x}{dy} \approx -\sigma_W \frac{(\bar{v}_{x,P} - \bar{v}_{x,w})}{y_P} \approx \frac{-\sigma_W \bar{v}_{x,P}}{y_P} \quad (1.451)$$

The corresponding dissipation rate term is approximated using (1.411), the Prandtl-Kolmogorov relation (1.409), the eddy viscosity hypothesis (1.386), and the non-equilibrium boundary layer shear stress approximation (1.447):

$$\begin{aligned} \varepsilon_{k,P} &\approx C_D \frac{k_P^{3/2}}{L} \approx C_D C_\mu' \frac{k_P^2}{\nu_t} \approx C_D C_\mu' \frac{k_P^2}{\sigma_W} \rho \frac{d\bar{v}_x}{dy} \approx C_D C_\mu' \frac{k_P^2}{\sigma_W} \rho \frac{\bar{v}_{x,P}}{y_P} \\ &\approx C_D C_\mu' k_P^2 \frac{v^+}{\bar{v}_{x,P} (C_D C_\mu')^{1/4} k^{1/2}} \frac{\bar{v}_{x,P}}{y_P} = (C_D C_\mu')^{3/4} k_P^{3/2} \frac{v^+}{y_P} \end{aligned} \quad (1.452)$$

- The energy dissipation rate reaches its highest value at the wall. This makes it difficult to estimate the flux towards the wall from the transport equation, as it would require a very fine grid resolution. The energy dissipation,  $\epsilon_P$ , is therefore roughly estimated as a fixed value by the equilibrium relation (1.435):

$$\epsilon_P \approx C_D^{3/4} \frac{v_*^3}{\kappa y_P}$$

In the non-equilibrium approaches the dissipation rate is calculated as a function of the level of turbulent kinetic energy at the wall:

$$\epsilon_P \approx (C_D C'_\mu)^{3/4} \frac{k_P^{3/2}}{\kappa y_P}$$

This approach works best within an iterative procedure, but can also be adopted in explicit discretization schemes calculating  $\epsilon_P^{n+1}$  from  $k_P^n$  in the previous time level.

### 1.3.5.6 Boundary Conditions

The solution of the governing reactor model equations are subjected to the boundary conditions specified. The number of boundary conditions required depends on the mathematical properties of the equations (e.g., elliptical, parabolic, hyperbolic, or mixed).

For single-phase turbulent reactor flows, the typical boundary conditions include impermeable solid walls, free surfaces, pressure boundaries, symmetry axis, inlet- and outlet conditions.

An impermeable solid wall is specified assuming that the no-slip velocity condition at the boundary is valid. In general, the scalar variable boundaries are specified by Neumann, Dirichlet- or mixed conditions.

A free surface is determined by fixing the normal component of the velocity at the surface to zero, and the partial derivative normal to the free surface of all other scalar quantities are set to zero.

An axis of symmetry is determined by fixing the radial component of the velocity to zero, whereas the partial derivative with respect to  $r$  of all the scalar variables is set to zero.

An inlet boundary is determined when the normal velocity component and the known scalar variables are specified. The turbulence quantities are generally estimated based on simple empirical relations.

An outlet boundary can be determined assuming that the flow is fully developed, thus the partial derivatives of all scalar variables are set to zero normal to the outlet surface plane.

A pressure boundary is determined by specifying the absolute pressure value.

Further details on the boundary condition implementations are given in Chap. 12 outlining the numerical algorithms, discretizations and solvers.

### 1.3.5.7 Mean Kinetic Energy and Its Interaction with Turbulence

We learn quite a lot about the physics of turbulence by considering the ways in which energy is transported from one place to another, and transformed from one energy form to another. For the general case of a fluid occupying a global volume  $V$  bounded by a surface  $S$ , the total kinetic energy of macroscopic fluid motion  $E_T$  can be expressed in terms of the instantaneous velocity field  $v_i(t, \mathbf{r})$  as:

$$2E_T = \sum_i \int_V \rho v_i^2 dv \quad (1.453)$$

An equation for  $E_T$  can be derived from the Navier-Stokes equation (1.133) in the form (i.e., noting that a few terms vanish when integrated)

$$\frac{dE_T}{dt} = \int_V \rho v_i g_i dv - \int_V \rho \epsilon dv \quad (1.454)$$

where, for simplicity, we have considered an incompressible flow of a one component mixture.  $g_i(t, \mathbf{r})$  is an externally applied force (per unit mass of fluid).  $\epsilon$  is the energy dissipation per unit time and per unit mass of fluid, given by:

$$2\epsilon = \nu \sum_i \sum_j \left( \frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i} \right)^2 \quad (1.455)$$

Equation (1.454) tells us that the global rate of change of energy is equal to the rate at which the external forces do work on the fluid minus the rate at which viscous effects convert kinetic energy into heat. Note that the non-linear terms in the Navier-Stokes equation do no net work on the system. Mathematically, it can be shown that any term which appears as a divergence in the local energy equation vanishes when integrated over the system volume in order to obtain the global equation [107]. Furthermore, the viscous term can be divided into two parts, of which one is diffusive in character and vanishes when integrated, and the other is dissipative and given by (1.455) for incompressible fluids.

In the turbulent case the total kinetic energy equation (1.453) is readily generalized to the form:

$$2E_T = \sum_i \int_V \rho \bar{v}_i^2 dv + \sum_i \int_V \rho \overline{v_i'^2} dv \quad (1.456)$$

Normally, as discussed earlier, in reactor modeling we are interested in the energy associated with the velocity fluctuations  $v'_i$  only. The appropriate turbulent kinetic energy balance equation, the  $k$  equation, has therefore been derived via an equation for the Reynolds stress tensor.

The turbulent kinetic energy budget involves the production of turbulent kinetic energy by interaction of turbulence with the mean velocity. It was stated in the previous analysis that the production of  $k$  was accompanied by a corresponding loss of kinetic energy from the mean flow. No quantitative derivation was given at that point. To study this mechanism, a procedure analog to the derivation of the instantaneous kinetic energy equation can be applied to derive an equation for the mean kinetic energy of the flow.

We start with the transport equation for mean velocity in turbulent flow (1.393), multiply by  $\bar{v}_i$ , and use the chain rule to derive the following equation for mean kinetic energy per unit mass:

$$\frac{\partial(\frac{1}{2}\bar{v}_i^2)}{\partial t} + \bar{v}_j \frac{\partial(\frac{1}{2}\bar{v}_i^2)}{\partial x_j} + \bar{v}_i \frac{\partial \overline{v'_i v'_j}}{\partial x_j} = -\frac{\bar{v}_i}{\rho} \frac{\partial \bar{p}}{\partial x_i} + \nu \bar{v}_i \frac{\partial^2 \bar{v}_i}{\partial x_j \partial x_j} \quad (1.457)$$

The *first term on the LHS* represents the rate of accumulation of mean kinetic energy within the control volume. The *second term on the LHS* describes the advection of mean kinetic energy by the mean velocity. The *third term on the LHS* represents the interaction between the mean flow and turbulence. The *first term on the RHS* represents the production of MKE when pressure gradients accelerate the mean flow. The *second term on the RHS* represents the molecular dissipation of mean motions.

Using the product rule, the interaction term (i.e., the third term on the LHS) can be rewritten as:

$$-\bar{v}_i \frac{\partial \overline{v'_i v'_j}}{\partial x_j} = \overline{v'_i v'_j} \frac{\partial \bar{v}_i}{\partial x_j} - \frac{\partial (\overline{v'_i v'_j} \bar{v}_i)}{\partial x_j} \quad (1.458)$$

This gives:

$$\frac{\partial(\frac{1}{2}\bar{v}_i^2)}{\partial t} + \bar{v}_j \frac{\partial(\frac{1}{2}\bar{v}_i^2)}{\partial x_j} = -\frac{\bar{v}_i}{\rho} \frac{\partial \bar{p}}{\partial x_i} + \nu \bar{v}_i \frac{\partial^2 \bar{v}_i}{\partial x_j \partial x_j} + \overline{v'_i v'_j} \frac{\partial \bar{v}_i}{\partial x_j} - \frac{\partial (\overline{v'_i v'_j} \bar{v}_i)}{\partial x_j} \quad (1.459)$$

If we compare the  $k$  equation (1.407) with the mean kinetic energy equation (1.459) we see that they both contain a term describing the interaction between the mean flow and turbulence. We are of course referring to the velocity variance production term, which is the second last term in (1.459). The sign of this term differ in the two equations. Thus, the energy that is mechanically produced as turbulence is lost from the mean flow, and vice versa.

### 1.3.5.8 Generalized Transport Equations for Specific Turbulent Fluxes and Variances of the Scalar Variables

Let  $\psi$  be a general instantaneous scalar variable representing quantities like energy, heat, temperature, species mass concentration, etc.. In Cartesian coordinates the general transport equation for  $\psi$  can be written as:

$$\frac{\partial \rho \psi}{\partial t} + \frac{\partial}{\partial x_j} (\rho v_j \psi) = \frac{\partial}{\partial x_j} \left( \Gamma_\psi \frac{\partial \psi}{\partial x_j} \right) + S_\psi \quad (1.460)$$

where  $\Gamma_\psi$  is the molecular diffusion coefficient of quantity  $\psi$ , and  $S_\psi$  is the source term for the remaining processes not already in the equation, such as for example chemical reactions in the species transport equation. The physical interpretation of the terms in the general equation has been discussed earlier for the individual quantities of interest.

The general equation for the corresponding mean Reynolds averaged variables in a turbulent flow is derived in the following way. We start with the basic transport equation (1.460) and expand  $\psi$  into its mean and fluctuating parts (e.g., [67, 154, 168]):

$$\begin{aligned} \frac{\partial \rho \bar{\psi}}{\partial t} + \frac{\partial \rho \psi'}{\partial t} + \frac{\partial}{\partial x_j} (\rho \bar{v}_j \bar{\psi}) + \frac{\partial}{\partial x_j} (\rho \bar{v}_j' \bar{\psi}) + \frac{\partial}{\partial x_j} (\rho \bar{v}_j \psi') + \frac{\partial}{\partial x_j} (\rho \bar{v}_j' \psi') \\ = \frac{\partial}{\partial x_j} \left( \Gamma_\psi \frac{\partial \bar{\psi}}{\partial x_j} \right) + \frac{\partial}{\partial x_j} \left( \Gamma_\psi \frac{\partial \psi'}{\partial x_j} \right) + \bar{S}_\psi \end{aligned} \quad (1.461)$$

where we still assume that the fluid is incompressible (i.e.,  $\rho$  and  $\Gamma_\psi$  are constant). In addition, we have assumed that the remaining net source term,  $\bar{S}_\psi$ , is a mean forcing. Note that the latter assumption is not valid for many multicomponent reactive systems.

Next, we Reynolds average the instantaneous equation and get:

$$\frac{\partial \rho \bar{\psi}}{\partial t} + \frac{\partial}{\partial x_j} (\rho \bar{v}_j \bar{\psi} + \overline{\rho \bar{v}_j' \psi'}) = \frac{\partial}{\partial x_j} \left( \Gamma_\psi \frac{\partial \bar{\psi}}{\partial x_j} \right) + \bar{S}_\psi \quad (1.462)$$

The *first term on the LHS* denotes the rate of accumulation of the mean quantity  $\bar{\psi}$  within the control volume per unit volume. The *second term on the LHS* denotes the convection of the mean quantity  $\bar{\psi}$  by the mean velocity. The *third term on the LHS* represents the divergence of the turbulent  $\bar{\psi}$  flux. The *first term on the RHS* represents the mean molecular diffusion of the  $\bar{\psi}$  quantity. The *second term on the RHS* denotes the mean net body source term for additional  $\psi$  processes.<sup>40</sup>

<sup>40</sup> Note that for multicomponent reactive systems the source term needs to be treated in a more sophisticated way if the time scale of the reaction rate is at the same order as the time scale of the turbulent fluctuations. For very rapid reactions, like in most combustion processes, the turbulent

The general transport equation for the scalar quantity variance can be formulated, in analogy to the procedure applied for momentum, by subtracting (1.462) from (1.461) to obtain an equation for the turbulent fluctuations (e.g., [154, 155, 168]):

$$\begin{aligned} \frac{\partial \rho \psi'}{\partial t} + \frac{\partial}{\partial x_j} (\rho v_j' \bar{\psi}) + \frac{\partial}{\partial x_j} (\rho \bar{v}_j \psi') + \frac{\partial}{\partial x_j} (\rho v_j' \psi') - \frac{\partial}{\partial x_j} (\overline{\rho v_j' \psi'}) \\ = \frac{\partial}{\partial x_j} (\Gamma_\psi \frac{\partial \psi'}{\partial x_j}) \end{aligned} \quad (1.463)$$

Multiplying this equation by  $2\psi'$ , and using the product rule of calculus to covert terms like  $2\psi' \partial \psi' / \partial t$  into terms like  $\partial \psi'^2 / \partial t$ , yields:

$$\begin{aligned} \frac{\partial \rho \psi'^2}{\partial t} + 2\psi' \frac{\partial}{\partial x_j} (\rho v_j' \bar{\psi}) + \frac{\partial}{\partial x_j} (\rho \bar{v}_j \psi'^2) + \frac{\partial}{\partial x_j} (\rho v_j' \psi'^2) \\ = 2\psi' \frac{\partial}{\partial x_j} (\overline{\rho v_j' \psi'}) + 2\psi' \frac{\partial}{\partial x_j} (\Gamma_\psi \frac{\partial \psi'}{\partial x_j}) \end{aligned} \quad (1.464)$$

Next, we average, applying the Reynolds averaging rules, and rearrange the terms in the equation:

$$\frac{\partial \overline{\rho \psi'^2}}{\partial t} + \frac{\partial}{\partial x_j} (\overline{\rho \bar{v}_j \psi'^2}) = -2\overline{\psi' \frac{\partial}{\partial x_j} (\rho v_j' \bar{\psi})} - \frac{\partial}{\partial x_j} (\overline{\rho v_j' \psi'^2}) + 2\overline{\psi' \frac{\partial}{\partial x_j} (\Gamma_\psi \frac{\partial \psi'}{\partial x_j})} \quad (1.465)$$

The first term on the right hand side is usually reformulated by use of the continuity equation for the fluctuations, and the last term is slightly rearranged assuming that  $\Gamma_\psi$  is a constant:

$$\frac{\partial \overline{\rho \psi'^2}}{\partial t} + \frac{\partial}{\partial x_j} (\overline{\rho \bar{v}_j \psi'^2}) = -2\overline{\rho \psi' v_j' \frac{\partial \bar{\psi}}{\partial x_j}} - \frac{\partial}{\partial x_j} (\overline{\rho v_j' \psi'^2}) + 2\overline{\Gamma_\psi \psi' \frac{\partial^2 \psi'}{\partial x_j^2}} \quad (1.466)$$

As was done for momentum, the last term in the equation is split into two parts, one determining the molecular diffusion of the  $\psi$  variance which is assumed to be small enough to be neglected. The remaining part is defined as twice the molecular dissipation term,  $\epsilon_\psi$ , by analogy with the kinetic energy term:

---

(Footnote 40 continued)

fluctuations will not influence the reaction rate directly but indirectly through the mixing properties of turbulence. Therefore, these reactions are often referred to as dispersion-controlled reactions. Further details are given by Jones [80], Baldyga and Bourne [5] and Fox [49]. For (very) slow reactions, like in many chemical processes, the turbulent transport processes perform relatively rapid mixing, thus allowing time for fresh reagent to mix with the local fluid. Therefore, calculating the average reaction rate the local reagent concentrations are assumed premixed and the turbulent species concentration variances appears to be small.

$$\epsilon_\psi \approx \Gamma_\psi \overline{\left(\frac{\partial \psi'}{\partial x_j}\right)^2} \quad (1.467)$$

Thus, the transport equation for the general scalar quantity  $\psi$  variance is:

$$\frac{\partial \overline{\rho \psi'^2}}{\partial t} + \frac{\partial}{\partial x_j} (\rho \bar{v}_j \overline{\psi'^2}) = -2 \overline{\rho \psi' v'_j} \frac{\partial \bar{\psi}}{\partial x_j} - \frac{\partial}{\partial x_j} (\overline{\rho v'_j \psi'^2}) - 2 \epsilon_\psi \quad (1.468)$$

*The first term on the LHS* represents the local rate of accumulation of the variance  $\psi'^2$ . *The second term on the LHS* describes the convection of the quantity  $\psi$  variance by the mean velocity. *The first term on the RHS* denotes a production term, associated with the turbulent motions occurring within a mean  $\psi$  gradient. *The second term on the RHS* represents the turbulent transport of the  $\psi$  variance. *The third term on the RHS* denotes the molecular dissipation.

The general transport equation for the specific turbulent fluxes of scalar variables is derived in analogy to the corresponding momentum flux equations, i.e., the Reynolds stress equations. The derivation combines two equations for the fluctuations to produce a flux equation. For the first equation we start with the momentum fluctuation equation (1.395), multiply it by the scalar quantity perturbation  $\psi'$ , and Reynolds average:

$$\overline{\psi' \frac{\partial v'_i}{\partial t}} + \overline{\bar{v}_j \psi' \frac{\partial v'_i}{\partial x_j}} + \overline{\psi' v'_j \frac{\partial \bar{v}_i}{\partial x_j}} + \overline{\psi' v'_j \frac{\partial v'_i}{\partial x_j}} = -\frac{1}{\rho} \overline{\psi' \frac{\partial p'}{\partial x_i}} + \overline{\nu \psi' \frac{\partial^2 v'_i}{\partial x_j \partial x_j}} \quad (1.469)$$

Similarly for the second equation, we start with the equation for the fluctuating scalar variable (1.463) and multiply by  $v'_i$  and Reynolds average:

$$\overline{v'_i \frac{\partial \rho \psi'}{\partial t}} + \overline{v'_i \frac{\partial}{\partial x_j} (\rho v'_j \bar{\psi})} + \overline{v'_i \frac{\partial}{\partial x_j} (\rho \bar{v}_j \psi')} = -\overline{v'_i \frac{\partial}{\partial x_j} (\rho v'_j \psi')} + \overline{v'_i \frac{\partial}{\partial x_j} (\Gamma_\psi \frac{\partial \psi'}{\partial x_j})} \quad (1.470)$$

Some of the terms can be reformulated using the two forms of the continuity equation and the assumption that the fluid is incompressible:

$$\overline{v'_i \frac{\partial \psi'}{\partial t}} + \overline{v'_i v'_j \frac{\partial \bar{\psi}}{\partial x_j}} + \overline{\bar{v}_j v'_i \frac{\partial \psi'}{\partial x_j}} + \overline{v'_i v'_j \frac{\partial \psi'}{\partial x_j}} = \frac{\Gamma_\psi}{\rho} \overline{v'_i \frac{\partial^2 \psi'}{\partial x_j^2}} \quad (1.471)$$

Next, we add these two equations, put the turbulent flux divergence term into the flux form by using the continuity equations, and combine terms. The result is:

$$\begin{aligned}
\frac{\partial \overline{\psi'v'_i}}{\partial t} + \bar{v}_j \frac{\partial \overline{\psi'v'_i}}{\partial x_j} + \overline{\psi'v'_j} \frac{\partial \bar{v}_i}{\partial x_j} + \bar{v}'_i v'_j \frac{\partial \bar{\psi}}{\partial x_j} + \frac{\partial \overline{\psi'v'_i v'_j}}{\partial x_j} \\
= -\frac{1}{\rho} \overline{\psi' \frac{\partial p'}{\partial x_i}} + \overline{\nu \psi' \frac{\partial^2 v'_i}{\partial x_j \partial x_j}} + \frac{\Gamma_\psi}{\rho} \overline{v'_i \frac{\partial^2 \psi'}{\partial x_j^2}}
\end{aligned} \quad (1.472)$$

Then, we split the pressure term into two parts, and assume  $\nu \approx \frac{\Gamma_\psi}{\rho}$  to combine the molecular diffusion terms:

$$\begin{aligned}
\frac{\partial \overline{\psi'v'_i}}{\partial t} + \bar{v}_j \frac{\partial \overline{\psi'v'_i}}{\partial x_j} = -\overline{\psi'v'_j} \frac{\partial \bar{v}_i}{\partial x_j} - \bar{v}'_i v'_j \frac{\partial \bar{\psi}}{\partial x_j} - \frac{\partial \overline{\psi'v'_i v'_j}}{\partial x_j} \\
- \frac{1}{\rho} \left[ \overline{\frac{\partial p' \psi'}{\partial x_i}} - \overline{p' \frac{\partial \psi'}{\partial x_i}} \right] + \nu \overline{\frac{\partial^2 \psi' v'_i}{\partial x_j \partial x_j}} - 2\nu \left( \frac{\partial \bar{v}'_i}{\partial x_j} \right) \left( \frac{\partial \bar{\psi}}{\partial x_j} \right) \quad (1.473)
\end{aligned}$$

The terms in this equation have physical interpretations analogous to those in the momentum flux equation (1.400), except for the additional term (i.e., the second term on the RHS), which is a production/loss term related to the mean scalar quantity gradient. Physically, this term suggests production of the scalar quantity flux when there is a momentum flux in a mean scalar quantity gradient. The turbulent momentum flux implies a turbulent movement of the fluid. If that movement occurs across a mean scalar quantity gradient, then the scalar quantity fluctuation would be expected. Note that an additional term must be added if the source is assumed to fluctuate too.

Substituting  $2\epsilon_{u_i\psi}$  for the last term, and neglecting the pressure diffusion term and the molecular diffusion term leaves:

$$\frac{\partial \overline{\psi'v'_i}}{\partial t} + \bar{v}_j \frac{\partial \overline{\psi'v'_i}}{\partial x_j} = -\overline{\psi'v'_j} \frac{\partial \bar{v}_i}{\partial x_j} - \bar{v}'_i v'_j \frac{\partial \bar{\psi}}{\partial x_j} - \frac{\partial \overline{\psi'v'_i v'_j}}{\partial x_j} + \frac{1}{\rho} \left[ \overline{p' \frac{\partial \psi'}{\partial x_i}} \right] - 2\epsilon_{u_i\psi} \quad (1.474)$$

where the first and second terms on the LHS are the rate of accumulation and advection terms, the first and second terms on the RHS relate to production/consumption, the third term on the RHS denotes turbulent transport, the fourth term on the RHS denotes redistribution, and the fifth term on the RHS denotes the molecular destruction or dissipation of the turbulent scalar quantity flux.

Turbulence closure models for the unknown terms in the flux- and variance equations for single phase reactor systems are discussed extensively by Baldyga and Bourne [5] and Fox [49, 50]. However, the application of these model closures should be treated with care as most of these parameterizations are expressed in terms of the turbulent eddy and other scalar dissipation rates (and dissipation energy spectra) which are about the weakest links in turbulence modeling. The predictive capabilities of the Reynolds averaged models are thus very limited, and in most papers the use of these statistical concepts are restricted to the reproduction of known concentration and reaction rates. More elaborated statistical approaches have been proposed in which the governing equations are conditionally averaged invoking probability

density functions and moments of the modeled quantities [122]. However, in this book no further consideration is given to the second order closure models.

For the purpose of reactor modeling, and in particular for multiphase systems, virtually only first order closures are adopted. Extensive use is made of the simple gradient transport hypothesis, even though it has long been realized that a gradient transport model requires (among other things) that the characteristic scale of the transporting mechanism must be small compared with the distance over which the mean gradient of the transported property changes appreciably [24]. In practice, this requirement is often violated and there exists experimental evidence that the gradient-diffusion models are not sufficiently accurate for variable density flows (e.g., [49]). Counter-gradient (or up-gradient) transport may even occur in certain occasions [101, 155]. In atmospheric simulations this phenomenon might be physically explained by large eddy transport of heat from hot to cold areas, regardless of the local gradient of the background environment. Nevertheless, the second order closure models are avoided and usually not employed in industrial reactor flow simulations due to their complexity, negligible gain in accuracy and predictivity, and because of additional numerical convergence- and stability problems. Rather, the present trend in reactor modeling is to explore the capabilities of the large eddy simulation (LES) model.

### 1.3.6 Large Eddy Simulation

In this section the elementary concepts of the large eddy simulation (LES) technique are examined. The LES approach has been thoroughly assessed by [27, 29, 30, 45, 46, 53, 66, 98–100, 106, 109, 110, 122, 129, 134, 138, 141, 142, 144, 151, 175]. These reports are recommended for complementary studies.

In some flows in boundary layer meteorology there appears to be a distinct lack of velocity variations at certain intervals of time periods or frequency intervals (e.g., [172]). The separation of scales is evident in the measured spectrum where the spectral gap appears as a wave number region containing very low energy separating the micro scale from the macro scale peaks. Motion to the left of the gap are said to be associated with *the mean flow*. Motions to the right constitute *turbulence*. Hence, *the spectral gap* provides a means to separate the turbulent from the non-turbulent influences on the flow (see also [138], p. 82). Most of the operational numerical weather prediction models use grid spacings or wavelength cutoffs that fall within the spectral gap. This means that larger scale motions can be explicitly resolved and deterministically forecasted. The smaller scale motions, namely turbulence, are not explicitly resolved. Rather, the effects of those sub-grid scales on the larger scales are approximated by turbulence models. These smaller size motions are said to be parameterized by sub-grid scale stochastic (statistical) approximations or modes. The referred experimental data analyzes of the flow in the atmospheric boundary layer determine the basis for the large eddy simulation (LES) approach developed by meteorologists like Deardorff [27, 29, 30]. Large-Eddy Simulation (LES) is thus a relatively new approach to the calculation of turbulent flows. The basic idea also stems from two additional experimental observations (see also the historical LES out-

line by Moin and Kim [110]). First, the large-scale structure of turbulent flows varies greatly from flow to flow and is consequently difficult, if not impossible, to model in a general way. Secondly, the small-scale turbulence structures are nearly isotropic, very universal in character, and hence much more amenable to general modeling. In LES, one actually calculates the large-scale motions in a time-dependent, three-dimensional computation, using for the large-scale field dynamical equations that incorporate relative simple models for small-scale turbulence. Only the part of the turbulence field with scales that are small relative to the overall dimensions of the flow field is modeled. This in contrast to phenomenological turbulence modeling, in which all the deviations from the mean velocity profile are modeled. A typical LES calculation for wall-bounded turbulent flows imposes a great demand on computer speed and memory. At present, therefore, the use of LES for practical engineering applications is admittedly uneconomical. Thus, according to Reynolds [129], LES came to the attention of the engineering research community about a decade after it had been pioneered by scientists in weather forecast [102]. However, several considerations motivate the present development of the LES method in the engineering community. First, the information generated by simple flow calculations can be used as a research tool in studies of the structure and dynamics of turbulence. Secondly, the various correlations that can be obtained from the computed large-scale field may be used in developing phenomenological turbulence models for complex flows. Thirdly, the great bulk of routine engineering calculations of turbulent flows will always be made with the most economical representations of the turbulence that provide adequate predictions. For complex flows that are three dimensional, 3D calculations must be made with an appropriate approach. For these flows LES may actually prove to be faster and cheaper than the other turbulence models having the sophistication necessary to capture the complex effects [129]. The main reason for this is that the present methods based on the time (or ensemble) averaged Navier-Stokes equations require considerable experimental validation to be useful since it is difficult to develop a universal turbulence model representing all eddy sizes. Therefore, even with the experimental data available, the range of applicability of a particular model may be limited. However, the cost of experimental research requires that model simulations should be carried out minimizing the number of experiments needed. Large eddy simulations is a compromise which attempts to fill the gap. The hypothesis is that by modeling just the small eddies, it may be possible to develop models which are sufficiently flow independent. According to Ferziger and Leslie [46], this is the premise of LES. To provide an introductory mathematical description of the basic idea of Large Eddy Simulations, we consider the turbulent energy spectra. Suppose that we do not attempt to simulate all the wavenumber modes up to the viscous cutoff ( $> k_d$ ). Instead, we only simulate modes for which  $k \leq k_C$ , where the chosen cutoff wavenumber  $k_C$  satisfies the condition  $k_C \ll k_d$ . The situation we are envisaging in engineering practice is illustrated schematically in Fig. 1.8. Note that in engineering practice the cutoff wavenumber is often apparently arbitrarily chosen due to the missing energy gap in the energy spectrum, whereas in the geophysical sciences the choice of cutoff wavenumber  $k_C$  is not arbitrary but based on physical interpretations of experimental data (e.g., [155]).

**Fig. 1.8** The energy spectrum divided into resolved scales ( $k < k_C$ ) and subgrid scales ( $k > k_C$ ), for the purpose of large-eddy simulation

However, the theoretical interpretation of LES is that we are simulating the Fourier-transformed Navier-Stokes equation with its wavenumber representation truncated to the interval  $0 \leq k \leq k_C$ . In accordance with the theory of Taylor [165] the non-linear convection term couples all wave numbers together thus the overall effect is a net transfer of energy from any one wavenumber to higher wave numbers<sup>41</sup> [107]. Hence, if we truncate at  $k = k_C$ , we are removing the mechanism by which energy is transferred from wave numbers below  $k_C$  to those above. In practice, such a simulation would fail because energy would be cascaded down to  $k = k_C$  and would pile up at the cutoff. To solve this problem we usually introduce an apparent viscosity, an analog to the eddy viscosity known from the foregoing discussion but with a different physical interpretation, to represent the effect of energy transfers to  $k > k_C$ . As can be seen from Fig. 1.8, the larger eddies ( $\lambda > \lambda_C$ , or  $k < k_C$  as  $\lambda = 2\pi/k$ ) carry most of the turbulent kinetic energy and most of the turbulent fluxes. Accordingly, in the ideal case, the smallest eddies carry only a small fraction of the turbulent kinetic energy and hardly any turbulent fluxes. Therefore, assuming that the energy flux to  $k > k_C$  is almost negligible, a rough model for it may still be sufficient providing accurate solutions for the larger eddies. LES can also be performed in physical space, using the governing equations in a more familiar

<sup>41</sup> If energy is feed into a certain band of scales, then turbulence has the tendency to distribute energy in a wave number space from the given mode to all other possible modes. In the absence of sources and sinks of energy, this process will continue to complete redistribution. However, in reality, geometry limits the lower end wave numbers and the viscosity damps out energy at high wave numbers. In order to balance the dissipation, more energy has to be transported from the large to small length scales. This is the reason for having a one-way transfer of energy from small to high wave numbers. Thus, the sub-grid scale model has to mimic the drainage of energy from the large scales.

form. *The flow problems are then simulated using a 3D time-dependent numerical integration scheme which numerically resolves scales in between a lower limit of the order  $\Delta$  as given by the grid scale or any equivalent resolution limit of the numerical integration scheme, and an upper limit as given by the size of the computational domain.* Basically, in further details, there are four conceptual steps in LES ([122], Chap. 13):

1. A *filtering* operation is defined to decompose the velocity,  $\mathbf{v}(\mathbf{r}, t)$ , into the sum of a filtered (or resolved) component,  $\tilde{\mathbf{v}}(\mathbf{r}, t)$ , and a residual (or sub-grid-scale, SGS) component,  $\mathbf{v}'(\mathbf{r}, t)$ :

$$v_i = \tilde{v}_i + v'_i \quad (1.475)$$

2. The equations for the evolution of the filtered velocity field are derived from the Navier-Stokes equations.
3. Closure is obtained by modeling the residual-stress tensor, most simply by an eddy-viscosity model.
4. The filtered model equations are solved numerically for  $\tilde{\mathbf{v}}(\mathbf{r}, t)$ , which provides a 3D and time dependent approximation to the large scale motions in one realization of the turbulent flow.

There are, however, two viewpoints on the separation of the modeling issues (i.e., points 1–3 above) from the numerical solution (i.e., point 4 above):

- In one point of view, as expressed by Reynolds [129], the two issues are considered separately. The filtering and modeling are independent of the numerical method, and the closures are independent of the numerical grid used. Hence, the terms ‘filtered’ and ‘residual’ are more appropriate than the usual ‘resolved’ and ‘sub-grid’ phrases. In this case it is also expected that the numerical method provides accurate solutions to the filtered equations. In practice, however, the modeling and numerical issues are always connected. In this approach the governing equations are usually transformed and solved numerically in wave number space by use of very accurate spectral methods. The present LES concept has in most cases been used as a research tool to study isotropic and homogeneous turbulence within the more theoretical fields of science. Note that the residual-stress models for homogeneous turbulence are not adequate describing industrial non-isotropic inhomogeneous turbulent flows ([122], Chap. 13; [138]).
- The alternative interpretation is that modeling and numerical issues should deliberately be combined. The governing equations are then solved in physical space often using a second order accurate finite difference or finite volume algorithm. This LES concept is usually preferred in engineering practice. Note also that the residual-stress models used in physical space are usually different from those used in wave number space ([122], Chap. 13; [138]). In the numerical solution of the LES momentum equation, various numerical errors are incurred, the most important being the spatial truncation error. One way to express this error is through

the modified equation, which is the PDE satisfied by the numerical solution. The modified equation corresponding to the LES momentum equation can be written:

$$\frac{\tilde{D}\tilde{v}_j}{\tilde{D}t} = \nu \frac{\partial^2 \tilde{v}_j}{\partial x_i \partial x_i} - \frac{\partial}{\partial x_j} (\tilde{\sigma}_{ij}^R - \tilde{\sigma}_{ij}^n) - \frac{1}{\rho} \frac{\partial \tilde{p}}{\partial x_j} \quad (1.476)$$

It is noted that the spatial-truncation error appears as an additional numerical stress,  $\tilde{\sigma}_{ij}^n$ , which depends on the grid spacing  $h$ . If the spatial discretization is  $p$ -th order accurate, then  $\tilde{\sigma}_{ij}^n$  is of order  $h^p$ .

There are also differing viewpoints on the role of the numerical stress in LES. The simplest view is that the LES equations should be solved accurately. That is, for a given filter width,  $\Delta$ , the grid spacing  $h$  should be chosen to be sufficiently small so that the numerical stress,  $\tilde{\sigma}_{ij}^n$ , is negligible compared with the modeled residual stress  $\tilde{\sigma}_{ij}^R$ . Kinetic energy is removed from the resolved motions by numerical dissipation at the rate  $\epsilon_{\text{num}} = -\tilde{\sigma}_{ij}^n \tilde{S}_{ij}$ . The opposite viewpoint, advocated by Boris et al. [16], is that no explicit filtering should be performed and no explicit residual stress model should be used ( $\tilde{\sigma}_{ij}^R = 0$ ). Instead, an appropriate numerical method is used to attempt to solve the Navier-Stokes equation for  $\tilde{\mathbf{v}}(\mathbf{r}, t)$ . Because the grid is not fine enough to resolve the solution to the Navier-Stokes equation, significant numerical stresses  $\tilde{\sigma}_{ij}^n$  arise. Thus, filtering and residual-stress modeling are performed implicitly by the numerical method. The numerical stress  $\tilde{\sigma}_{ij}^n$  depends on the type of numerical method used, and hence this choice is crucial. The ideal scheme is accurate for the well-resolved contributions to  $\tilde{\mathbf{v}}(\mathbf{r}, t)$ , while it attenuates poorly resolved shorter-wave length contributions. Compared with explicit modeling of the residual stresses, this approach has advantages and disadvantages, advocates and detractors. The advantages are that for a given grid size as much as possible of the turbulent motion is represented explicitly by the LES velocity field  $\tilde{\mathbf{v}}(\mathbf{r}, t)$ , and that energy is removed from  $\tilde{\mathbf{v}}(\mathbf{r}, t)$  only where and when it is necessary to do so. A further advantage is that the time and effort required to develop and test a residual-stress model are eliminated. The primary disadvantage is that the modeling and the numerics are inseparably coupled. Another disadvantage is that there is no representation or estimation of the sub-grid scale motions that can be used for defiltering or in models for other sub-grid scale processes.

Leonard [98] was apparently the first to use the term *Large Eddy Simulation*. He also introduced the idea of filtering as a formal convolution operation on the velocity field and gave the first general formulation of the method. Since Leonard's approach form the basis for application of LES to chemical reactor modeling, we discuss this approach in further details.

Leonard [98] defined a generalized filter as a convolution integral<sup>42</sup>:

---

<sup>42</sup> *Convolution*, the word comes from the folding together, one part upon another. In mathematics convolution can be considered as a generalized product of functions. In this context the purpose for introducing a convolution integral is to extend the integral over the whole flow field domain. Lower limit is  $-\infty$ , and upper limit is  $\infty$ . The filtering function  $G(\mathbf{r} - \boldsymbol{\xi}; \Delta)$  is a normalized weighting function with characteristic length  $\Delta$ . The argument  $\mathbf{r} - \boldsymbol{\xi}$  is a reminder for the limits of the original

**Fig. 1.9** Possible spatial filters defining large-scale quantities with  $G = G_1 G_2 G_3$ . The filter denoted by **a** is the volume-averaged box filter, the filter denoted by **b** is the Gaussian filter, and the filter denoted by **c** is the sharp cutoff filter. Note that the position vector,  $\mathbf{x}$ , used by Leonard corresponds to  $\mathbf{r}$  in this book. Reprinted from Leonard [98] with permission from Elsevier

$$\tilde{v}_i(\mathbf{r}, t) = \iiint G(\mathbf{r} - \boldsymbol{\xi}; \Delta) v_i(\boldsymbol{\xi}, t) d^3 \boldsymbol{\xi} \quad (1.477)$$

where  $G$  represents the filter function and the tilde denotes the large scale (or resolved) part of the velocity field. Over the years numerous filters have been proposed and used for performing the spatial scale separation (e.g., [138]).

The *filter function*,  $G$ , is normalized by requiring that:

$$\iiint G(\mathbf{r} - \boldsymbol{\xi}; \Delta) d^3 \boldsymbol{\xi} = 1 \quad (1.478)$$

Three classical filters for large eddy simulation, as given by Leonard [98], are sketched in Fig. 1.9.

---

(Footnote 42 continued)

integral,  $\boldsymbol{\xi} \in (\mathbf{r} - \frac{1}{2}\Delta\mathbf{r}, \mathbf{r} + \frac{1}{2}\Delta\mathbf{r})$ . The symbol  $d\boldsymbol{\xi}$  should still be thought of as simply an indication of what the independent variables are.

In terms of the filter function (1.477), the volume-averaged box filter as defined in (1.492) is given by (e.g., [98, 138, 185]):

$$G(r_i - \xi_i; \Delta) = \begin{cases} 1/\Delta & \text{if } |r_i - \xi_i| \leq \Delta r_i/2, \\ 0 & \text{Otherwise} \end{cases} \quad (1.479)$$

The filter is sketched in Fig 1.9a. The physical box filter is not sharp in wave number space.

A Gaussian filter as sketched in Fig. 1.9b, is defined by:

$$G(r_i - \xi_i; \Delta) = \left(\frac{6}{\pi\Delta^2}\right)^{1/2} \exp\left(-6\frac{|r_i - \xi_i|^2}{\Delta^2}\right) \quad (1.480)$$

The Gaussian filter is fairly sharp both in physical space and in wave number space. This filter was for example used by Ferziger [45]. The Fourier transform of (1.477) is  $\widehat{\widehat{v}}_i(\mathbf{k}, t) = \widehat{G}(\mathbf{k})\widehat{v}_i(\mathbf{k}, t)$ , where  $\widehat{v}_i$  and  $\widehat{G}$  represent the Fourier transforms of  $v_i$  and  $G$ , respectively (e.g., [122, 134, 138, 185]).

A Fourier transform of the filter shown in Fig. 1.9c is a spectrally sharp cutoff filter, a kind of box filter in  $\mathbf{k}$ -space rather than  $\mathbf{r}$ -space. The spectrally sharp top-hat filter, i.e., the filter normally used in spectral simulations, is in physical space defined by (e.g., [98, 107]):

$$G(r_i - \xi_i; \Delta) = \frac{2 \sin(\pi(r_i - \xi_i)/\Delta)}{\pi(r_i - \xi_i)} \quad (1.481)$$

In physical space this filter is not sharp, as shown from the sketch in Fig. 1.9c.

The significance of the sharp spectral filter is apparent, it annihilates all Fourier modes of wave number  $|k|$  greater than the cutoff wave number,  $k_C = \pi/\Delta$ , whereas it has no effect on the lower wave number modes.

Illustrating the Reynolds averaging procedure in the previous sects. we started by formulating the average incompressible conservation equations for mass and momentum written in Cartesian coordinates, i.e., (1.388) and (1.389). Performing the corresponding derivation of the filtered LES equations we highlight the main similarities and differences between these two modeling approaches. The filter operation defined by (1.477) is sometimes written in the contracted form (e.g., [107, 138]), intending to make the text more easy to follow:

$$\widetilde{v}_i(\mathbf{r}, t) = G^* \{v_i\} \quad (1.482)$$

The continuity equation is a relatively simple starting point formulating the LES equations, neatly demonstrating the filtering procedure. Applying the mathematical operator  $G$ , defined according to (1.482), on (1.388) using a homogeneous filter (e.g.,

[122], Chap. 13; [141], p. 380) yields<sup>43</sup>:

$$G^*\left\{\frac{\partial v_i}{\partial x_i}\right\} = \frac{\partial}{\partial x_i}(G^*\{v_i\}) = \frac{\partial \tilde{v}_i}{\partial x_i} = 0 \quad (1.488)$$

It follows from (1.388), (1.482), and (1.488) that the resolved scales satisfy the continuity equation given by:

$$\frac{\partial \tilde{v}_i}{\partial x_i} = 0 \quad (1.489)$$

Considering the Navier-Stokes equation (1.389), the linear terms are straightly treated in a similar manner but, as in the Reynolds averaging procedure, the non-linear terms require further analysis. Applying the filter operator (1.482) on the non-linear terms in (1.389), yields:

$$\frac{\partial \tilde{v}_i}{\partial t} + \frac{\partial \tilde{\sigma}_{ij}}{\partial x_j} = -\frac{1}{\rho} \frac{\partial \tilde{p}}{\partial x_i} + \nu \frac{\partial^2 \tilde{v}_i}{\partial x_j \partial x_j} \quad (1.490)$$

in which the filtered non-linear term,  $\tilde{\sigma}_{ij}$ , is given by [98]:

---

<sup>43</sup> This result can be proven by integration by parts with respect to  $\xi$ , provided only that  $v_i$  vanishes on the boundaries [107]:

$$\frac{\partial}{\partial x_i} \int G v_i d^3 \xi = \int \frac{\partial}{\partial x_i} (G v_i) d^3 \xi = \int G \frac{\partial v_i}{\partial x_i} d^3 \xi + \int \frac{\partial G}{\partial x_i} v_i d^3 \xi \quad (1.483)$$

or

$$\frac{\partial}{\partial x_i} (G^*\{v_i\}) = G^*\left\{\frac{\partial v_i}{\partial x_i}\right\} + \int \frac{\partial G}{\partial x_i} v_i d^3 \xi \quad (1.484)$$

It is noted that:

$$\int \frac{\partial G}{\partial x_i} v_i d^3 \xi = 0 \quad (1.485)$$

provided that  $v_i = 0$  at the boundaries.

Then,

$$G^*\left\{\frac{\partial v_i}{\partial x_i}\right\} = \frac{\partial}{\partial x_i} (G^*\{v_i\}) = \frac{\partial \tilde{v}_i}{\partial x_i} \quad (1.486)$$

thus the resolved scales satisfy the continuity equation.

Pope ([122], p. 562) shows that the operation of filtering and differentiating with respect to time commute. Pope also indicate that if we differentiate (1.477) with respect to  $x_j$  we will obtain the result

$$\frac{\partial \tilde{v}_i}{\partial x_i} = \widetilde{\frac{\partial v_i}{\partial x_i}} + \int v_i \frac{\partial G(\xi, \mathbf{r})}{\partial x_i} d^3 \xi \quad (1.487)$$

showing that the operations of filtering and differentiation with respect to position do not commute in general, but do so for homogeneous filters.

$$\begin{aligned}
\tilde{\sigma}_{ij} &= G^*\{v_i v_j\} = G^*\{\tilde{v}_i \tilde{v}_j + v'_i \tilde{v}_j + \tilde{v}_i v'_j + v'_i v'_j\} \\
&= \widetilde{v_i v_j} = \widetilde{\tilde{v}_i \tilde{v}_j} + \widetilde{v'_i \tilde{v}_j} + \widetilde{\tilde{v}_i v'_j} + \widetilde{v'_i v'_j} \\
&= \tilde{v}_i \tilde{v}_j + (\widetilde{\tilde{v}_i \tilde{v}_j} - \tilde{v}_i \tilde{v}_j) + (\widetilde{v'_i \tilde{v}_j} + \widetilde{\tilde{v}_i v'_j}) + \widetilde{v'_i v'_j} \\
&= \tilde{v}_i \tilde{v}_j + \tilde{L}_{ij} + \tilde{C}_{ij} + \tilde{R}_{ij} \\
&= \tilde{v}_i \tilde{v}_j + \tilde{\sigma}_{ij}^R
\end{aligned} \tag{1.491}$$

where the instantaneous velocity field has been decomposed into resolved and sub-grid scales by use of (1.475).

The above equations describe the large-scale motion.  $\tilde{L}_{ij}$  represents the interactions among the large scales. The effect of small scales appears through the residual stress tensors (i.e.,  $\tilde{C}_{ij}$  and  $\tilde{R}_{ij}$ ). In particular,  $\tilde{C}_{ij}$  represents the interactions between the large and small scales, and  $\tilde{R}_{ij}$  reflects the interactions between subgrid scales. The tensors  $\tilde{L}_{ij}$ ,  $\tilde{C}_{ij}$  and  $\tilde{R}_{ij}$  are known as the *Leonard stress*, *cross-term stress* and the *residual Reynolds stress*, respectively. At first sight comparing the Reynolds decomposition and time averaging procedure with the corresponding steps in the filtering procedure there are certainly similarities, but also a few essential differences. Obviously, considering the Leonard stress terms, the filtering differs from the standard Reynolds averaging in one important respect,  $\tilde{\tilde{v}}_i \neq \tilde{v}_i$ . That is, a second averaging yields a different result from the first averaging ([53], Chap. 6). In a similar manner, considering the cross-term stress, we recognize that  $\tilde{v}'_i \neq 0$ . Comparing the resulting filtered equations of motion with the corresponding equations of mean motion obtained by Reynolds averaging the instantaneous equations, it is noted that the continuity equation (1.489) is formally identical with (1.392) for continuity, if we replace  $\tilde{\tilde{v}}_i$  by  $\tilde{v}_i$ . There are also similarities between the Reynolds averaged and the Leonard filtered Navier-Stokes equations, as given by (1.393) and (1.490), respectively. The important differences lie in the presence of the cross-term stress term,  $\tilde{C}_{ij}$ , and the Leonard stress,  $\tilde{L}_{ij}$ , in (1.490). The Leonard stress term on the RHS of (1.491) is not a residual tensor, as it involves only the explicit scales and the filter function. The computation of the Leonard stresses may still cause practical difficulties as it requires a second application of the filter, but in principle there is no fundamental closure problem. However, even though there are formal similarities, an essential conceptual difference is that the Reynolds equations involve a mean field which is stationary, or slowly varying with time, and varies smoothly in space, while the large eddy simulations involve a field which may be extremely chaotic in space and time if the numerical grid spacing is small enough [99]. If the grid spacing is increased too much, however, the solution of the LES will, in some sense, converge towards the mean flow. In the other extreme limit, reducing the grid spacing sufficiently, a direct numerical simulation (DNS) is achieved.

In the following paragraphs only the engineering LES practice is considered, as this approach is relatively simple and based upon FD and FVM algorithms (i.e., note that almost all reactor models are discretized by the FVM). The first engineering LES was Deardorff's [27] simulation of plane channel flow. Deardorff used Reynolds

(spatial) averaging, applied to a unit cell of the finite difference mesh, to define the larger (or resolved) scales, and introduced the terminology *filtered variables*. Although only 6720 grid points were used, the comparison with literature laboratory experiments was sufficient favorable for the feasibility of the method to have been established. The volume-average box filter used by Deardorff [27] is sketched in Fig. 1.9a. In Cartesian coordinates the filter is [138, 185]<sup>44</sup>:

$$\tilde{v}_i(\mathbf{r}, t) = \frac{1}{\Delta^3} \int_{x-\frac{1}{2}\Delta x}^{x+\frac{1}{2}\Delta x} \int_{y-\frac{1}{2}\Delta y}^{y+\frac{1}{2}\Delta y} \int_{z-\frac{1}{2}\Delta z}^{z+\frac{1}{2}\Delta z} v_i(\boldsymbol{\xi}, t) d\xi d\eta d\zeta \quad (1.492)$$

The quantity  $\tilde{v}_i$  denotes the *resolvable-scale filtered velocity*.

For finite difference and finite volume discretizations using the box filter, the *filter width*,  $\Delta$ , yields:

$$\Delta = h = (\Delta x \Delta y \Delta z)^{\frac{1}{3}} \quad (1.493)$$

To fully understand this concept of filtering, note that the values of flow properties at discrete points in a numerical simulation represent averaged values. To illustrate this explicitly, Rogallo and Moin [134] considered the central difference approximation for the first derivative of a continuous variable,  $v(x)$ , in a grid with points spaced a distance  $h$  apart. We can write this as follows (e.g., [134], p. 103; [185], p. 323):

$$\frac{d\tilde{v}}{dx} \approx \frac{\tilde{v}(x+h) - \tilde{v}(x-h)}{2h} = \frac{d}{dx} \left[ \frac{1}{2h} \int_{x-h}^{x+h} v(\xi) d\xi \right] \quad (1.494)$$

This shows that the central-difference approximation can be thought of as an operator that filters out scales smaller than the mesh size. Furthermore, the approximation yields the derivative of an averaged value of  $\tilde{v}(x)$ .

In practice, the Leonard stress is often dominated by the numerical errors inherent in the finite difference (and finite volume) representation and is thus neglected or lumped into the deviatoric stress tensor (e.g., [98, 107]; [185], p. 325). Consequently, as the box filter is applied to the Navier-Stokes equation, the residual stresses assume the form of sub-grid scale stresses:

$$\tilde{\sigma}_{ij}^R = \widetilde{v_i v_j} - \tilde{v}_i \tilde{v}_j = (\widetilde{v_i v_j} - \tilde{v}_i \tilde{v}_j) + (\widetilde{v'_i v'_j} + \widetilde{v'_i v'_j}) + \widetilde{v'_i v'_j} = \tilde{L}_{ij} + \tilde{C}_{ij} + \tilde{R}_{ij} \approx \tilde{C}_{ij} + \tilde{R}_{ij} \quad (1.495)$$

These stresses are similar to the classical Reynolds stresses that result from time or ensemble averaging of the advection fluxes, but differ in that they are consequences of a spatial averaging and go to zero if the filter width  $\Delta$  goes to zero. For LES performed in physical space, the basic sub-grid stress model is the eddy-viscosity

<sup>44</sup> Note that in these formulations a formal mathematical notation is used.  $\mathbf{r}$  is the position vector, while in the integrand we strictly need to use a vector which has components somewhere between the integration limits. The symbols  $d\xi$ ,  $d\eta$ , and  $d\zeta$  should be thought of as simply an indication of what the independent variables are.

model proposed by Smagorinsky.<sup>45</sup> The Smagorinsky model is based on the gradient transport hypothesis and the sub-grid viscosity concept, just as the Reynolds stress models based on the Boussinesq eddy viscosity hypothesis, and expressed as:

$$\tilde{\sigma}_{ij}^R = -2\nu_{SGS,t}\tilde{S}_{ij} + \frac{\delta_{ij}}{3}(\tilde{C}_{kk} + \tilde{R}_{kk}) \quad (1.496)$$

The model is based on the assumption of proportionality between the anisotropic part of the SGS-stress tensor,  $\tilde{\sigma}_{ij}^d = \tilde{\sigma}_{ij}^R - \frac{\delta_{ij}}{3}(\tilde{C}_{kk} + \tilde{R}_{kk})$ , and the large scale strain-rate tensor,  $\tilde{S}_{ij}$ . Hence,

$$\tilde{\sigma}_{ij}^d = -2\nu_{SGS,t}\tilde{S}_{ij} \quad (1.497)$$

where  $\tilde{\sigma}_{ij}^d$  denotes the deviator of  $\tilde{\sigma}_{ij}^R$ . This deviatoric tensor is necessary since the residual stress model being proportional to the large scale strain-rate tensor has a zero trace, thus we can only model a tensor that also has a zero trace.

Leonard [98] defined the complementary tensor,  $\frac{\delta_{ij}}{3}(\tilde{C}_{kk} + \tilde{R}_{kk})$ , and suggested that this term can be added to the filtered pressure,  $\tilde{p} + \frac{\delta_{ij}}{3}(\tilde{C}_{kk} + \tilde{R}_{kk})$ . In this way the complementary tensor requires no modeling. Analogous to the average turbulent kinetic energy quantity, one can also define a sub-grid scale kinetic energy variable,  $k_{SGS} = \frac{1}{2}(\tilde{C}_{ii} + \tilde{R}_{ii})$ . Hence, the anisotropic SGS tensor is given by  $\tilde{\sigma}_{ij}^d = \tilde{\sigma}_{ij}^R - \frac{2}{3}k_{SGS}\delta_{ij}$ . Thereafter, the closure consists in determining the SGS eddy viscosity parameter. By analogy to the mixing length hypothesis, the Smagorinsky [151] model is defined as:

$$\nu_{SGS,t} = l_S^2 \tilde{S} \approx (C_S \Delta)^2 \tilde{S} \quad (1.498)$$

where  $\tilde{S} \approx (2\tilde{S}_{ij}\tilde{S}_{ij})^{1/2}$  is the characteristic filter rate of strain,  $\tilde{S}_{ij} = \frac{1}{2}(\frac{\partial \tilde{v}_i}{\partial x_j} + \frac{\partial \tilde{v}_j}{\partial x_i})$ ,  $C_S$  denotes the Smagorinsky constant,  $l_S$  denotes the Smagorinsky lengthscale (analogous to the mixing length), and the generalized filter width  $\Delta$  is a characteristic length scale of the resolved eddies (e.g., [99, 107]; [122], Chap. 13; [134, 151, 185]). Recall that in the present case,  $\Delta$  is proportional to the grid spacing,  $h$ .

If the grid scale  $h$  is close to the scale of the most energetic motions, such a simulation is called a *very large eddy simulation* (VLES) [129]. In LES, the filtered velocity field accounts for the bulk (say 80 %) of the turbulent kinetic energy everywhere in the flow field ([122], Chap. 13). In VLES the grid and filter are too large to resolve the energy-containing motions, and instead a substantial fraction of the energy resides in the residual motions. A VLES thus demands for more accurate sub-grid scale models than a LES in which the sub-grid scale fluxes and variances are small. Accurate modeling of the fluxes itself is necessary only where the sub-grid

<sup>45</sup> The original idea of performing LES is due to Smagorinsky [151], who applied the technique to shear flows calculating the general circulation of the atmosphere on a finite difference grid and represented the drain of energy to turbulent scales smaller than the grid spacing  $h$  (i.e., the *sub-grid scales*) by a sub-grid model based on the effective viscosity hypothesis.

scales fluxes get large in comparison to the resolved fluxes. However, such a VLES may still be more accurate than a turbulence model which aims to describe all scales of motion together in one model [144]. Some researchers reserve the term LES for the case where the filter scale  $\Delta$  corresponds to a wavenumber in the  $k^{-5/3}$  inertial range, and the term VLES when the residual field begins before the inertial range [129]. The reason for this filter scale limit of subdivision between LES and VLES stems from the derivation of the Smagorinsky constant. Basically, the early LES models were constructed assuming that turbulence at the sub-grid scales corresponds to the Kolmogorov [84] inertial range of turbulence [102]. In particular, adopting the five-third law valid at these scales theoretical values for the Smagorinsky constant can be derived (e.g., [102, 122, 138]). For a coarser filter width, as those adopted in VLES, the assumption that the sub-grid scales corresponds to the inertial range of turbulence is significantly violated and the micro eddy movement is far from being isotropic and is not sufficiently independent of the macro eddy movement. Therefore, in VLES no analytical estimate of the Smagorinsky constant exists. However, apparently the value of  $C_S$  is not universal in LES either. In practice,  $C_S$  is adjusted to optimize the model results. Deardorff [28, 29] quoted several values of  $C_S$  based on Lilly's estimates. The exact value chosen depends on various factors like the filter used, the numerical method used, resolution, and so forth, but they are generally of the order of  $C_S = 0.2$ . However, from comparison with experimental results, Deardorff concluded that the constant in the Smagorinsky effective viscosity model should be smaller than this, and a value of about  $C_S = 0.10$  was used. In addition, for the case of an anisotropic resolution (i.e., having different grid width  $\Delta x$ ,  $\Delta y$  and  $\Delta z$  in the different co-ordinate directions), the geometry of the resolution has to be accounted for. Like all other models, LES requires the specification of proper boundary and initial conditions in order to fully determine the system and obtain a mathematically well-posed problem. However, this concept deviates from the more familiar average models in that the boundary conditions apparently represent the whole fluid domain beyond the computational domain. Therefore, to specify the solution completely, these conditions must apply to all of the space-time modes it comprises.

For 3D simulations of chemical reactors we generally need to specify inlet-, outlet- and wall boundary conditions. In such wall bounded flows the finest grid resolution is determined by the flow near walls where most of the turbulence energy production occurs. For industrial reactor simulations it is thus desirable to avoid the high cost of resolving the wall boundary layer by adopting the statistically average wall function approach based on the logarithmic law of the wall in line with the work of Deardorff [27], Schumann [141] and Moin and Kim [110]. The boundary conditions normally used in practical LES applications are neatly examined by Sagaut [138] and Pope [122]. It is noticed that the structure of the boundary layer flow has certain characteristics that require special treatment in LES [138]. That is, experimental and numerical investigations have revealed important dynamic processes within the boundary layer (e.g., anisotropic and intermittent bursting events, quasi-longitudinal and arch structures, etc.) that induce strong variations in the Reynolds stresses, and in the production and dissipation of the turbulent kinetic energy. Resolving these near wall dynamics directly is still not feasible, and the existing sub-grid wall models

are not sufficiently accurate. Another severe difficulty occurs at the reactor outlet boundary. Unfortunately, at such open boundaries the flow variables depend on the unknown flow outside the domain. However, this issue is not specific to LES, but constitutes a problem for most reactor simulations. The specification of accurate inlet conditions may also be a problem, since the flow upstream of the computational domain is usually not known in sufficient details (i.e., recall that we need to specify the space-time modes). In addition, the influence of the upstream conditions may persist for large distances downstream. Apparently, it is generally not clear how to specify suitable boundary conditions performing reactor LES analysis.

In an ideal single phase reactor flow situation a LES simulation could be initiated as a laminar flow, and by gradually increasing the inlet velocity the flow will evolve to a sufficiently high Reynolds number laminar flow. Then, by any physical disturbance the flow will sustain these instabilities and a flow regime transition from laminar to turbulent flow will take place. In a numerical simulation the necessary sustainable instabilities required for the flow regime transition to occur are caused by numerical instabilities normally emerging after a relatively long simulation time period. Of course, it is also possible that these numerical instabilities might grow or sustain as a pure numerical mode and do not represent physical turbulence so a proper validation procedure is necessary. To reduce the simulation time for the initial stage of the flow calculation obtaining fully turbulent flows, forced perturbations are commonly added to make the flow unstable and then evolving to become turbulent if the Reynolds number is sufficiently large. That is, it might not be necessary to add such perturbations deliberately as it is very difficult to specify consistent 3D fields for all the physical quantities involved to initialize the calculation. In practice, using inaccurate initial conditions, the flow develops neatly becoming fully turbulent but the higher order statistics might be physically realistic only after a certain adjustment period [134].

Applying LES the numerical resolution used is crucial achieving sufficiently accurate solutions. Schumann [144] stated that the size of the calculation domain should be large in comparison to the scale of the most energetic eddies. A reason for this requirement is that in LES the resolution requirements are determined directly by the range of scales contributing to the desired statistics and indirectly by the accuracy of the model [134]. The less accurate the model, the further the model scales must be separated from the scales of interest. This requirement may represent a problem in reactor simulations as the largest eddies are comparable to the reactor dimensions. Accordingly, if the size of the calculation domain adopted is too small we may neither get sufficient data for reliable statistics. Another numerical resolution requirement is that the scale  $h$  has to be much smaller than the scale of the large eddies. In VLES the grid scale  $h$  may be close to the most energetic motions but still smaller.

Validating LES, comparing the model predictions with experimental results, is also crucial. One must then ensure that the filtered experimental statistics are compared with the corresponding statistics of the filtered field. Alternatively, one can compare the total field statistics from the simulation with the corresponding experimental data [129].

Progress in LES has taken place in various directions. Seeking more accurate models it might be natural to incorporate non-local effects through transport equations for the residual stresses and other quantities related to the residual motions. These LES model closures parallel the conventional turbulence modeling of Reynolds averaged closures. We have already stated that the Smagorinsky model is deduced from the mixing-length model. Moreover, transport equation models analogous to one-equation models, Reynolds stress models and PDF models have been proposed [122]. The most important difference between the two concepts is that in LES the filter width  $\Delta$  is taken as the characteristic lengthscale of the residual motions, so that no equation is needed for the turbulent length scale (analogous to the model equation for  $\epsilon$ ). The most sophisticated SGS model used so far (i.e., counting the number of PDEs) was designed by Deardorff [30] for application to the atmospheric boundary layer. The model consists of 10 partial differential equations and bears a strong resemblance to a second-order closure model (a Reynolds Stress Model, RSM). In this particular model the dissipation rate is taken to be isotropic, hence the instantaneous dissipation rate  $\epsilon_{SGS}$  of the residual or sub-grid scale kinetic energy ( $k_{SGS} = \frac{1}{2} \tilde{\sigma}_{ii}^R$ ) is related to  $k_{SGS}$  and the filter width by:

$$\epsilon_{SGS} = \frac{C_E k_{SGS}^{3/2}}{\Delta} \quad (1.499)$$

where  $C_E = 0.7$ .

While the model apparently leads to improved predictions, its complexity has discouraged many researchers. Therefore, in a later study Deardorff [31] reverted to an isotropic eddy-viscosity model in order to decrease the computational costs. In the latter model version an additional equation was used to determine the residual kinetic energy, as the eddy viscosity  $\nu_{SGS}$  was expressed by:

$$\nu_{SGS} = C_\nu k_{SGS}^{1/2} \Delta \quad (1.500)$$

where  $C_\nu \approx 0.10$ .

Using the latter two relations we may also approximate the residual dissipation rate, e.g., in terms of the residual viscosity determined by other LES closures, in case this parameter is needed for reactor modeling purposes like in population balance kernels and in species mixing model parameterizations provided that the overall closure models remain consistent [21].

Germano et al. [56] and Germano [57] have devised a new concept that they describe as a *Dynamic SGS Model*. Their formulation is also based on the Smagorinsky eddy-viscosity approximation. However, rather than fixing the value of  $C_S$  a priori, they permit it to be computed as the LES proceeds. This is accomplished by using two filters. A few rather preliminary attempts at performing LES describing turbulent reactive flows have also been reported (e.g., [121, 143]). For the study of chemical processes within the atmospheric boundary layer zero-equation models are usually adopted for the mass fluxes. The variances are generally neglected.

Moin et al. [111] and Erlebacher et al. [44] pushed the frontiers of LES research into compressible flows. They derived a compressible flow SGS model and exercised it in computation of compressible isotropic turbulence. The main difference between incompressible and compressible flow formulations is that, instead of spatial filtering, it is customary to introduce mass weighted or Favre filtering,  $\tilde{f}^\rho = \tilde{\rho}f/\tilde{\rho}$ , in the latter case (e.g., [53]). The Favre-filtered SGS-stresses and the heat flux are then,  $\tilde{\sigma}_{ij} = \tilde{\rho}(\widetilde{v_i v_j} - \tilde{v}_i \tilde{v}_j)$  and  $\tilde{Q}_k = c_P \tilde{\rho}(\widetilde{v_k T} - \tilde{v}_k \tilde{T})$ , where  $T$  is the temperature and  $c_P$  is the specific heat at constant pressure. The results presented are apparently in excellent agreement with DNS results. McComb [107] classified the various LES runs which have been carried out so far as, in effect, tests for sub-grid models. It was noted that variations from one simulation to another, in terms of choice of filter, filter width, grid resolution, and other numerical factors, can easily obscure differences between sub-grid models. Based on an evaluation of several investigations which have been performed specifically aiming at testing sub-grid models, the overall conclusion was that the Smagorinsky model predicts reasonable results and that the various modifications to it have little net effect on the actual LES. It was, however, indicated that when formulating the sub-grid models for LES, as for any constitutive equations, attention have to be drawn to the need to chose sub-grid models in such a way that the equation of motion for the large eddies is invariant under Galilean transformations. This simple requirement may lead to improved sub-grid models. Nevertheless, numerical aliasing errors can violate these invariance properties and lead to nonlinear numerical instabilities [134]. In conclusion, for chemical reactor simulations LES holds promise as a future design tool, especially as computers continue to increase in speed and memory. Basically, it turns out that the VLES approach performs well essentially due to the fine numerical grid resolution used thus an explicit SGS model is of minor importance. The approach is thus very appealing, as the tedious work fitting the turbulence closure to experimental data might be avoided. Apparently, the closure complexity represented by the Smagorinsky model seems sufficient for chemical reactor LES analyzes. Defining proper boundary conditions are presently more demanding.

## Chapter 2

# Elementary Kinetic Theory of Gases

In this chapter emphasis is placed on the mathematical derivation of the governing equations of gas dynamics from first principles using the kinetic theory concepts. The prerequisite elementary concepts and notation of classical mechanics are introduced. The modeling procedure consists in deriving the Boltzmann- or Maxwell-Boltzmann equation determining the evolution of the microscopic single distribution function in phase space. This includes details of the collision operator derivation for elastic binary molecular interactions. The moment of equation of the Boltzmann equation results in the generic equation of change of molecular properties. From this equation the macroscopic conservation equations can be deduced. The closure laws for equilibrium—and non-equilibrium flows give rise to the Euler- and Navier-Stokes equations, respectively. For dilute gases brief surveys of the Enskog theory for solving the Boltzmann equation and the ultra simplified mean free path concept are provided, both shown to be useful methods deriving fundamental closures for the transport coefficients. The extended kinetic theory considering multi-component mixtures is sketched, and three different mass diffusion flux formulations are examined both on the mass and molar basis. An overview of the Enskog theory extending the Boltzmann equation by including volume—and finite molecular size corrections to denser gases is given. The modified Boltzmann equation derived by Enskog is called the *Enskog's equation*. The moment of equation of the Enskog equation constitutes the equation of change of molecular properties for dense gases. Because of the inherent corrections this moment equation contains two contributions to the dense gas fluxes, the flux due to the motion of molecules between collisions as for dilute gas and another flux associated with the collisional transfer which is important in dense gases but vanishes for dilute gas. The closure laws for non-equilibrium flows give rise to the dense gas dynamics equations. For dense gas the estimates of the transport coefficients obtained by use of the Enskog theory for solving the Enskog equation and the ultra simplified mean free path concept are also provided. The resulting set of dense gas conservation equations is the mathematical fundament for the theory of granular material flows considered in Chap. 4.

## 2.1 Introduction

The science of mechanics constitutes a vast number of sub-disciplines commonly considered beyond the scope of the standard chemical engineering education. However, when dealing with kinetic theory-, granular flow- and population balance modeling in chemical reactor engineering, basic knowledge of the principles of mechanics is required. Hence, a very brief but essential overview of the disciplines of mechanics and the necessary prescience on the historical development of kinetic theory are given before the more detailed and mathematical principles of kinetic theory are presented.

*Mechanics* is a branch of physics concerned with the motions of physical bodies and the interacting forces. The science of mechanics is commonly divided into two major disciplines of study called *classical mechanics* and *quantum mechanics*. Classical mechanics, which can be seen as the prime discipline of mechanics, describes the behavior of bodies with forces acting upon them. Quantum mechanics is a relatively modern field of science invented at about 1900. The term classical mechanics normally refers to the motion of relatively large objects, whereas the study of motion at the level of the atom or smaller is the domain of quantum mechanics. Classical mechanics is commonly divided into *statics* and *dynamics*. Statics deals with bodies at rest, while dynamics deals with bodies in motion. The study of dynamics is sometimes further divided into *kinematics* and *kinetics*. Kinematics denotes the description of motion without regard to its cause, while in kinetics one intends to explain the change in motion as a result of forces. A third and very recent branch of dynamics is *non-linear dynamics and chaos*, which denotes the study of systems in which small changes in a variable may have large effects. Frequently we also need to describe the behavior of large populations of interacting molecules in solids, gases and liquids, particulate systems, dense suspensions and dispersions. The science of classical mechanics may thus be grouped according to the state of matter being studied, into *solid mechanics* and *fluid mechanics*, both disciplines are often considered sub-disciplines of *continuum mechanics*<sup>1</sup> dealing with continuous matter. Hence, fluid mechanics or *fluid dynamics* denotes the study of the macroscopic physical properties and behavior of fluids. The continuity assumption, however, considers fluids to be continuous. That is, properties such as density, pressure, temperature, and velocity are taken to be well-defined at infinitely small points, and are assumed to vary continuously from one point to another. The discrete, molecular nature of a fluid is ignored. Hence, in many physical sciences this mathematical representation of the system is considered a simplifying engineering approach often useful in engineering practice, but of limited accuracy especially when the system considered doesn't allow sufficient inherent separation of scales. For those problems for which the continuity assumption does not give answers of desired accuracy we may (not always!)

---

<sup>1</sup> Continuum mechanics is to a large degree based on the Leonhard Euler (1707–1783) axioms published in his book *Mechanica* in 1736–1737.

obtain better results using more fundamental concepts. *Statistical mechanics*<sup>2</sup> is the application of statistics, which includes mathematical tools for dealing with large populations, to the field of dynamics [47, 115, 116, 150]. Although the nature of each individual element of a system and the interactions between any pair of elements may both be well understood, the large number of elements and possible interactions present an infeasible problem to the investigators who seek to understand the behavior of the system. Statistical mechanics provides a mathematical framework upon which such an understanding may be built. There have apparently been two parallel developments of the statistical mechanics theory, which are typified by the work of Boltzmann [10] and Gibbs [47]. The main difference between the two approaches lies in the choice of statistical unit [23]. In the method of Boltzmann the statistical unit is the molecule and the statistical ensemble is a large number of molecules constituting a system, thus the system properties are said to be calculated as average over a phase space trajectory resembling time average properties [53]. In the method of Gibbs the entire system is taken as a single statistical unit and the statistics are those of an ensemble of such systems, hence the system properties are calculated as averages over a large collection of imaginary systems each of which is an independent replica of the system of interest. The collection of independent systems supposedly spans the assembly of all possible micro-states consistent with the constraints with which the system is characterized macroscopically. The very first steps developing the theory dealing with irreversible processes was principally in accordance with the method of Boltzmann as outlined shortly. In the more modern research in statistical mechanics the method of Gibbs [47] has achieved considerable attention as it can be extended in a relatively simple and general way to the description of irreversible processes. The discussion on the implications of choosing either of these methods usually goes along the following lines. If the positions and velocities of all the particles in a given system were known at any time, the behavior of the system could be determined by applying the laws of classical and quantum mechanics. This procedure is, of course, not feasible firstly because the actual positions and velocities of the individual particles are not known and secondly because the computational efforts needed calculating the macroscopic properties from the states of the individual particles are prohibitively great taking into consideration the large number of particles commonly present in the systems of interest. Instead, statistical methods are introduced with the object of predicting the most probable behavior of a large collection of particles without actually being concerned with the precise states of the individual particles. For this purpose the most probable particle states or a hypothetical ensemble of systems are considered calculating the macroscopic properties. Therefore, we may loosely say that the main reason for introducing the idea of an ensemble was to make it easier to accomplish averaging in statistical mechanics [80]. However, as the experimental characteristics are usually given as time average properties, the equivalence of the calculation and measurement data may be questionable. The ultimate question is whether the average over the ensemble of systems is the same as the average over

---

<sup>2</sup> The expression *statistical mechanics* was apparently first used in 1902 by Josiah Willard Gibbs in the title of his book *Elementary Principles in statistical Mechanics* [47].

an infinite time for a single system. Time averages and micro-canonical ensemble averages are commonly assumed to be identical by the *ergodic hypothesis*.<sup>3</sup>

Statistical mechanics is normally further divided into two branches, one dealing with equilibrium systems, the other with non-equilibrium systems. Equilibrium statistical mechanics is sometimes called *statistical thermodynamics* [100]. *Kinetic theory* of gases is a particular field of non-equilibrium statistical mechanics that focuses on dilute gases which are only slightly removed from equilibrium [39]. The main objective of performing kinetic theory analyses is to explain physical phenomena that are measurable at the macroscopic level in a gas at—or near equilibrium in terms of the properties of the individual molecules and the intermolecular forces. For instance, one of the original aims of kinetic theory was to explain the experimental form of the ideal gas law from basic principles [95]. The kinetic theory of transport processes determines the transport coefficients (i.e., conductivity, diffusivity, and viscosity) and the mathematical form of the heat, mass and momentum fluxes. Nowadays the kinetic theory of gases originating in statistical mechanics is thus strongly linked with irreversible- or non-equilibrium thermodynamics which is a modern field in thermodynamics describing transport processes in systems that are not in global equilibrium.

In a series of impressive publications, Maxwell [95–98] provided most of the fundamental concepts constituting the statistical theory recognizing that the molecular motion has a random character. When the molecular motion is random, the absolute molecular velocity cannot be described deterministically in accordance with a physical law so a probabilistic (stochastic) model is required. Therefore, the conceptual ideas of kinetic theory rely on the assumption that the mean flow, transport and thermodynamic properties of a collection of gas molecules can be obtained from the knowledge of their masses, number density, and a probabilistic velocity distribution function. The gas is thus described in terms of the *distribution function*<sup>4</sup> which contains information of the spatial distributions of molecules, as well as about the molecular velocity distribution, in the system under consideration. An important introductory result was the Maxwellian velocity distribution function heuristically derived for a gas at equilibrium. It is emphasized that a gas at thermodynamic equilibrium contains no macroscopic gradients, so that the fluid properties like velocity, temperature and density are uniform in space and time. When the gas is out of equilibrium non-uniform spatial distributions of the macroscopic quantities occur, thus additional phenomena arise as a result of the molecular motion. The random movement of molecules from one region to another tend to transport with them the macroscopic properties of the region from which they depart. Therefore, at their destination the molecules find themselves out of equilibrium with the properties of the region in which they arrive. At the continuous macroscopic level the net effect

<sup>3</sup> In this context the *ergodic hypothesis* states that the time average of a property and the property average over a statistical ensemble of systems result in the same average property measure.

<sup>4</sup> The distribution function is sometimes given other names. Chapman [18, 19] and Chapman and Cowling [20], for example, introduced the name *velocity distribution function* which is also frequently used.

of these molecular transport processes is expressed through the non-equilibrium phenomena of viscosity, heat conduction and diffusion. Nowadays the phrase *transport processes* thus refers to the transport of mass, momentum and energy within a fluid smoothing out the macroscopic gradients in the physical variable fields enabling non-equilibrium systems to approach equilibrium states.

Analytical formulas quantifying the transport coefficients have been deduced in several ways, mostly based on the mean free path concept, the Maxwellian moment equations, and the Boltzmann equation.<sup>5</sup> A preliminary theory of transport processes was suggested by Maxwell [95] in which the transport coefficients were determined on the basis of Clausius' empirical mean free path hypothesis.<sup>6</sup> In a subsequent study by Maxwell [96] the *equation of transfer* for non-equilibrium gases was derived, describing the total rate of change of any mean property of a gas consisting of molecules having certain predefined properties, neatly simplifying the analytical solution. The so-called *Maxwellian molecules* are point centers of force repelling each other with forces which are inversely proportional to the fifth power of their mutual distance. The resulting *equations of change for the mean variables* (or moments of the distribution function), also called *moment equations* or equations of transfer, play an important role in kinetic theory (e.g., [157], p. 319 and p. 346; [109]). Based on these equations and the Maxwellian molecular model, Maxwell deduced more accurate analytical relationships for the transport coefficients.

A few years later Boltzmann [10] presented the derivation of a more general integro-differential equation which describes the evolution of the distribution function in phase space and time. Two approximate methods for the determination of the transport coefficients were proposed independently by Chapman [18, 19] and Enskog [35, 36], leading to almost the same novel relations. Enskog made the explicit solution of Boltzmann equation by successive approximation the basis for his work,<sup>7</sup> whereas Chapman followed Maxwell by using the (moment) equations of transfer rather than attempting to solve the Boltzmann equation explicitly [20, 39, 90]. The method by which Enskog solved the Boltzmann equation is considered a more complete formal solution and thus preferred compared to the Chapman method. However, as Chapman and Enskog did propose the same transport coefficient relations, Enskog's method is often referred to as the Chapman-Enskog expansion method. The first order solutions to the Boltzmann equation in the Chapman-Enskog procedure results in the equilibrium (Euler) equations. Each successive iterate in the Chapman-Enskog expansion yields a more detailed set of gas dynamics equations. The second iterate gives the non-equilibrium equations (or the set of Navier-Stokes equations). The third iterate gives the Burnett equations. Another important contribution by Boltzmann [10] was the H-theorem showing that the molecular collisions tend to increase entropy in an

<sup>5</sup> In order to indicate Maxwell's association with the ideas formulated by Boltzmann, the Boltzmann equation is sometimes termed the *Maxwell-Boltzmann equation* (e.g., see [20], p. 46).

<sup>6</sup> The mean free path is the average distance traveled by a molecule between successive collisions. The concept of mean free path was introduced by Clausius (1822–1888) in 1858 [14].

<sup>7</sup> Note that in 1949 Harold Grad (1923–1986) published an alternative method of solving the Boltzmann equation systematically by expanding the solution into a series of orthogonal polynomials [50].

irreversible manner providing a firm theoretical justification of the second law of thermodynamics which was already accepted at that time.<sup>8</sup>

A spin-off result of the foregoing analysis of Enskog [35, 36] determining the transport coefficients, a rigorous procedure deriving the governing equations of gas dynamics from first principles was established. It is stressed that in classical fluid dynamics the continuum hypothesis is used so that the governing equations of change are derived directly on the macroscopic scales applying the balance principle over a suitable control volume, as described in Chap. 1. Thereafter, closure laws are required relating the internal stresses and diffusive transport fluxes of mass and energy (heat) to the gradients of the macroscopic quantities (e.g., Newton's law of viscosity, Fick's law of mass diffusion, and Fourier's law of conduction are commonly adopted). By using these constitutive relationships we also introduce several unknown parameters, the so-called transport coefficients of viscosity, mass diffusivities and thermal conductivity into the governing equations. Unfortunately, fluid dynamics does neither provide any guidelines on how to determine the mathematical form of the constitutive relations nor the values of transport coefficients. Therefore, a unique application of kinetic theory emerges provided that an approximate solution of the Boltzmann equation is available. In this case particular moments of the distribution function can be obtained multiplying the Boltzmann equation by an invariant function (i.e., successively representing molecular mass, momentum and energy), and thereafter integrating the resulting equation over the whole velocity space. The moments of the distribution function (also called the probability-weighted average functions) represent macroscopic (ensemble) mean quantities like gas velocity, pressure, mass density, temperature and energy. In this way it is possible to derive rigorous equations of change for the evolution of the mean quantities starting out from the Boltzmann equation. Historically, the moment equation of the Boltzmann equation that was published in 1872 is equivalent to Maxwell's moment equation, originally called the *equation of transfer*, that was derived by Maxwell [96] in 1867, so the moment equation is sometimes named the *Maxwell's transport equation* [129]. The moment equation resulting from the Boltzmann equation is also frequently referred to as the *Enskog's equation of change* (e.g., [20], p. 49; [109], p. 232; [115], p. 527). The macroscopic moment equation of change by Enskog represents a generalization of the equation of transfer proposed by Maxwell [96]. The model generalization consists in the fact that Maxwell's equation refers to a function  $\psi(\mathbf{c})$  of  $\mathbf{c}$  alone whereas Enskog's equation is formulated for  $\psi(\mathbf{C}, \mathbf{r}, t)$  of  $\mathbf{C}$ ,  $\mathbf{r}$ ,  $t$  (see [20], p. 49). Moreover, since both Maxwell and Enskog did contribute to the development of the moment equation, the moment equation of change is also referred to as the *Maxwell-Enskog equation* (e.g., [93], p. 56). The resulting macroscopic moment conserva-

---

<sup>8</sup> The pioneering work in the direction of the second law of thermodynamics is considered to be performed in 1825 by Sadi Carnot investigating the Carnot cycle [57, 80]. Carnot's main theoretical contribution was that he realized that the production of work by a steam engine depends on a flow of heat from a higher temperature to a lower temperature. However, Clausius (1822–1888) was the first that clearly stated the basic ideas of the second law of thermodynamics in 1850 [21] and the mathematical relationship called the *inequality of Clausius* in 1854 [80]. The word *entropy* was coined by Clausius in 1854 [80].

tion equations are recognized as being analogue to the conservation equations of continuum mechanics. In addition, in contrast to the continuum mechanic formulation the ensemble averaged equations obtained from kinetic theory do not contain any unknown coefficients. That is, a particular set of closure laws is established. Alternatively, by comparing the kinetic theory results with the classical fluid dynamic equations, we may verify both the form of the constitutive laws and the values of the transport coefficients.

The kinetic theory of multi-component non-reactive mixtures was first described by Maxwell [95, 97] and Stefan [142, 143] and later thoroughly described by Hirschfelder et al. [55]. Hirschfelder et al. [55] also considers reactive systems. The latest contributions are reviewed by Curtiss and Bird [26, 27].

The Boltzmann equation is considered valid as long as the density of the gas is sufficiently low and the gas properties are sufficiently uniform in space. Although an exact solution is only achieved for a gas at equilibrium for which the Maxwell velocity distribution is supposed to be valid, one can still obtain approximate solutions for gases near equilibrium states. However, it is evident that the range of densities for which a formal mathematical theory of transport processes can be deduced from Boltzmann's equation is limited to *dilute* gases, since this relation is reflecting an asymptotic formulation valid in the limit of no collisional transfer fluxes and restricted to binary collisions only. Hence, this theory cannot without ad hoc modifications be applied to dense gases and liquids.

Enskog [37] made the first heuristic attempt to extend the kinetic theory of dilute mono-atomic gases to higher density gas systems. Enskog introduced corrections to the Boltzmann equation accounting for the finite size of the colliding molecules (a free volume correction), and that the centers of the two colliding particles are no longer at the same point. These model extensions resulted in a novel flux accounting for the mechanisms of instantaneous momentum and energy transfer over the distance separating the centers of the two colliding molecules. The extended Boltzmann equation for dense gas is named the *Enskog's equation* (e.g., [39], p. 359). It is later stated that even at moderate densities the collisional transfer fluxes may become significant compared to the kinetic contribution, and they may dominate at slightly higher densities.

Nowadays the standard literature of kinetic theory of dilute gases usually refers to the books of Chapman and Cowling [20], Hirschfelder et al. [55], Huang [57], Reif [115], Present [109], Vincenti and Kruger [157], Ferziger and Kaper [39], Résibois and De Leener [117], Liboff [90], and Cercignani et al. [14]. Additional reviews on classical mechanics, for example the books of Goldstein [49], Arnold [4], McCall [99], Iro [60], and Panat [105], might also be useful deriving the elements of statistical mechanics, and in particular the dynamics of binary collisions. Moreover, the extensions of the elementary kinetic theory to liquid and polymeric liquid systems are examined by Hansen and McDonald [53] and Bird et al. [8], respectively. The contents of the this chapter are to a large extent based on these reviews and the pioneering work summarized in this introductory section. The reader is encouraged to consult this literature for further details of the kinetic theory.

## 2.2 Elementary Concepts in Classical Mechanics

This section is devoted to an outline of the pertinent principles of dynamics and classical statistical mechanics. Much of the notation required in order to present the kinetic theory concepts is thus established. It is important to recognize that several mathematical frameworks for the description of dynamic systems are in common use. In this context classical mechanics can be divided into three disciplines denoted by *Newtonian mechanics*, *Lagrangian mechanics* and *Hamiltonian mechanics* reflecting three conceptually different mathematical apparatus of model formulation [4, 8, 49, 53, 81, 89, 90, 147].

### 2.2.1 Newtonian Mechanics

The initial stage in the development of classical mechanics is often referred to as Newtonian mechanics, and is characterized by the mathematical methods invented by Newton, Galileo (the principle of relativity [4]), among others. Numerous books contain introductory synopses of the basic principles of the Newtonian mechanics, see for example the books by Arnold [4], Ferziger and Kaper [39] and Cercignani et al. [14].

Although some of the physical ideas of classical mechanics is older than written history, the basic mathematical concepts are based on Isaac Newton's axioms published in his book *Philosophiae Naturalis Principia Mathematica* or *principia* that appeared in 1687. Translated from the original Latin, the three axioms or the laws of motion can be approximately stated [13] (p. 13) :

Law I: *Every body continues in its state of rest, or of uniform motion in a right line, unless it is compelled to change that state by forces impressed on it.*

Law II: *The change of motion is proportional to the motive force impressed; and is made in direction of the right line in which that force is impressed.*

Law III: *To every action there is always an opposite and equal reaction: or, the mutual actions of two bodies upon each other are always equal, and directed to contrary parts.*

The basic concepts of Newtonian mechanics include the use of point masses or particles, which is an object with negligible size with respect to the typical length scales of the system considered [60]. Point masses are thus mathematical points having mass but no structure. The motion of a point particle is characterized by a small number of parameters, i.e., the particle position, mass, and the forces applied to it. For an ensemble of particles, the center of mass of a composite object behaves like a point particle. The position of a point particle is defined with respect to an arbitrary point in space, which is called the origin,  $O$ . A point is represented by the position vector  $\mathbf{r}$  from  $O$  to the particle. A vector  $\mathbf{r}_c$  representing the average of the radii vectors of the particles, weighted in portion to their mass as:

$$\mathbf{r}_c = \frac{\sum_i m_i \mathbf{r}_i}{\sum_i m_i} = \frac{\sum_i m_i \mathbf{r}_i}{M} \quad (2.1)$$

defines a point known as the center of mass, or more loosely as the center of gravity (see e.g., [105], p. 11).

Newton's second law relates the mass and velocity of a particle to a vector quantity known as a force. This fundamental law is also referred to as the equation of motion:

$$\frac{d(m\mathbf{c})}{dt} = \mathbf{F} \quad (2.2)$$

where the quantity  $m\mathbf{c}$  is called the momentum.

Given the initial coordinates and momenta of the particles, the particle position and velocity at any later time can in principle be obtained as the solution to Newton's equations of motion. Typically, the mass is constant in time, hence Newton's law can be written in the conventional form:

$$\mathbf{F} = m \frac{d\mathbf{c}}{dt} = m\mathbf{a} = m\dot{\mathbf{c}} = m\ddot{\mathbf{r}} \quad (2.3)$$

Newton used this equation as the basis of mechanics, hence it is sometimes called Newton's equation [4]. Note that Newton's 1. and 3. laws merely emerge as particular simplifications of the 2nd law and are thus not explicitly stated.

A particular class of forces, known as conservative forces,<sup>9</sup> can be expressed as the gradient of a scalar potential energy function (or potential) denoted by  $E_p$ :

$$m\ddot{\mathbf{r}} = \mathbf{F} = -\nabla E_p(\mathbf{r}) \quad (2.4)$$

It is noticed that Newton's second law of motion forms a set of second order differential equations.

In order to formulate Newton's laws, a suitable reference frame has to be chosen (as briefly sketched above). The inertial coordinate systems defined by the Galileo's principle of relativity are at rest or moving with a constant velocity [81]. In classical mechanics, Newton's laws are valid in all inertial coordinate systems, since the rate of change of velocity equals the absolute acceleration of the system. Moreover, all coordinate systems in uniform rectilinear motion with respect to an inertial frame are themselves inertial. Strictly speaking Newton's laws are no longer valid if a system undergoes accelerations [52]. However, the Newtonian formulation can be extended for systems with arbitrary relative motion [105]. The modified relations are obtained by establishing the equations of motion in a fixed system and thereafter transforming them into the accelerated system. In the non-inertial frame of reference additional

---

<sup>9</sup> A force field  $\mathbf{F}$ , defined everywhere in space, is said to be a conservative force or conservative vector field if it meets any of the following three equivalent conditions [105]: (1) The curl of  $\mathbf{F}$  is zero,  $\nabla \times \mathbf{F} = 0$ . (2) There is zero net work ( $W$ ) done by the force  $\mathbf{F}$  when moving a particle through a trajectory constituting a closed curve  $C$ ,  $W = \oint_C \mathbf{F} \cdot d\mathbf{r} = 0$ . (3) The force can be written as the negative gradient of a potential energy function of position  $E_p(\mathbf{r})$ :  $\mathbf{F} = -\nabla E_p(\mathbf{r}) = 0$ .

fictitious forces (e.g., the Coriolis, centripetal and centrifugal forces) arise to account for the motion which is actually caused by the acceleration of the frame of reference.

Moreover, to understand the basic principles of kinetic theory, granular flows and population balances it is required to widen the knowledge of classical mechanics. Newton's mathematical formulation of the laws of motion is perhaps the most intuitive point of view considering familiar quantities like mass, force, acceleration, velocity and positions and as such preferred by chemical engineers. However, this framework is inconvenient for mathematical generalizations as required describing the motion of large populations of particles for which it is necessary to take into account the *constraints* that limit the motion of the system. In this book we restrict ourselves to holonomic constraints because most of the microscopic world has holonomic constraints. If the conditions of constraint can be expressed as equations connecting the coordinates of the particles and the time having the form:

$$f(\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_1, \dots, t) = 0 \quad (2.5)$$

then the constraints are said to be *holonomic* [49, 105]. The constraints which cannot be expressed in the form of algebraic equations are non-holonomic constraints.<sup>10</sup>

Two types of difficulties in the solution of mechanical problems are introduced imposing constraints on the system. First, the coordinates of the  $N$  particles,  $\mathbf{r}_i$ ,  $i = 1, \dots, N$ , are no longer all independent as they are connected by the equations of constraint, hence the set of  $N$  equations determining the motion of the individual particles are no longer independent. Second, interacting forces may be created by the constraints and are thus not known a priori as required in the Newtonian concepts [60]. Therefore, after Newton the field of classical mechanics became more general, mathematical and abstract. In the case of holonomic constraints, the first difficulty is solved by the introduction of *generalized coordinates*. The second difficulty is avoided by re-formulating the original theory of motion and forces in accordance with the Lagrangian and Hamiltonian formalisms. These two alternative formulations circumvent the concept of force, instead they are referring to other quantities such as energy, generalized coordinates, generalized velocities and generalized momenta for describing mechanical systems. It is stressed that Lagrangian mechanics and Hamiltonian mechanics are equivalent to Newtonian mechanics, but these re-formulations are more convenient solving complex problems describing the behavior of a system of interacting particles. The main disadvantage of the Newtonian approach is that it is formally tied to the Cartesian coordinate system.<sup>11</sup> The Lagrangian and Hamiltonian formulations are independent of the coordinate system employed. That is, with the Lagrangian formalism one re-formulates the mechanical problem in terms of two scalar functions denoting the kinetic- and potential energy

<sup>10</sup> For the readers that are not familiar with the basics of Newtonian mechanics and the concepts of constraints, Chap. 1 of Goldstein [49] and Chaps. 1–4 of Panat [105] may serve as a understandable introduction to the subject.

<sup>11</sup> In principle, Newton regarded both space and time absolute entities, implying that they are the same for everyone [99]. No such frame does exist in nature, so in practice it is usually feasible to set up a coordinate system that comes as close to this idealization as may be required [49, 100, 105].

respectively, and this notation can greatly simplify the solution of many problems utilizing possible symmetries in the system in a better way. The Hamiltonian viewpoint is not particularly superior to the Lagrangian one for the direct solution of mechanical problems, but the Hamiltonian framework provides a better basis for theoretical generalizations in many areas of physics. In this context it is emphasized that the Hamiltonian formulation provides much of the language with which statistical mechanics and kinetic theory are constructed.

### 2.2.2 Lagrangian Mechanics

The Lagrange's equations can in general be expressed using either of two types of variational principles. These are called the differential and the integral principles. The latter group of methods is also referred to as the principles of minimum action, since in all these procedures the quantity to be varied has the dimension of an action ( $= \text{energy} \times \text{time}$ ) [4, 52]. As an example we consider the Hamiltonian integral principle,<sup>12</sup> because it is the most general method and especially useful for holonomic systems with forces derivable from particular potentials. In the context of kinetic theory of dilute gases the application of the Lagrangian formulation may be convenient for the solution of scattering problems, i.e., the two-body mutual central force problem as viewed in the center of mass coordinate system [49, 105]. Nevertheless, the derivation of the Lagrangian equations merely serves as an intermediate step examining basic elements of the Hamiltonian formulation.

Considering a mechanical system consisting of a collection of particles which are interacting with each other in accordance with the equations of motion, the state of the system is completely described by the set of all the positions and velocities of the particles. In mechanics the minimum number of *independent parameters* necessary to uniquely determine the location and orientation of any system in physical space is called the number of *degrees of freedom*.<sup>13</sup> These quantities need not be the Cartesian coordinates of the particle, as was the case in Newton's work. Rather, the conditions of the problem may render some other more convenient choice of parameters. Any  $N$  independent parameters  $\mathbf{q} = \{q_1, q_2, \dots, q_N\}$  which completely define the position of a system with  $N$  degrees of freedom are called *generalized coordinates* of the system. The corresponding derivatives  $\dot{\mathbf{q}} = \{\dot{q}_1, \dot{q}_2, \dots, \dot{q}_N\}$  are called *generalized*

<sup>12</sup> An example of the alternative differential method is the principle of Jean Le Rond d'Alembert (1717–1783). Perspicuous descriptions of the d'Alembert principle and the derivation of the Lagrangian equations are, for example, given by Greiner [52] and Panat [105].

<sup>13</sup> The phrase *degrees of freedom* is not interpreted identically when it is used in the different branches of science. In physics and chemistry, each independent mode in which a particle or system may move or be oriented is one degree of freedom. In mechanical engineering, degrees of freedom describes flexibility of motion. In statistics, the degrees of freedom are the number of parameter values in probability distributions that are free to be varied. In statistical mechanics the number of degrees of freedom a given system has is equal to the minimum number of independent parameters necessary to uniquely determine the location and orientation of the system in physical space.

*velocities*. For a system placed in a conservative force field an alternative form of the equations of motion is obtained by introducing a Lagrangian function defined as the difference between the kinetic energy,  $T(\dot{\mathbf{q}}, \mathbf{q})$ , and the potential energy,  $E_p(\mathbf{q}, t)$ :

$$L(\dot{\mathbf{q}}(t), \mathbf{q}(t), t) = T(\dot{\mathbf{q}}(t), t) - E_p(\mathbf{q}(t), t) = \frac{1}{2}m\dot{q}^2 - E_p(\mathbf{q}, t) \quad (2.6)$$

It is emphasized that Lagrangian mechanics is the description of a mechanical system in terms of generalized coordinates  $\mathbf{q}$  and generalized velocities  $\dot{\mathbf{q}}$ . The final task in the Lagrangian procedure is to derive a differential equation for  $L(\mathbf{q}, \dot{\mathbf{q}}, t)$  by use of rather complex variational principles. Briefly stated, we are considering the effect of small excursions along the path of the system. The variation denotes a virtual displacement and the trajectory of an object is derived by finding the path which minimizes the action, a quantity which is the integral of the Lagrangian over time. Just a brief outline of the method is given in this book, because the main aim is restricted to the introduction of elements of the notation to be used in kinetic theory analysis shortly. Further details on the technique are given elsewhere [49, 81, 90, 147].

The Hamiltonian variational principle states that the motion of the system between two fixed points, denoted by  $(q, t)_1$  and  $(q, t)_2$ , renders the action integral<sup>14</sup>:

$$S = \int_{t_1}^{t_2} L(q, \dot{q}, t) dt \quad (2.7)$$

a minimum. The necessary condition for  $S$  to have a minimum is that the variation of the integral is zero. Hence, the variational principle of least action is written in the form:

$$\delta S = \delta \int_{t_1}^{t_2} L(q, \dot{q}, t) dt = 0 \quad (2.8)$$

where  $\delta$  denotes a variation about the motion of the system.

Employing this concept to obtain a differential equation for  $L(q, \dot{q}, t)$ , which is defined by (2.6), the first variation of the action  $S$  is expressed by:

$$\delta S = \int_{t_1}^{t_2} L(q + \delta q, \dot{q} + \delta \dot{q}, t) dt - \int_{t_1}^{t_2} L(q, \dot{q}, t) dt = 0 \quad (2.9)$$

By expanding the first integral to first order, the variation can be expressed as:

---

<sup>14</sup> For brevity we drop the vector font on the  $q$ 's and  $\dot{q}$ 's and assume a single degree of freedom.

$$\delta S = \int_{t_1}^{t_2} \left( \frac{\partial L}{\partial q} \delta q + \frac{\partial L}{\partial \dot{q}} \frac{d\delta q}{dt} \right) dt \quad (2.10)$$

Reformulating the second term of the integrand in accordance with:

$$\frac{d}{dt} \left( \frac{\partial L}{\partial \dot{q}} \delta q \right) = \frac{\partial L}{\partial \dot{q}} \frac{d\delta q}{dt} + \delta q \frac{d}{dt} \left( \frac{\partial L}{\partial \dot{q}} \right) \quad (2.11)$$

implies that:

$$\delta S = \frac{\partial L}{\partial \dot{q}} \delta q \Big|_{t_1}^{t_2} + \int_{t_1}^{t_2} \left( \frac{\partial L}{\partial q} - \frac{d}{dt} \left( \frac{\partial L}{\partial \dot{q}} \right) \right) \delta q dt \quad (2.12)$$

The first term on the RHS vanishes, since the end points of the trajectory are held fixed in the variation. The second integral must vanish for any arbitrary, infinitesimal variation  $\delta q$ , hence the integrand is zero. The result is:

$$\frac{d}{dt} \left( \frac{\partial L}{\partial \dot{q}} \right) - \frac{\partial L}{\partial q} = 0 \quad (2.13)$$

The above derivation can be generalized to a system of  $N$  particles, noting that the variation must be effected for each variable independently. Hence, in terms of  $L$ , the equations of motion are:

$$\frac{d}{dt} \left( \frac{\partial L}{\partial \dot{q}_i} \right) - \frac{\partial L}{\partial q_i} = 0 \quad i = 1, 2, 3, \dots, N \quad (2.14)$$

This set of equations are the famous Lagrangian equations.<sup>15</sup>

The second term on the LHS denotes the generalized forces defined by:

$$F_i = \frac{\partial L}{\partial q_i} \quad (2.15)$$

It can now be shown that the Lagrangian equations are equivalent to the more familiar Newton's second law of motion. If  $q_i = r_i$ , the generalized coordinates are simply the Cartesian coordinates. Introducing this definition of the generalized coordinates and the corresponding Lagrangian function (2.6) into the Lagrangian equations of motion (2.14), we get:

$$\frac{d}{dt} (m\dot{q}) = - \frac{\partial E_p}{\partial q} \quad (2.16)$$

---

<sup>15</sup> The mathematical Lagrangian formalism in classical mechanics was first published in the book *Mécanique Analytique* by Joseph Louis Lagrange in 1788 [133].

in which the LHS and the RHS of the Lagrangian equations (2.14) have been reformulated by use of the Lagrangian function definition (2.6):

$$\begin{aligned} \frac{d}{dt} \left( \frac{\partial L}{\partial \dot{q}_i} \right) &= \frac{d}{dt} \left( \frac{\partial}{\partial \dot{q}_i} (T(\dot{q}_i, t) - E_p(q_i, t)) \right) = \frac{d}{dt} \left( \frac{\partial}{\partial \dot{q}_i} \left( \frac{1}{2} m \dot{q}_i^2 - E_p(q_i, t) \right) \right) \\ &= \frac{d}{dt} \left( \frac{\partial}{\partial \dot{q}_i} \left( \frac{1}{2} m \dot{q}_i^2 \right) \right) = \frac{d}{dt} (m \dot{q}_i) \end{aligned} \quad (2.17)$$

$$\begin{aligned} \frac{\partial L}{\partial q_i} &= \frac{\partial}{\partial q_i} (T(\dot{q}_i, \mathbf{q}) - E_p(q_i, t)) = \frac{\partial}{\partial q_i} \left( \frac{1}{2} m \dot{q}_i^2 - E_p(q_i, t) \right) \\ &= - \frac{\partial}{\partial q_i} (E_p(q_i, t)) \end{aligned} \quad (2.18)$$

Moreover, since the gradient of the time independent potential energy field denotes a conservative force [60], the relation can be expressed in terms of a force:

$$m \ddot{q}_i = F(q_i, t) \quad (2.19)$$

The resulting relation is identical to the equation obtained in the Newtonian representation (2.3).

Given the Lagrangian for a system of interacting particles, a number of fundamental system properties can be deduced. Among these properties are the basic conservation laws<sup>16</sup> which can be deduced invoking the principle of homogeneity of time and space for closed systems that do not interact with any external forces.

In this context examination of the total time derivative of the Lagrangian is informative. The relation can be expressed as:

$$\begin{aligned} \frac{d}{dt} (L(q_i(t), \dot{q}_i(t), t)) &= \sum_i \frac{\partial L}{\partial q_i} \dot{q}_i + \sum_i \frac{\partial L}{\partial \dot{q}_i} \ddot{q}_i + \frac{\partial L}{\partial t} \\ &= \sum_i \frac{d}{dt} \left( \dot{q}_i \frac{\partial L}{\partial \dot{q}_i} \right) + \frac{\partial L}{\partial t} \end{aligned} \quad (2.20)$$

or, by reorganizing the terms:

$$\sum_i \frac{d}{dt} \left( \dot{q}_i \frac{\partial L}{\partial \dot{q}_i} - L \right) = - \frac{\partial L}{\partial t} \quad (2.21)$$

Several classes of transformations between two frames or coordinate systems leave the Newtonian equation of motion invariant [60, 81]. The invariance of physical

---

<sup>16</sup> During the motion of a mechanical system, the generalized coordinates and generalized velocities which specify the state of the system vary with time. However, a set of functions of these quantities exist whose values remain constant during the motion of the system and depend only on the initial conditions. These functions are referred to as integrals of motion, and the quantities represented by these integrals are said to be conserved [81].

systems under translations of the coordinate system is often referred to as the *homogeneity of space*. The analogue invariance under rotations of the coordinate system is named the *isotropy of space*. Translations of the time origin also make the equation of motion remain invariant, this property is called the *homogeneity of time*. By virtue of the homogeneity of time, the Lagrangian of a closed system does not depend explicitly on time. Therefore, using (2.21) with  $L$  as defined by (2.6), it is verified that the energy of the system is conserved, as the quantity:

$$\sum_i \dot{q}_i \frac{\partial L}{\partial \dot{q}_i} - L(q_i(t), \dot{q}_i(t), t) = T(\dot{q}_i(t), t) + E_p(q_i(t), t) = E(q_i(t), \dot{q}_i(t), t) \quad (2.22)$$

remains constant in time during the motion of the system.

In a similar manner the homogeneity in space leads to the law of conservation of linear momentum [60, 81]. In this case  $L$  does not depend explicitly on  $q_i$ , i.e., the coordinate  $q_i$  is said to be cyclic. It can then be seen exploring the Lagrange's equations (2.14) that the quantity  $\partial L / \partial \dot{q}_i$  is constant in time. By use of the Lagrangian definition (2.6), the relationship can be written in terms of more familiar quantities:

$$\frac{\partial L}{\partial \dot{q}_i} = m\dot{q}_i \quad (2.23)$$

It is stated that the momentum  $m\dot{q}_i$  is a constant of the motion, meaning that it is a conserved quantity. This result is, of course, only valid when all the interacting forces are conservative and there are no external forces acting on the system of particles. Note also that the isotropy of space is the basis for the derivation of the law of conservation of angular momentum [60, 81].

### 2.2.3 Hamiltonian Mechanics

Hamiltonian mechanics<sup>17</sup> is based on the description of mechanical systems in terms of generalized coordinates  $q_i$  and generalized momenta  $p_i$ . Starting out from Lagrangian mechanics in which the equations of motion are based on generalized coordinates  $q_i$  and the corresponding generalized velocities  $\dot{q}_i$ , ( $q_i, \dot{q}_i$ ),  $i = 1, 2, 3, \dots, N$ , the transformation of the problem to the Hamiltonian description can be performed adopting the Legendre's transformation technique. Hence, by replacing the generalized velocity variables  $\dot{q}_i$  with generalized momentum variables  $p_i$ , i.e., the latter quantities are also known as conjugate momenta, it is possible to further exploit the symmetry principles of mechanics. The concepts from

<sup>17</sup> Hamiltonian mechanics refers to a mathematical formalism in classical mechanics invented by the Irish mathematician William Rowan Hamilton (1805–1865) during the early 1830s arising from Lagrangian mechanics which was introduced about 50 years earlier by Joseph-Louis Lagrange (1736–1813). The Hamiltonian equations can however be formulated on the basis of a variational principle without recourse to Lagrangian mechanics [4, 147].

Hamiltonian mechanics are pertinent to the phase space treatment of problems in dynamics.

The Hamiltonian formulation thus provides the view in which the statistical mechanics and modern kinetic theory are constructed. We define the Hamiltonian function by the Legendre transform of the Lagrangian function (2.6) [49, 52]:

$$H(\mathbf{p}, \mathbf{q}, t) = \sum_i \dot{q}_i p_i - L(\dot{\mathbf{q}}, \mathbf{q}, t) \quad (2.24)$$

in which  $p_i$  is defined as:

$$p_i = \frac{\partial L}{\partial \dot{q}_i} \quad (2.25)$$

Furthermore, substituting the  $p_i$  into the Lagrange's equations of motion (2.14) gives:

$$\dot{p}_i = \frac{\partial L}{\partial q_i} \quad (2.26)$$

Given the Lagrange's equations of motion (2.14) and the Hamiltonian function (2.24), the next task is to derive the Hamiltonian equations of motion for the system. This can be achieved by taking the differential of  $H$  defined by (2.24).

Each side of the differential of  $H$  produces a differential expressed as:

$$\begin{aligned} dH(\mathbf{q}, \mathbf{p}, t) &= \sum_i \frac{\partial H}{\partial q_i} dq_i + \sum_i \frac{\partial H}{\partial p_i} dp_i + \frac{\partial H}{\partial t} dt \\ &= d\left(\sum_i \dot{q}_i p_i\right) - dL(\dot{\mathbf{q}}, \mathbf{q}, t) \\ &= \sum_i \left(p_i - \frac{\partial L}{\partial \dot{q}_i}\right) d\dot{q}_i + \sum_i \dot{q}_i dp_i - \sum_i \frac{d}{dt} \left(\frac{\partial L}{\partial \dot{q}_i}\right) dq_i - \frac{\partial L}{\partial t} dt \\ &= \sum_i \left(p_i - \frac{\partial L}{\partial \dot{q}_i}\right) d\dot{q}_i + \sum_i \dot{q}_i dp_i - \sum_i \dot{p}_i dq_i - \frac{\partial L}{\partial t} dt \end{aligned} \quad (2.27)$$

in which the total differential of  $L$  is defined as:

$$dL(\dot{\mathbf{q}}, \mathbf{q}, t) = \sum_i \frac{\partial L}{\partial \dot{q}_i} d\dot{q}_i + \sum_i \frac{\partial L}{\partial q_i} dq_i + \frac{\partial L}{\partial t} dt \quad (2.28)$$

Substituting the definition of the conjugate momenta (2.25) and the manipulated form of the Lagrangian equations (2.26) into (2.27) and matching coefficients,  $\sum_i (p_i - \frac{\partial L}{\partial \dot{q}_i}) d\dot{q}_i = 0$ , we obtain the equations of motion of Hamiltonian mechanics (i.e., also known as the canonical equations of Hamilton):

$$\dot{p}_i = -\frac{\partial H}{\partial q_i} \quad (2.29)$$

$$\dot{q}_i = \frac{\partial H}{\partial p_i} \quad (2.30)$$

An additional relationship of importance for explicitly time-dependent system functions, can be deduced by the same procedure and expressed as:

$$\frac{\partial L}{\partial t} = -\frac{\partial H}{\partial t} \quad (2.31)$$

The total time derivative of the Hamiltonian is achieved from (2.27) as:

$$\frac{dH}{dt} = \frac{\partial H}{\partial t} + \sum_i \frac{\partial H}{\partial q_i} \dot{q}_i + \sum_i \frac{\partial H}{\partial p_i} \dot{p}_i \quad (2.32)$$

Substitution of the Hamiltonian equations (2.29) and (2.30) shows that the last two terms cancel,

$$\frac{dH(\mathbf{p}, \mathbf{q}, t)}{dt} = \frac{\partial H}{\partial t} - \sum_i \dot{p}_i \dot{q}_i + \sum_i \dot{q}_i \dot{p}_i \quad (2.33)$$

Thus:

$$\frac{dH}{dt} = \frac{\partial H}{\partial t} \quad (2.34)$$

In particular, if the Hamiltonian function does not depend explicitly on time, then:

$$\frac{dH}{dt} = 0 \quad (2.35)$$

This means that  $H$  represents a conserved quantity. Eliminating the Lagrangian from (2.24) using (2.22) shows that the Hamiltonian function equals the total energy of the system,  $H = E$ .

By use of the Hamiltonian description established in this subsection, it can be shown that the Hamiltonian equations are equivalent to the more familiar Newton's second law of motion in Newtonian mechanics, adopting a transformation procedure similar to the one used assessing the Lagrangian equations. In this case we set  $q_i = r_i$  and substitute both the Hamiltonian function  $H$  (2.24) and subsequently the Lagrangian function  $L$  (2.6) into one of Hamilton's equations of motion (2.29). The preliminary results can be expressed as:

$$\frac{\partial E_p}{\partial r_i} = -\dot{p}_i \quad (2.36)$$

and by use of (2.25) yields:

$$\frac{1}{m_i} p_i = \dot{r}_i. \quad (2.37)$$

Then, we combine these two equations and introduce the force on particle  $i$ , defined in terms of the potential  $E_p$  by  $F_i = -(\partial E_p / \partial r_i)$ . The final result is thus given by  $\mathbf{F}_i = m_i \ddot{\mathbf{r}}_i$  in 3D which corresponds to Newton's second law of motion for particle  $i$  as expressed in the Newtonian formalism (2.3).

The Hamiltonian formalism has a number of important properties and implications. In the following paragraphs a few of them are sketched in the context of a time-independent Hamiltonian function. Most important, the concepts of Hamiltonian mechanics are fundamental to the phase space treatment of problems in dynamics. For a system with  $N$  degrees of freedom the set of  $2N$  canonically conjugate variables  $(\mathbf{p}, \mathbf{q})$  define a  $2N$ -dimensional *phase space* sometimes called the  $\Gamma$ -space<sup>18</sup> of the system [81, 90]. It is sometimes convenient to regard the phase space for a system as a whole as constructed out of the *configuration space* that corresponds to the set of coordinates chosen for the system taken together with the *momentum space* that corresponds to the set of momenta conjugate to those coordinates. Each point in phase space corresponds to a definite state of the system. When the system moves, the point representing it describes a curve called the phase path or *phase trajectory*. The motion of the phase point along its phase trajectory is determined by the canonical equations. Since the Hamiltonian equations are first order differential equations in time, the path of the representative point in phase space is determined by the initial point.

### 2.2.3.1 Preservation of Phase Volume: Liouville Theorem

In the Hamiltonian formulation, the Liouville equation can be seen as a continuity or advection equation for the probability distribution function. This theorem is fundamental to statistical mechanics and requires further attention. Considering an *ensemble*<sup>19</sup> of initial conditions each representing a possible state of the system, we express the probability of a given ensemble or density distribution of system points

---

<sup>18</sup> For a collection of  $N$  identical particles the state of the system may be specified by giving the coordinates of each particle so that the system as a whole is represented by a cloud of  $N$  points in phase space. Alternatively, the state of the system as a whole constituting the gas phase can be completely specified by a single point in phase space. The phase for the system as a whole is called a  $\gamma$ -space or sometimes a  $\Gamma$ -space, and the phase space for any individual kind of particles (molecules) contained in the system is called a  $\mu$ -space for that particle [39, 150]. These notations may be linked to the theory of Gibbs [47] and Boltzmann [10], respectively.

<sup>19</sup> Willard Gibbs (1839–1903) introduced the idea of an ensemble of systems in his book entitled *Elementary Principles in Statistical Mechanics* published in 1902 [47]. An ensemble is a large number of imaginary replicas of the system under consideration. Gibbs also introduced the ideas of canonical-, micro-canonical- and grand canonical ensembles which refer to ensembles having specific properties [80]. For example, the micro-canonical ensemble is the assembly of all states with fixed total energy  $E$ , and fixed size. The canonical ensemble, another example, considers all states with fixed size, but the energy can fluctuate [15].

in phase space  $\Gamma$  by a continuous function:

$$f = f(\mathbf{p}, \mathbf{q}, t) \quad (2.38)$$

which is a normalized quantity with the following property:

$$\int_{\text{all space}} f \Pi_i dp_i dq_i = 1, \quad (2.39)$$

where  $\Pi_i$  means product of all labeled variables and  $i$  runs from 1 to  $N$  degrees of freedom.

The distribution function  $f(\mathbf{q}, \mathbf{p}, t)$  is defined such that the product  $f(\mathbf{q}, \mathbf{p}, t) \Pi_i dp_i dq_i = f(\mathbf{q}, \mathbf{p}, t) d\Omega$  represents the number of system points in the phase volume  $d\Omega$  about the point  $(\mathbf{q}, \mathbf{p})$  at the time  $t$ . The product of differentials  $d\Omega = \Pi_i dp_i dq_i = dq_1 \dots dq_N dp_1 \dots dp_N$  may be regarded as an element of volume in phase space. It follows that the corresponding integral  $\int d\Omega$  taken over some region of phase space represents the volume of the particular region. This integral has the property of being invariant with respect to canonical transformations.<sup>20</sup> This means that the magnitude of a volume element in phase space is preserved under canonical transformations.<sup>21</sup> Therefore, at any given instant in time, the hypothetical ensemble points in the imaginary differential volume of  $\Gamma$ -space are consistently contained within a continuously closed surface. Thus, we let  $\Omega$  be an arbitrary volume element in  $\Gamma$ -space and  $S$  denotes its surface.

The rate of change of the number of phase points  $dN$ , within the infinitesimal phase space volume  $\Pi_i dp_i dq_i$  is obtained from a balance equation expressing that the system points in an ensemble are neither created nor destroyed [89]. Hence, the rate of change of the number of system points in the volume  $\Omega$ ,  $\int_{\Omega} f d\Omega$  is equal to the net flux of points that pass through the closed surface that bound  $\Omega$ :

$$\frac{\partial}{\partial t}(f d\Omega) + \sum_i \left\{ \frac{\partial}{\partial p_i} (\dot{p}_i f d\Omega) + \frac{\partial}{\partial q_i} (\dot{q}_i f d\Omega) \right\} = 0 \quad (2.40)$$

The rate of change of the density function at a fixed position in phase space is achieved dividing by a fixed element of volume in phase space  $d\Omega$ :

<sup>20</sup> The transformation from one pair of canonically conjugate coordinates  $\mathbf{q}$  and momenta  $\mathbf{p}$  to another set of coordinates  $\mathbf{Q} = \mathbf{Q}(\mathbf{p}, \mathbf{q}, t)$  and momenta  $\mathbf{P} = \mathbf{P}(\mathbf{p}, \mathbf{q}, t)$  is called a canonical transformation or point transformation. In this transformation it is required that the new coordinates  $(\mathbf{P}, \mathbf{Q})$  again satisfy the Hamiltonian equations with a new Hamiltonian  $H'(\mathbf{P}, \mathbf{Q}, t)$  [49, 60, 81].

<sup>21</sup> This theorem is known as the *Poincarè* theorem (1854–1912) [49, 60, 81], stating that:  $d\Omega = \Pi_i dp_i dq_i = \Pi_i dP_i dQ_i$ . The invariance rests on the property of the Jacobian determinant of a

canonical transformation:  $D = \det \left( \frac{\partial(\mathbf{Q}, \mathbf{P})}{\partial(\mathbf{q}, \mathbf{p})} \right) = 1$ . Consequently, the volume element is transformed as:  $\Pi_i dp_i dq_i = \Pi_i dP_i dQ_i = D \Pi_i dp_i dq_i$ . In particular, the evolution of a system in time also represents a canonical transformation which implies that the volume in phase space is conserved as it evolves in time. This is known as the *Liouville theorem* (1809–1882).

$$\frac{\partial f}{\partial t} = - \sum_i \left\{ \frac{\partial}{\partial p_i} (\dot{p}_i f) + \frac{\partial}{\partial q_i} (\dot{q}_i f) \right\} = \sum_i \left\{ \dot{p}_i \frac{\partial f}{\partial p_i} + f \frac{\partial \dot{p}_i}{\partial p_i} + \dot{q}_i \frac{\partial f}{\partial q_i} + f \frac{\partial \dot{q}_i}{\partial q_i} \right\} \quad (2.41)$$

Since the Hamiltonian equations satisfy the *incompressibility* condition,

$$\sum_i \left( \frac{\partial \dot{q}_i}{\partial q_i} + \frac{\partial \dot{p}_i}{\partial p_i} \right) = \sum_i \left( \frac{\partial^2 H}{\partial p_i \partial q_i} - \frac{\partial^2 H}{\partial q_i \partial p_i} \right) = 0 \quad (2.42)$$

any volume element in phase space is preserved under Hamiltonian flow. This relation is called the *Liouville's theorem* which represents a fundamental property of Hamiltonian systems [60, 89].

This theorem further implies that the second and fourth terms in the summation on the RHS of (2.41) cancel to obtain:

$$\frac{\partial f}{\partial t} + \sum_i \left( \dot{p}_i \frac{\partial f}{\partial p_i} + \dot{q}_i \frac{\partial f}{\partial q_i} \right) = 0 \quad (2.43)$$

This result is known as the *Liouville's equations* [90].

Notice that this equation is commonly written in the Poisson bracket form:

$$\frac{\partial f}{\partial t} + [H, f] = 0 \quad (2.44)$$

The Poisson bracket operator is defined by:

$$[H, f] = \sum_{i=1}^N \left( \dot{q}_i \frac{\partial f}{\partial q_i} + \dot{p}_i \frac{\partial f}{\partial p_i} \right) = \sum_{i=1}^N \left( \frac{\partial H}{\partial p_i} \frac{\partial f}{\partial q_i} - \frac{\partial H}{\partial q_i} \frac{\partial f}{\partial p_i} \right) \quad (2.45)$$

The Poisson bracket is an operator in Hamiltonian mechanics which has convenient inherent properties considering the time evolution of dynamic variables [90, 105]. The most important property of the Poisson bracket is that it is invariant under any canonical transformation.

While this compact notation is convenient for the experienced user, to grasp the basic concepts a rough description may be preferable. Therefore, for the beginners that is not familiar with the concepts of statistical mechanics we reiterate the presentation of the abstract theory using an alternative notation equivalent to what is common in the fluid dynamic literature [57, 90]. The purpose is to provide introductory ideas about the practical implications of the Liouville equations describing the ensemble flow in  $\Gamma$ -space. For this reason, we let  $\mathbf{u}$  denote a generalized velocity vector of the system points in the neighborhood of the element of surface  $dS$ :

$$\mathbf{u} = \{\dot{q}_1, \dot{q}_2, \dots, \dot{q}_N; \dot{p}_1, \dot{p}_2, \dots, \dot{p}_N\} \quad (2.46)$$

In the particular case, where the volume  $\Omega$  is thought to be fixed in phase space, the corresponding continuity equation can be expressed as:

$$\frac{\partial}{\partial t} \int_{\Omega} f d\Omega = - \oint_S \mathbf{u} \cdot f d\mathbf{S} \quad (2.47)$$

where the net ‘convective’ flux out of the volume through the closed surface  $S$  is  $\oint_S \mathbf{u} \cdot f d\mathbf{S}$ .

Now, using a variant of Gauss theorem in  $\Gamma$ -space,

$$\oint_S \mathbf{u} \cdot f d\mathbf{S} = \int_{\Omega} \nabla \cdot (f\mathbf{u}) d\Omega \quad (2.48)$$

The continuity equation thus yields,

$$\int_{\Omega} \left[ \frac{\partial f}{\partial t} + \nabla \cdot (f\mathbf{u}) \right] d\Omega = 0 \quad (2.49)$$

Requiring that the integrand must be equal to zero for any volume  $d\Omega$ , the resulting differential equation is given by:

$$\frac{\partial f}{\partial t} + \nabla \cdot (f\mathbf{u}) = 0 \quad (2.50)$$

With (2.46) and (2.42), it is found that:

$$\nabla \cdot \mathbf{u} = \sum_{i=1}^N \left( \frac{\partial \dot{q}_i}{\partial q_i} + \frac{\partial \dot{p}_i}{\partial p_i} \right) = \sum_{i=1}^N \left( \frac{\partial^2 H}{\partial q_i \partial q_i} - \frac{\partial^2 H}{\partial q_i \partial p_i} \right) = 0 \quad (2.51)$$

since the flow of system points is *incompressible*.

Introducing the *solenoidal* vector field into the continuity equation returns the Liouville equation, which now appears as:

$$\frac{\partial f}{\partial t} = -\mathbf{u} \cdot \nabla f - f \nabla \cdot \mathbf{u} = -\mathbf{u} \cdot \nabla f \quad (2.52)$$

In an engineering view, the ensemble of system points moving through phase space behaves much like a fluid in a multidimensional space, and there are numerous similarities between our imagination of the ensemble and the well known notions of fluid dynamics [49]. Then, the substantial derivative in fluid dynamics corresponds to a derivative of the density as we follow the motion of a particular differential volume of the ensemble in time. The material derivative is thus similar to the Lagrangian picture in fluid dynamics in which individual particles are followed in time. The partial derivative is defined at fixed  $(q, p)$ . It can be interpreted as if we consider a

particular fixed control volume in phase space and measure the time variation of the density as the ensemble of system points flows by us. The partial derivative at a fixed point in phase space thus resembles the Eulerian viewpoint in fluid dynamics.

### 2.2.3.2 BBGKY-Hierarchy

In the more theoretical fields of science the conventional derivation of the Boltzmann equation for the one-particle distribution function, assumed to be valid for dilute gases, is considered far too heuristic and accordingly does not form an adequate formal basis for rigorous analysis. In this point of view a formal derivation starts out from a complete knowledge of the probability density formulated in terms of a  $N$ -particle density function,<sup>22</sup>  $f_N(\mathbf{q}, \mathbf{p}, t)$ , providing a general way of deducing the Boltzmann equation from the laws of dynamics via approximations of this rigorous equation. Deriving the Boltzmann equation in this manner may also provide novel guidelines for the extension of Boltzmann equation to higher densities.

The time evolution of this phase space probability density is governed by the Liouville equation expressed as:

$$\frac{\partial f_N}{\partial t} = [H_N, f_N] \quad (2.53)$$

However, the description of the system governed by the complete phase space probability density is not feasible in practice for a large number of particles  $N$ . Therefore, one may rather consider the behavior of a subset of particles defining a reduced phase space distribution function. The unwanted information can be eliminated by integrating  $f_N$  over the coordinates and momenta of the remaining particles [53, 90] (i.e., resembling an averaging procedure). A particular system of integro-differential equations for such a reduced distribution function is known as the BBGKY-hierarchy (i.e., this abbreviation is written for N. N. Bogoliubov, M. Born, H. S. Greed, G. Kirkwood, and J. Yvon). Comprehensive discussions on this approach is given by Cercignani et al. [14] and Liboff [90]. Nevertheless, this approach is not very useful in practice since the BBGKY-hierarchy is not closed and an ad hoc problem contraction is required. It is noted that the first equation in this sequence is still most important as it governs the evolution of  $f_1(\mathbf{p}, \mathbf{q}, t)$  in time and space provided that an approximate closure for the pair density function  $f_2(\mathbf{p}', \mathbf{q}'; \mathbf{p}, \mathbf{q}, t)$  is available (i.e., this equation contains the lowest number of unknowns in the sequence), and it represents the generic form of all the kinetic equations. Much effort has been devoted to find approximate solutions to the BBGKY hierarchy on the basis of expressions that relate  $f_1(\mathbf{p}, \mathbf{q}, t)$  and  $f_2(\mathbf{p}', \mathbf{q}'; \mathbf{p}, \mathbf{q}, t)$ . The simplest approximation is to ignore the pair correlation altogether by writing:  $f_2(\mathbf{p}', \mathbf{q}'; \mathbf{p}, \mathbf{q}, t) = f_1(\mathbf{p}', \mathbf{q}', t) f_1(\mathbf{p}, \mathbf{q}, t)$ . This assumption implies that there is no statistical correlation between particles of states

---

<sup>22</sup>  $f_N$  denotes the  $N$ -body joint-probability density for the  $N$ -body system. This function gives the probability density of finding, at time  $t$ , particle 1 in the state  $(\mathbf{p}_1, \mathbf{q}_1)$ , particle 2 in the state  $(\mathbf{p}_2, \mathbf{q}_2)$ , ..., and particle  $N$  in the state  $(\mathbf{p}_N, \mathbf{q}_N)$ .

$(\mathbf{p}', \mathbf{q}')$  and  $(\mathbf{p}, \mathbf{q})$  at any time  $t$ . Various efforts along these lines have attempted to derive the Boltzmann equation from first principles. However, a number of assumptions come into play in all these derivations, which renders even the more formal analyzes somewhat ad hoc. Therefore, many practitioners do not consider the classical formalism worthwhile.

## 2.3 Basic Concepts of Kinetic Theory

In this section the statistical theorems or mathematical tools needed to understand the Boltzmann equation in itself, and the mathematical operations performed developing the macroscopic conservation equations starting out from the microscopic Boltzmann equation, are presented. Introductory it is stressed that a heuristic theory, which resembles the work of Boltzmann [10] and the standard kinetic theory literature, is adopted in this section and the subsequent sections deriving the Boltzmann equation. Irrespective, the notation and concepts presented in Sect. 2.2 are often referred, or even redefined in a less formal wrapping, thus the underlying elements of classical mechanics are prescience of outmost importance understanding the true principles of kinetic theory.

### 2.3.1 Potential Energy of Molecular Interactions

In kinetic theory a binary molecular interaction is generally specified as a rather abrupt change in the trajectories of two molecules as a result of their mutual interaction. It is sometimes distinguished between interactions with and without contact between the molecular particles. The choice of molecular model determines the kind of interaction that will take place, thus only the hard sphere or billiard ball model gives rise to interactions with contact. The three phrases molecular interaction, encounter and collision are considered to be synonyms. Besides, attention is restricted to interactions between electrically neutral molecules in which the force between the molecules depends only on the distance between their centers. For monoatomic gases, the spacing between the particles is considered large enough so that we can approximate the particles as points, or point centers of force. For this reason, in kinetic theory, a gas molecule is characterized by its position  $\mathbf{r}$  and its velocity  $\mathbf{c}$ . However, the intermolecular force laws play a central role in the model determining the molecular interaction terms (i.e., related to the collision term on the RHS of the Boltzmann equation). Classical kinetic theory proceeds on the assumption that this law has been separately established, either empirically or from quantum theory. The force of interaction between two molecules is assumed to be conservative thus it can be related to the potential energy function (2.4):

$$\mathbf{F}(\mathbf{r}) = -\nabla E_p(\mathbf{r}) \quad (2.54)$$

where  $\mathbf{r}$  is the distance between the two molecules.

For most purposes it is chosen to specify the potential energy of interaction  $E_P(\mathbf{r})$  rather than the force of interaction  $\mathbf{F}(\mathbf{r})$ . Suppose that the particle moves from position  $\mathbf{r}$  to position  $\infty$  under the action of a conservative force  $\mathbf{F}$ . These two functions are then related as:

$$E_P(\mathbf{r}) = - \int_r^{\infty} \mathbf{F}(\mathbf{r}) \cdot d\mathbf{r} \quad (2.55)$$

Several models for the molecular potential energy of interaction have been considered, each of them having certain advantages either in their physical interpretations or giving simple mathematical representations of the laws of interaction. The *billiard ball model* is one such exploratory molecular potential energy of interaction model which is frequently used because of its simplicity. In this model a molecule is viewed as a microscopic particle and approximated by a small featureless sphere, possessing a spherically-symmetric force field. For neutral particles this force field has a very short range, and the particles can be pictured as being almost rigid spheres, with an effective diameter equal to the range of the force field. Therefore, in an average sense each gas molecule is assumed to be a rigid, spherical, non-attracting, particle with diameter equivalent to the range of molecular interaction  $d = r_0$ , and mass  $m$ . This molecular model is thus sometimes named the *rigid sphere model* or the *hard sphere model*. As they have no structure, these particles have only energy of translation. The gas is further assumed to be sufficiently dilute for collisions involving more than two particles at a time to be ignored, thus only binary collisions are considered. The collisions between these gas molecules are considered perfectly elastic. Considering a binary *elastic collision* two bodies collide and thereafter move apart again in such a way that both the overall momentum and the total kinetic energy of the center of mass of the two bodies are conserved ([148], p. 13) [60]. In a binary *in-elastic collision*, on the other hand, the two bodies collide and stick together. The overall momentum is normally conserved in these collisions too, but the overall kinetic energy of the center of mass of the two bodies is not conserved ([148], p. 13). It is noted that during real collisions, the colliding molecules (particles) undergo both elastic and in-elastic deformations.

The hard sphere potential is defined as:

$$E_P(r) = \begin{cases} \infty & \text{if } r \leq r_0 \\ 0 & \text{if } r > r_0 \end{cases} \quad (2.56)$$

in which  $r_0$  denotes the range of binary molecular interaction. The hard spheres are defined as impenetrable spheres that cannot overlap in space. The molecular energy interaction potential model mimic the extremely strong repulsion of spherical molecules at very close distances.

The hard sphere model is frequently used considering mono-atomic uncharged molecules. However, this model gives a very crude representation of the actual

physics (e.g., repulsive forces and volume of sphere), since molecules in fact are complicated electronic structures, and can by no means resemble rigid spheres. Alternatively, the energy interaction potential of the *Maxwellian molecules* might be useful in exploratory calculations in which a differentiable potential function is needed. For these molecules the intermolecular force between pairs at a distance  $r$  apart is of the form  $Kr^{-5}$ , where  $K$  is a constant [96]. Adopting this particular potential representation the solution of the equation of transfer reduces to a feasible problem, thereby Maxwell [96] obtained analytical expressions for the transport coefficients as outlined earlier. It is noted that many alternative potential functions have been proposed in the literature. The most frequently used model potentials are; rigid sphere, point center of repulsion, Sutherland's model, Lennard-Jones potential, modified Buckingham potential, Kihara potential, Morse potential. Their advantages and disadvantages are thoroughly discussed elsewhere [39, 55]. In the two models adopted in this work, the force is always repulsive and varies inversely as some power of the distance between the molecular centers. No redistribution of energy between the internal and the translational energy forms are allowed. Depending on the molecular energy interaction potential model chosen, the interacting force may arise only upon contact, or act when the molecules are at any distance away from each other.

### 2.3.2 Phase Space, Distribution Function, Means and Moments

A collection of mono-atomic gas molecules are characterized by their position  $\mathbf{r}$  in space and their velocity  $\mathbf{c}$  at time  $t$ . An infinitesimal spatial space containing the point  $\mathbf{r}$  is denoted by  $d\mathbf{r}$  (e.g., in Cartesian coordinates  $= dx dy dz$ ). In a similar manner, an infinitesimal element in a hypothetical velocity space containing the velocity  $\mathbf{c}$  is denoted by  $d\mathbf{c}$  (e.g., in Cartesian coordinates  $= dc_x dc_y dc_z$ ). The imaginary or hypothetical space containing both  $d\mathbf{r}$  and  $d\mathbf{c}$  constitutes the six-dimensional *phase space*.<sup>23</sup> Therefore, by a macroscopic point  $(\mathbf{r}, \mathbf{c}, t)$  in phase space is meant an infinitesimal volume,  $d\mathbf{r} d\mathbf{c}$ , centered at the point  $(\mathbf{r}, \mathbf{c}, t)$ , having an extension sufficient to contain a large number of molecules as required for a statistical description to be valid, but still small compared with the scale of the natural changes in the macroscopic quantities like pressure, gas velocity, temperature and density of mass.

A concept of principal importance in kinetic theory is the distribution function. The probabilistic *distribution function* containing the desired information about the spatial distribution of molecules and their velocity distribution is denoted by  $f(\mathbf{r}, \mathbf{c}, t)$ .

<sup>23</sup> The classical phase space is formally defined in terms of generalized coordinates and momenta following the Hamiltonian mechanics notation, because it is in terms of these variables that Liouville's theorem holds. However, in Cartesian coordinates as used in the present section it is usually still true that  $p_i = mc_i$  under the particular system conditions specified considering the kinetic theory of dilute gases, hence phase space can therefore be defined in terms of the coordinate and velocity variables in this particular case. Nevertheless, in the general case, for example in the presence of a magnetic field, the relation between  $p_i$  and  $c_i$  is more complicated and the classical formulation is required [115].

This probability function is defined in such a way that  $f(\mathbf{c}, \mathbf{r}, t) d\mathbf{c} d\mathbf{r}$  denotes the probable number of molecules in the volume element  $d\mathbf{r}$  located at  $\mathbf{r}$ , whose velocities lie in the range  $d\mathbf{c}$  about  $\mathbf{c}$  at time  $t$ . We treat  $f$  as being a continuous and differentiable function of its arguments. When the distribution function is given, the macroscopic properties of the gas are determined using the concept of moments (or probability-weighted averages). We may now define a molecular *state vector*  $(\mathbf{r}, \mathbf{c})$  denoting the independent variables needed to specify the rate of change of the macroscopic properties.

The macroscopic property obtained by integrating  $f d\mathbf{c}$  over the whole velocity space is the *number density*,  $n(\mathbf{r}, t)$ , which denotes the number of particles per unit volume at the location  $\mathbf{r}$  at time  $t$ :

$$n(\mathbf{r}, t) = \int_{-\infty}^{\infty} f(\mathbf{r}, \mathbf{c}, t) d\mathbf{c} \quad (2.57)$$

The mass *density* of the collection of gas molecules at  $\mathbf{r}$ , at time  $t$ , yields:

$$\rho(\mathbf{r}, t) = mn(\mathbf{r}, t) \quad (2.58)$$

Statistics means and moments are defined in terms of a suitable probability density function (PDF). Therefore, in the present context these statistical measures are expressed in terms of the normalized distribution function,  $P(\mathbf{r}, \mathbf{c}, t) = f(\mathbf{r}, \mathbf{c}, t)/n(\mathbf{r}, t)$ , having the important mathematical property of a PDF:

$$\int_{-\infty}^{\infty} P(\mathbf{r}, \mathbf{c}, t) d\mathbf{c} = \int_{-\infty}^{\infty} \frac{f(\mathbf{r}, \mathbf{c}, t)}{n} d\mathbf{c} = \frac{n}{n} = 1 \quad (2.59)$$

The mean (or expectation) of the random variable  $\mathbf{c}$  is defined by [107, 115, 116, 157]:

$$\mathbf{v}(\mathbf{r}, t) = \langle \mathbf{c}(\mathbf{r}, t) \rangle_M = \int_{-\infty}^{\infty} \mathbf{c} P(\mathbf{r}, \mathbf{c}, t) d\mathbf{c} \quad (2.60)$$

This measure is also referred to as the probability-weighted average of all possible values of  $\mathbf{c}$ .

More generally, let  $\psi(\mathbf{r}, \mathbf{c}, t)$  be a generalized physical function that denotes a property of the molecules located at time  $t$  near  $\mathbf{r}$  with a velocity near  $\mathbf{c}$ . Since  $\psi(\mathbf{r}, \mathbf{c}, t)$  is a function of  $\mathbf{c}$ , the mean of  $\psi$  is:

$$\langle \psi(\mathbf{r}, t) \rangle_M = \int_{-\infty}^{\infty} \psi(\mathbf{r}, \mathbf{c}, t) P(\mathbf{r}, \mathbf{c}, t) d\mathbf{c} = \frac{1}{n(\mathbf{r}, t)} \int_{-\infty}^{\infty} \psi(\mathbf{r}, \mathbf{c}, t) f(\mathbf{r}, \mathbf{c}, t) d\mathbf{c} \quad (2.61)$$

The  $n$ -th *moment about the origin* is defined to be:

$$\mu_n = \langle \mathbf{c}^n \rangle_M = \int_{-\infty}^{\infty} \mathbf{c}^n P(\mathbf{r}, \mathbf{c}, t) d\mathbf{c} \quad (2.62)$$

A first-order moment of  $\psi$  can thus be defined as:

$$\langle \psi(\mathbf{r}, t) \rangle_M = \int_{-\infty}^{\infty} \psi(\mathbf{r}, \mathbf{c}, t) P(\mathbf{r}, \mathbf{c}, t) d\mathbf{c} \quad (2.63)$$

It is noted that the first moment (2.63) equals the mean (2.61).

It follows that the mean or macroscopic *fluid velocity* at the position  $\mathbf{r}$  and time  $t$ , yields:

$$\mathbf{v}(\mathbf{r}, t) = \frac{1}{n(\mathbf{r}, t)} \int_{-\infty}^{\infty} \mathbf{c} f(\mathbf{r}, \mathbf{c}, t) d\mathbf{c} = \frac{1}{\rho(\mathbf{r}, t)} \int_{-\infty}^{\infty} m \mathbf{c} f(\mathbf{r}, \mathbf{c}, t) d\mathbf{c} \quad (2.64)$$

The translational motion of a particular collection of molecules can either be specified by their velocity  $\mathbf{c}$  relative to a standard frame of reference, or by their velocity relative to a frame moving with a specified velocity. The molecular velocity defined in the frame of reference which moves with the local fluid velocity  $\mathbf{v}$  is called the *peculiar velocity* of the collection of molecules. The peculiar velocity is defined by:

$$\mathbf{C} = \mathbf{c} - \mathbf{v} \quad (2.65)$$

It follows from the above definitions that the average peculiar velocity equals zero.

## 2.4 The Boltzmann Equation

The Boltzmann integro-differential equation is an equation of change for the one-particle (single) distribution function defined such that  $dN = f(\mathbf{r}, \mathbf{c}, t) d\mathbf{c} d\mathbf{r}$  represents the number of molecules that have velocities between  $\mathbf{c}$  and  $\mathbf{c} + d\mathbf{c}$  and positions between  $\mathbf{r}$  and  $\mathbf{r} + d\mathbf{r}$  at time  $t$ . All the derivations of the Boltzmann equation are based on a number of assumptions and hypotheses, making the analyzes somewhat ad hoc irrespective of the formal mathematical rigor and complexity accomplished. So in this book a heuristic theory, which is physically revealing and equally ad hoc to the more fundamental derivations of the Boltzmann equation, is adopted. It is stressed that the notation used resembles that introduced by Boltzmann [10] and is not strictly in accordance with the formal mathematical methods of classical mechanics. However, some aspects of the formal formulations and vocabulary outlined in

Sect. 2.2 are incorporated although somewhat based on intuition and empirical reasoning rather than fundamental principles as discussed in Sect. 2.3.

The Boltzmann equation can be derived using a procedure founded on the Liouville theorem. That is, a simplified interpretation of the Liouville theorem, outlined in Sect. 2.2, is employed intending to make the formulation more easily available for beginners. In this case the balance principle is applied to a control volume following a trajectory in phase space, expressed as:

$$\frac{\mathbb{D}}{\mathbb{D}t} \int \int f d\mathbf{r} d\mathbf{c} = \int \int \left( \frac{\partial f}{\partial t} \right)_{\text{Collision}} d\mathbf{r} d\mathbf{c} \quad (2.66)$$

This relation is denoting that the rate of change of  $f$  for a system of a number of particles moving with the phase space velocity vector  $(\frac{d\mathbf{r}}{dt}, \frac{d\mathbf{c}}{dt})$  equals the rate at which  $f$  is altered by collisions.

Applying numerous theorems, similar but not identical to those used in Chap. 1 deriving the governing equations in fluid dynamics, one arrives at the Boltzmann equation on the form:

$$\frac{\partial f}{\partial t} + \mathbf{c} \cdot \frac{\partial f}{\partial \mathbf{r}} + \mathbf{F} \cdot \frac{\partial f}{\partial \mathbf{c}} = \left( \frac{\partial f}{\partial t} \right)_{\text{Collision}} \quad (2.67)$$

where  $\mathbf{c}$  and  $\mathbf{r}$  are considered independent coordinates. In addition, the force  $\mathbf{F}$  per unit mass is assumed to be independent of  $\mathbf{c}$  and replaces the instantaneous acceleration.

Symbolically the Boltzmann equation can be written as [57]:

$$\frac{\mathcal{D}f}{\mathcal{D}t} = \left( \frac{\partial f}{\partial t} \right)_{\text{Collision}} \quad (2.68)$$

where the LHS denotes the translational motion and the RHS represents the impact of collisions.

The model derivation given above using the Liouville theorem is in many ways equivalent to the Lagrangian balance formulation [115]. Of course, a consistent Eulerian balance formulation would give the same result, but includes some more manipulations of the terms in the number balance (see Sect. 2.4.1). However, the Eulerian formulation is of special interest as we have adopted this framework in the preceding discussion of the governing equations of classical fluid dynamics, Chap. 1.

For binary collisions the RHS of the Boltzmann equation (2.68) assumes the form:

$$\left( \frac{\partial f}{\partial t} \right)_{\text{Collision}} = \int_{\mathbf{c}_1} \int_{4\pi} (f' f'_1 - f f_1) g \sigma_A(\boldsymbol{\Omega}) d\boldsymbol{\Omega} d\mathbf{c}_1 \quad (2.69)$$

where the un-primed distribution function refer to the state before collision, and the primed distribution function refer to the state after the collision. Moreover, for convenience, a shorthand notation is introduced for the distribution function:  $f' \equiv f(\mathbf{c}', \dots)$ ,  $f'_1 \equiv f(\mathbf{c}'_1, \dots)$ ,  $f \equiv f(\mathbf{c}, \dots)$ , and  $f_1 \equiv f(\mathbf{c}_1, \dots)$ .

A key contribution by Boltzmann was to determine the collision term solely due to two-body collisions between particles that are assumed to be uncorrelated prior to the collision (i.e., the Stosszahlansatz). Under this assumption the collision term can be written as a velocity-space integral over the product of one-particle (single) distribution functions. The velocities and the corresponding distribution functions of any two particles of the same type are conveniently distinguished by the labels  $\mathbf{c}$  and  $\mathbf{c}_1$  and  $f$  and  $f_1$ , respectively.

A survey of the kinetic theory required deriving the Boltzmann equation, for a dilute gas constituting identical molecular particles of mass  $m$ , is provided in the succeeding subsections. The translational part of the equation in the limit of no collisions is discussed first, before the more complex collision term closure is outlined.

### 2.4.1 The Boltzmann Equation in the Limit of No Collisions

Preliminarily, deriving the terms on the LHS of the Boltzmann equation, it is assumed that the effects of collisions are negligible. The molecular motion is thus purely translational. It is further assumed that in an average sense each molecule of mass  $m$  is subjected to an external force per unit mass,  $\mathbf{F}(\mathbf{r}, t)$ , which doesn't depend on the molecular velocity  $\mathbf{c}$ . This restriction excludes magnetic forces, while the gravity and electric fields which are more common in chemical and metallurgical reactors are retained. Two alternative approaches for deriving the generalized advection equation are available. These procedures are outlined in the subsequent paragraphs within this section.

#### 2.4.1.1 Ensemble of System Points Moving Along Their Trajectories in Phase Space

In this paragraph the translational motion of the distribution function is examined employing the framework of a generalized advection equation [20, 55, 57, 109, 115, 162]. The collection of molecules which at time  $t$  have positions and velocities in the range  $d\mathbf{r}d\mathbf{c}$  near  $\mathbf{r}$  and  $\mathbf{c}$  will, at an infinitesimal time  $dt$  later, have the positions and velocities in the range  $d\mathbf{r}'d\mathbf{c}'$  near  $\mathbf{r}'$  and  $\mathbf{c}'$  as a result of their motion under the influence of the force  $\mathbf{F}$ .

It follows that:

$$\mathbf{r}' = \mathbf{r} + \mathbf{c}dt \quad (2.70)$$

$$\mathbf{c}' = \mathbf{c} + \mathbf{F}dt \quad (2.71)$$

In mathematical terms the translational motion can be expressed as:

$$f(\mathbf{r}', \mathbf{c}', t) d\mathbf{r}' d\mathbf{c}' = f(\mathbf{r}, \mathbf{c}, t) d\mathbf{r} d\mathbf{c} \quad (2.72)$$

The Lagrangian like control volume  $d\mathbf{r} d\mathbf{c}$  in the six dimensional phase space may become distorted in shape as a result of the motion. But, in accordance with the Liouville's theorem, discussed in Sect. 2.2.3.1, the new volume is simply related to the old one by the relation (e.g., [109], p. 225):

$$d\mathbf{r}' d\mathbf{c}' = |J| d\mathbf{r} d\mathbf{c} \quad (2.73)$$

where  $J$  is the Jacobian determinant (value) of the transformation relations (2.70) and (2.71) from the old variables  $d\mathbf{r} d\mathbf{c}$  to the new variables  $d\mathbf{r}' d\mathbf{c}'$ . In this particular case where the force  $\mathbf{F}$  does not depend on the velocity  $\mathbf{c}$  of the molecules,  $J = 1$  due to the Poincarè theorem (see Sect. 2.2.3.1, p. 226). Hence,

$$f(\mathbf{r}', \mathbf{c}', t) = f(\mathbf{r}, \mathbf{c}, t) \quad (2.74)$$

or

$$f(\mathbf{r} + \mathbf{c} dt, \mathbf{c} + \mathbf{F} dt, t + dt) - f(\mathbf{r}, \mathbf{c}, t) = 0 \quad (2.75)$$

This means that in the limit of no molecular interactions, for which the collision term  $(\frac{\partial f}{\partial t})_{\text{Collision}}$  vanishes,  $f$  remains unchanged if the observer moves along with the system points in phase space.

Expanding the first term in (2.75) to the first order in  $dt$ , the generalized advection equation for the distribution function is obtained as  $dt \rightarrow 0$ :

$$\left[ \left( \frac{\partial f}{\partial x} c_x + \frac{\partial f}{\partial y} c_y + \frac{\partial f}{\partial z} c_z \right) + \left( \frac{\partial f}{\partial c_x} F_x + \frac{\partial f}{\partial c_y} F_y + \frac{\partial f}{\partial c_z} F_z \right) + \frac{\partial f}{\partial t} \right] dt = 0 \quad (2.76)$$

The terms in brackets equal an operator analogous to the substantial time derivative known from the transport phenomena literature. The total differential of  $f(\mathbf{r}, \mathbf{c}, t)$  is given by:

$$\begin{aligned} \mathcal{D}f &= \frac{\partial f}{\partial t} \mathcal{D}t + \left( \frac{\partial f}{\partial x} dx + \frac{\partial f}{\partial y} dy + \frac{\partial f}{\partial z} dz \right) + \left( \frac{\partial f}{\partial c_x} dc_x + \frac{\partial f}{\partial c_y} dc_y + \frac{\partial f}{\partial c_z} dc_z \right) \\ &= \frac{\partial f}{\partial t} \mathcal{D}t + \nabla_r f \cdot d\mathbf{r} + \nabla_c f \cdot d\mathbf{c} = \left[ \frac{\partial f}{\partial t} + \nabla_r f \cdot \mathbf{c} + \nabla_c f \cdot \mathbf{F} \right] \mathcal{D}t \end{aligned} \quad (2.77)$$

where  $\mathcal{D}t$  is taken to be infinitesimal and represents the total change in  $f$  resulting from changes in the seven variables on which  $f$  depends explicitly by means of the first partial derivatives.

Equation (2.76) can thus be written more compactly on the vector form:

$$\frac{\mathcal{D}f}{\mathcal{D}t} \equiv \frac{\partial f}{\partial t} + \mathbf{c} \cdot \frac{\partial f}{\partial \mathbf{r}} + \mathbf{F} \cdot \frac{\partial f}{\partial \mathbf{c}} = 0 \quad (2.78)$$

where  $\nabla_{\mathbf{r}} \equiv \frac{\partial}{\partial \mathbf{r}}$ ,  $\nabla_{\mathbf{c}} \equiv \frac{\partial}{\partial \mathbf{c}}$  are the gradient operators with respect to  $\mathbf{r}$  and  $\mathbf{c}$ , respectively.

### 2.4.1.2 Ensemble of System Points Moving Through a Fixed Volume in Phase Space

In this paragraph the translational motion of the distribution function is examined employing the framework of a generalized continuity equation [115, 117, 157]. Consider a fixed 6-dimensional control volume in phase space (i.e., an imaginary extension of the Eulerian control volume known from fluid dynamics, Fig. 1.2), containing a given range of molecular positions between  $\mathbf{r}$  and  $\mathbf{r} + d\mathbf{r}$  and of velocities between  $\mathbf{c}$  and  $\mathbf{c} + d\mathbf{c}$ . The number of molecules in the control volume  $d\mathbf{r}d\mathbf{c}$  of phase space changes as the positions and velocities of the molecules change. The net accumulation of molecules in this range in time  $dt$  is given by  $(\frac{\partial f}{\partial t})d\mathbf{r}d\mathbf{c}dt$ . The net change in the number of molecules within the control volume is determined by the number of molecules entering and leaving this range  $d\mathbf{r}d\mathbf{c}$  as a result of the random molecular motion. In Cartesian coordinates the number of molecules entering the control volume,  $d\mathbf{r}d\mathbf{c}$ , in time  $dt$  through the face  $x = \text{constant}$  equals  $f(c_x dt)dydzdc_xdc_ydc_z$ . The corresponding number of molecules leaving through the face  $x + dx = \text{constant}$  is given by  $[fc_x + \frac{\partial}{\partial x}(fc_x)dx]dtdydzdc_xdc_ydc_z$  where both  $f$  and  $c_x$  are evaluated at  $x + dx$  and thereafter approximated using a first order Taylor expansion. Hence, the number of molecules entering the control volume  $d\mathbf{r}d\mathbf{c}$  in time  $dt$  through the different control volume faces are approximated by:

Net inflow in x- direction:

$$f(c_x dt)dydzdc_xdc_ydc_z - [fc_x + \frac{\partial}{\partial x}(fc_x)dx]dtdydzdc_xdc_ydc_z = -\frac{\partial}{\partial x}(fc_x)d\mathbf{r}d\mathbf{c}dt \quad (2.79)$$

Net inflow in y- direction:

$$f(c_y dt)dx dzdc_xdc_ydc_z - [fc_y + \frac{\partial}{\partial y}(fc_y)dy]dtdxdzdc_xdc_ydc_z = -\frac{\partial}{\partial y}(fc_y)d\mathbf{r}d\mathbf{c}dt \quad (2.80)$$

Net inflow in z- direction:

$$f(c_z dt)dxdydc_xdc_ydc_z - [fc_z + \frac{\partial}{\partial z}(fc_z)dz]dtdxdydc_xdc_ydc_z = -\frac{\partial}{\partial z}(fc_z)d\mathbf{r}d\mathbf{c}dt \quad (2.81)$$

Net inflow through the  $c_x$  face of the velocity space:

$$\begin{aligned}
& f(F_x dt) dx dy dz dc_y dc_z - [f F_x + \frac{\partial}{\partial c_x}(f F_x) dc_x] dt dx dy dz dc_y dc_z \\
& = -\frac{\partial}{\partial c_x}(f F_x) d\mathbf{r} d\mathbf{c} dt
\end{aligned} \tag{2.82}$$

Net inflow through the  $c_y$  face of the velocity space:

$$\begin{aligned}
& f(F_y dt) dx dy dz dc_x dc_z - [f F_y + \frac{\partial}{\partial c_y}(f F_y) dc_y] dt dx dy dz dc_x dc_z \\
& = -\frac{\partial}{\partial c_y}(f F_y) d\mathbf{r} d\mathbf{c} dt
\end{aligned} \tag{2.83}$$

Net inflow through the  $c_z$  face of the velocity space:

$$\begin{aligned}
& f(F_z dt) dx dy dz dc_x dc_y - [f F_z + \frac{\partial}{\partial c_z}(f F_z) dc_z] dt dx dy dz dc_x dc_y \\
& = -\frac{\partial}{\partial c_z}(f F_z) d\mathbf{r} d\mathbf{c} dt
\end{aligned} \tag{2.84}$$

Overall, the net inflow of molecules into the phase space  $d\mathbf{r} d\mathbf{c}$  is balanced by the transient term, hence:

$$\begin{aligned}
\left(\frac{\partial f}{\partial t}\right) d\mathbf{r} d\mathbf{c} dt & = -\left[\frac{\partial}{\partial x}(f c_x) + \frac{\partial}{\partial y}(f c_y) + \frac{\partial}{\partial z}(f c_z)\right] d\mathbf{r} d\mathbf{c} dt \\
& \quad -\left[\frac{\partial}{\partial c_x}(f F_x) + \frac{\partial}{\partial c_y}(f F_y) + \frac{\partial}{\partial c_z}(f F_z)\right] d\mathbf{r} d\mathbf{c} dt
\end{aligned} \tag{2.85}$$

Or, after dividing by  $d\mathbf{r} d\mathbf{c} dt$  and adopting Einsteins summation index notation:

$$\begin{aligned}
\left(\frac{\partial f}{\partial t}\right) & = -\frac{\partial}{\partial x_i}(f c_i) - \frac{\partial}{\partial c_i}(f F_i) \\
& = -\left[c_i \frac{\partial f}{\partial x_i} + F_i \frac{\partial f}{\partial c_i}\right] - f\left[\frac{\partial c_i}{\partial x_i} + \frac{\partial F_i}{\partial c_i}\right]
\end{aligned} \tag{2.86}$$

Further simplification can be achieved as we recall that the variables  $\mathbf{r}$  and  $\mathbf{c}$  are independent, hence:

$$\frac{\partial c_i}{\partial x_i} = 0 \tag{2.87}$$

In a similar manner,

$$\frac{\partial F_i}{\partial c_i} = 0 \tag{2.88}$$

since  $\mathbf{F}$  does not depend on  $\mathbf{c}$ .

Using the latter two relations the terms within the last bracket in (2.86) vanish, so the Boltzmann equation reduces to:

$$\frac{\partial f}{\partial t} = -\mathbf{c} \cdot \frac{\partial f}{\partial \mathbf{r}} - \mathbf{F} \cdot \frac{\partial f}{\partial \mathbf{c}} \quad (2.89)$$

This relation is known as the Liouville theorem as discussed in Sect. 2.2.3.1.

Introducing a generalized form of the substantial derivative, measuring the rate of change as the observer moves along with the system points in phase space, a compact form similar to (2.78) is achieved. Note also that it is common in the mechanics literature to assume that there always exists a sufficiently differentiable and single-valued function defining the position vector, even though it is unknown. In this interpretation the molecular positions and velocities changes in accordance with (2.70) and (2.71) [92] (Sect. 4.3).

### 2.4.2 The Boltzmann Equation Collision Term Approximation

To determine the rate of change of  $f$  caused by molecular collisions a number of simplifying assumptions concerning the molecular motion and collisions are introduced. The most important assumptions are [20, 39, 115]:

- The system under consideration in the classical kinetic theory is a dilute gas of  $N$  mono-atomic molecules enclosed in a box of volume  $V$ . It is assumed that the particles in the system are identical having mass  $m$ .
- The gas density is assumed to be very low so that only elastic binary collisions need to be taken into account. At higher densities, ternary and higher order interactions become significant.
- The interactions with the external boundaries of the system are ignored. That is, the physical walls of the container are replaced by idealized surfaces which reflect the particles by elastic collisions.
- All possible effects which can be exerted by the external force per unit mass,  $\mathbf{F}$ , on the magnitude of the collisional cross section are neglected.
- The *local equilibrium* assumption is imposed. This means that the distribution function  $f(\mathbf{r}, \mathbf{c}, t)$  does not vary appreciably (homogeneous) during a time interval of the order of the duration of a molecular collision, nor does it vary appreciably over a spatial distance of the order of the range of intermolecular forces.
- The *molecular chaos* assumption is imposed. This assumption implies that the dilute gas point particles are uncorrelated outside the range of interaction  $r_0$ . Moreover, the range of interaction is considered infinitesimal relative to the mean free path of the molecular particles  $l$ , thus  $r_0/l \ll 1$ . Equivalently, the interaction volume  $V_0 \propto r_0^3$  and the interaction time  $\tau_0$  is considered infinitesimal relative to the average volume per particle and the mean free time between the interactions. This constraint ensures rectilinear particle trajectories before and after a collision. This assumption is sometimes referred to as the Stosszahlansatz. In the original paper by

Boltzmann [10], it is rather assumed that in a given volume element the expected number of collisions between molecules that belong to different velocity ranges can be computed statistically. This assumption was then referred to as the Boltzmann *Stosszahlansatz* (German for: Collision number assumption). This assumption is difficult to justify because it introduces statistical arguments into a problem that is in principle purely mechanical [117]. Criticism against the Boltzmann equation was raised in the past related to this problem. Nowadays it is apparently accepted that the molecular chaos assumption is needed only for the molecules that are going to collide. After the collision the scattered particles are of course strongly correlated, but this is considered irrelevant for the calculation since the colliding molecules come from different regions of space and have met in their past history other particles and are therefore entirely uncorrelated. Furthermore, the molecular chaos assumption also implies that the pair distribution function can be approximated by the product of two single distribution functions. If the pair distribution function can be expressed as the sum of the product of two single distribution functions and a pair correlations function, the following approximation holds:

$$\begin{aligned} f^{(2)}(\mathbf{r}, \mathbf{c}_1, \mathbf{r}, \mathbf{c}_2, t) &= \frac{N-1}{N} \left[ f^{(1)}(\mathbf{r}, \mathbf{c}_1, t) f^{(2)}(\mathbf{r}, \mathbf{c}_2, t) + f_{\text{Correlation}} \right] \\ &\approx f^{(1)}(\mathbf{r}, \mathbf{c}_1, t) f^{(2)}(\mathbf{r}, \mathbf{c}_2, t) \end{aligned} \quad (2.90)$$

The chaos assumption thus allows the pair correlation to be neglected outside the range of molecular interaction, thus  $f_{\text{Correlation}} \approx 0$  when  $|\mathbf{r}_2 - \mathbf{r}_1| > r_0$ .

A result of the Boltzmann *H-theorem* analysis is that the latter statistical assumption makes Boltzmann's equation irreversible in time (e.g., [39], Sect. 4.2).

No exact expression for  $(\frac{\partial f}{\partial t})_{\text{Collision}}$  has been obtained since the nature of the interaction between the colliding molecules is not known in sufficient details. It is rather assumed by hypothesis some laws of interaction which are validated comparing the overall results with experimental data. Nevertheless, detailed experimental analysis of gases shows that, at distances large compared to the molecular dimensions, weak intermolecular forces exist, whereas at distances of the order of the molecular dimensions the molecules repel each other strongly. Moreover, collisions between complex molecules may in general also redistribute energy between the translational and internal energy forms but as the present analysis is restricted to mono-atomic gases it is presupposed that no energy is redistributed between these energy forms. To close the statistical Boltzmann equation determining the evolution of the distribution function, it is considered advantageous to derive constitutive relations for the collision term based on mechanistic analysis of simplified images or models of binary particle collisions. In this context simplifying assumptions about the nature of the forces between the two molecules during collisions must be made. Several molecular models have been considered, as already mentioned in Sect. 2.3.1. In the following, the molecules of the gas are approximated as hard spheres resembling billiard balls. Moreover, all the particles have the same mass and the particle collisions are elastic. Taking into account the molecular interactions a mathematical expression for the

rate at which the distribution function  $f$  is being altered by collisions is required. In the Boltzmann equation, these phenomena are represented by the net rate at which collisions increase or decrease the number of molecules entering the phase volume  $d\mathbf{r}d\mathbf{c}$ :

$$\left(\frac{\partial f}{\partial t}\right)_{\text{Collision}} = \left(\frac{\partial f}{\partial t}\right)_{\text{Collision}}^+ - \left(\frac{\partial f}{\partial t}\right)_{\text{Collision}}^- \quad (2.91)$$

where the number of particles injected into  $d\mathbf{r}d\mathbf{c}$  due to collisions during the time  $dt$  is denoted by  $\left(\frac{\partial f}{\partial t}\right)_{\text{Collision}}^+ d\mathbf{r}d\mathbf{c}dt$ , while the number of particles ejected is  $\left(\frac{\partial f}{\partial t}\right)_{\text{Collision}}^- d\mathbf{r}d\mathbf{c}dt$ . It is in specifying these terms the assumption that the system is a dilute gas becomes relevant.

The conventional collision term  $\left(\frac{\partial f}{\partial t}\right)_{\text{Collision}}$  closure is further discussed in the paragraph called *generalized collision term* in the current subsection, presenting an outline of the derivation of the approximate constitutive relations for  $\left(\frac{\partial f}{\partial t}\right)_{\text{Collision}}^+$  and  $\left(\frac{\partial f}{\partial t}\right)_{\text{Collision}}^-$ . Meanwhile, the prerequisite understanding of the fundamental nature of the dynamics of binary particle collisions, and the mechanical relations between the velocities before and after the interaction, the scattering cross sections, the symmetry properties of the collision, the concept of solid angle, and an estimate of the expected number of molecular collisions are outlined in the subsequent paragraphs within this section.

#### 2.4.2.1 Dynamics of Elastic Binary Molecular Interactions

It is required to express either pair of molecular velocities before and after the interaction in terms of the other pair, and of two independent geometrical variables ( $b$  and  $\phi$ ) in order to complete the specification of the encounter. The original Boltzmann equation derivation considers elastic collisions in free space between two spin-less molecules of equal mass. However, due to the major interest in multicomponent mixtures, the theory outline consider elastic collisions between two spin-less mono-atomic molecules in an ideal gas mixture. The theory may be useful even if the molecules are not mono-atomic, provided that their states of internal motion (i.e., rotation and vibration) are not affected by the collisions. The two molecules under consideration are treated as point particles with respective masses  $m_1$  and  $m_2$ . In the *laboratory frame*, the incoming molecule positions are denoted by  $\mathbf{r}_1$  and  $\mathbf{r}_2$ , and the particle velocities are indicated by  $\mathbf{c}_1$  and  $\mathbf{c}_2$ . The corresponding positions and velocities after the encounter are  $\mathbf{r}'_1$ ,  $\mathbf{r}'_2$  and  $\mathbf{c}'_1$ ,  $\mathbf{c}'_2$ , respectively. The classical trajectories for two interacting molecules presented in the laboratory system frame are viewed in Fig. 2.1. It is supposed that the particle interaction is determined by conservative potential interaction forces only. Any external forces which might act on the molecules are considered negligible compared to the potential forces involved locally in the collision. The relative position vectors in the laboratory frame are defined by:

$$\mathbf{r} = \mathbf{r}_2 - \mathbf{r}_1 \text{ and } \mathbf{r}' = \mathbf{r}'_2 - \mathbf{r}'_1 \quad (2.92)$$

**Fig. 2.1** A binary particle interaction or scattering event as viewed in the laboratory coordinate system

Accordingly, the relative displacements are:

$$r = |\mathbf{r}_2 - \mathbf{r}_1| \text{ and } r' = |\mathbf{r}'_2 - \mathbf{r}'_1| \quad (2.93)$$

To express the dynamics of a binary interaction in mathematical terms, a more precise definition of an encounter is needed. A molecular interaction, or particle scattering event, is divided into three epochs: before, during, and after the interaction. Both before and after the interaction, molecules are free and do not interact with one another. We may then introduce a measure  $r_0$  that denotes the range of interaction. In the present analysis of an ideal gas mixture, the hard sphere molecular model (2.56), given at page 232, is employed. This parameter is thus defined so that, when the particles are sufficiently far away from each other ( $r > r_0$ ), the interaction vanishes. By definition, when the particles enter the interaction domain ( $r \leq r_0$ ), they experience a collision. The meaning of before and after collision is thus given in terms of the potential of interaction  $E_P(r)$  or the range of interaction  $r_0$ . Before interaction denotes the interval in which the particles are approaching one another and  $r > r_0$  or, equivalently,  $E_P(r) = 0$ . After collision denotes the interval in which the particles are receding from one another and, again,  $E_P(r) = 0$  and  $r > r_0$ . Before the particles are entering the interaction region,  $r > r_0$ , the two particles move freely with constant momenta towards each other. The total energy of the system equals the sum of the kinetic energies:

$$E_{\text{Total}} = \frac{\mathbf{p}_1^2}{2m_1} + \frac{\mathbf{p}_2^2}{2m_2} \quad (2.94)$$

After the particles are exiting the interaction region,  $r > r_0$ , they again move freely with constant momenta but now away from each other.

The energy after interaction is:

$$E'_{\text{Total}} = \frac{\mathbf{p}'_1{}^2}{2m_1} + \frac{\mathbf{p}'_2{}^2}{2m_2} = E_{\text{Total}} \quad (2.95)$$

In the interaction region,  $r \leq r_0$ , the kinetic energy of the particles is generally converted partly into potential energy. The total energy of the two particles is still conserved<sup>24</sup>:

$$E'_{\text{Total}} = \frac{\mathbf{p}_1'^2}{2m_1} + \frac{\mathbf{p}_2'^2}{2m_2} + E_p(r) = E_{\text{Total}} \quad (2.97)$$

It is assumed that the interaction force is conservative. A conservative force is a force with the property that the work done in moving a particle between two points is independent of the path taken. For this reason the force depends only on the position of the particle.

In the laboratory frame<sup>25</sup> the equations of motion (i.e., Newtons 2. law) for each of the interacting particles are:

$$m_1 \frac{d^2 \mathbf{r}_1}{dt^2} = \mathbf{F}_{12} \quad (2.98)$$

$$m_2 \frac{d^2 \mathbf{r}_2}{dt^2} = \mathbf{F}_{21} \quad (2.99)$$

where the force exerted on molecule 1 by molecule 2 is denoted by  $\mathbf{F}_{12}$ , and the force exerted on molecule 2 by molecule 1 is denoted by  $\mathbf{F}_{21}$ . The Newtons laws and the total energy balance, including an approximate molecular energy interaction potential model, determine the movement of point centers with specified masses thus the corresponding position vector trajectories reproduce the movement of actual molecules of finite size.

The law of conservation of total energy for the binary particle system can be derived from the equations of motion in the following manner. In the first step we multiply, by the scalar vector product, the particle velocity  $\mathbf{c}_1 = \dot{\mathbf{r}}_1$  with the vector equation (2.98), and the particle velocity  $\mathbf{c}_2 = \dot{\mathbf{r}}_2$  with the vector equation (2.99). Second, the LHS terms are manipulated using simple derivation rules. Finally, the resulting two equations are added and the forces are eliminated using the definition (2.54):

$$m_1 \frac{d(\frac{1}{2}c_1^2)}{dt} + m_2 \frac{d(\frac{1}{2}c_2^2)}{dt} = -\nabla E_p(|\mathbf{r}_1 - \mathbf{r}_2|) \cdot \frac{d\mathbf{r}_1}{dt} - \nabla E_p(|\mathbf{r}_2 - \mathbf{r}_1|) \cdot \frac{d\mathbf{r}_2}{dt} \quad (2.100)$$

---

<sup>24</sup> Note that the Hamiltonian of two particles interacting under an energy potential  $E_p(r)$ , in the laboratory frame, is written [90]:

$$H(\mathbf{r}_1, \mathbf{r}_2, \mathbf{p}_1, \mathbf{p}_2) = \frac{\mathbf{p}_1^2}{2m_1} + \frac{\mathbf{p}_2^2}{2m_2} + E_p(r = |\mathbf{r}_2 - \mathbf{r}_1|) = E_{\text{Total}}. \quad (2.96)$$

<sup>25</sup> In physics, the laboratory frame of reference is the reference frame in which the laboratory is at rest. The laboratory frame name is obtained as the experiment is presumed to be made by laboratory instruments.

Since  $dt$  vanishes by multiplication, undetermined integrations provide the result denoting the law of conservation of total energy [60]:

$$E_{\text{Total}} = \frac{1}{2}m_1c_1^2 + \frac{1}{2}m_2c_2^2 + \Delta E_p(|\mathbf{r}_2 - \mathbf{r}_1|) = \text{Constant} \quad (2.101)$$

where the kinetic theory regards the range  $r \leq r_0$  over which  $\Delta E_p(|\mathbf{r}_2 - \mathbf{r}_1|)$  is effective as being small (i.e., both  $E_p(|\mathbf{r}_2 - \mathbf{r}_1|) \rightarrow 0$  and  $E_p(|\mathbf{r}_1 - \mathbf{r}_2|) \rightarrow 0$  for  $r = |\mathbf{r}_2 - \mathbf{r}_1| \geq r_0$ ). Equivalently, the time duration of the interactions is assumed to be so small that we may consider them instantaneous compared to the time period between successive collisions. Moreover, considering elastic collisions of hard sphere – billiard ball particles (2.56), there are no loss in kinetic energy (i.e.,  $\Delta E_p(|\mathbf{r}_2 - \mathbf{r}_1|) \rightarrow 0$  for  $r \leq r_0$ ). For these reasons, henceforth our interest lies on the particles' dynamics before and after the interaction takes place.

For an ideal gas mixture only elastic collisions take place, hence the kinetic energy is conserved and the kinetic energy before and after a collision equals:

$$\frac{1}{2}m_1c_1^2 + \frac{1}{2}m_2c_2^2 = \frac{1}{2}m_1c_1'^2 + \frac{1}{2}m_2c_2'^2 = E_{\text{Total}} \quad (2.102)$$

Similarly, the sum of the cross products of (2.98) and (2.99) with  $\dot{\mathbf{r}}_1$  and  $\dot{\mathbf{r}}_2$ , respectively, leads to the law of conservation of total angular momentum:

$$L_{\text{Total}} = m_1\mathbf{r}_1 \times \dot{\mathbf{r}}_1 + m_2\mathbf{r}_2 \times \dot{\mathbf{r}}_2 = \text{Constant} \quad (2.103)$$

In the laboratory frame the coordinate  $\mathbf{r}_c$  of the center of mass of two point particles is given by the weighted average of their coordinates  $\mathbf{r}_1$  and  $\mathbf{r}_2$ :

$$\mathbf{r}_c = \frac{m_1\mathbf{r}_1 + m_2\mathbf{r}_2}{m_1 + m_2} \quad (2.104)$$

where  $m_c = m_1 + m_2$  is the total mass. The coordinates of the center of mass point  $\mathbf{r}_c$  lies on the straight line connecting the positions  $\mathbf{r}_1$  and  $\mathbf{r}_2$  of point masses  $m_1$  and  $m_2$ , respectively.

In the laboratory frame, the velocity of the center of mass is given by:

$$\mathbf{G} = \dot{\mathbf{r}}_c = \frac{d\mathbf{r}_c}{dt} \quad (2.105)$$

It follows that the center of mass acceleration vanishes as:

$$m_c \frac{d\mathbf{G}}{dt} = m_c \frac{d^2\mathbf{r}_c}{dt^2} = m_1 \frac{d^2\mathbf{r}_1}{dt^2} + m_2 \frac{d^2\mathbf{r}_2}{dt^2} = \mathbf{F}_{12} + \mathbf{F}_{21} = 0 \quad (2.106)$$

since the Newton 3. law of action and reaction states that  $\mathbf{F}_{12} = -\mathbf{F}_{21}$ . Note also that when the forces are given by the molecular energy interaction potential  $E_p(r)$ , the local problem is spherically symmetric [60].

It follows from (2.106), when integrated in time, that the conservation of linear momentum yields:

$$m_c \mathbf{G} = m_1 \mathbf{c}_1 + m_2 \mathbf{c}_2 = m_1 \mathbf{c}'_1 + m_2 \mathbf{c}'_2 = \mathbf{P} = \text{Constant} \quad (2.107)$$

This relation is showing that the velocities are not independent. In fact (2.107) states that the total mass  $m_c$  of the two molecules moves uniformly throughout the collision. That is, the center of mass velocity  $\mathbf{G}$  remains unchanged since  $\mathbf{P}$  is conserved (constant) for elastic collisions.

The ratio between the kinetic energy (2.102) and momentum (2.107) is:

$$\frac{m_1(\mathbf{c}'_1{}^2 - \mathbf{c}_1^2)}{m_1(\mathbf{c}'_1 - \mathbf{c}_1)} = -\frac{m_2(\mathbf{c}'_2{}^2 - \mathbf{c}_2^2)}{m_2(\mathbf{c}_2 - \mathbf{c}'_2)} \quad (2.108)$$

and, after simple manipulations

$$\mathbf{c}'_1 + \mathbf{c}_1 = \mathbf{c}_2 + \mathbf{c}'_2 \text{ or equivalently } \mathbf{g}'_{21} = -\mathbf{g}_{21} \quad (2.109)$$

Accordingly, by integration in time we also get:  $\mathbf{r}' = -\mathbf{r}$ .

It is noticed that *in-elastic* collisions are characterized by the degree to which the relative speed is no longer conserved. For this reason, the coefficient of restitution  $e$  in a collision is defined (i.e., with basis in (2.109)) as the ratio of the relative velocity after collision, divided by the relative velocity of approach [63, 99]:

$$\mathbf{c}'_2 - \mathbf{c}'_1 = -e(\mathbf{c}_2 - \mathbf{c}_1) \quad (2.110)$$

where  $e = 1$  denotes elastic collisions, whereas  $e = 0$  for totally inelastic collisions.

Another quantity of interest is the relative velocity. Let  $\mathbf{g}_{21}$  and  $\mathbf{g}'_{21}$ , and  $\mathbf{g}_{12}$  and  $\mathbf{g}'_{12}$  denote respectively the relative velocities before and after the interaction either defined as the second molecule relative to the first, or of the first relative to the second:

$$\mathbf{g}_{21} = \mathbf{c}_2 - \mathbf{c}_1 = -\mathbf{g}_{12} \text{ and } \mathbf{g}'_{21} = \mathbf{c}'_2 - \mathbf{c}'_1 = -\mathbf{g}'_{12} \quad (2.111)$$

The magnitudes of the relative velocities before collision are equal and denoted by  $g$ , likewise the relative velocities after collision are equal and denoted  $g'$ .

Thus, for elastic collisions the following relations hold:

$$g_{21} = g_{12} = g \text{ and } g'_{21} = g'_{12} = g' \quad (2.112)$$

By means of (2.107) and (2.111) we can express  $\mathbf{c}_1$  and  $\mathbf{c}_2$ , and  $\mathbf{c}'_1$  and  $\mathbf{c}'_2$  in terms of  $\mathbf{G}$  and  $\mathbf{g}_{21}$ , as given by:

$$\begin{aligned}
\mathbf{c}_1 &= \mathbf{G} - \frac{\mu}{m_1} \mathbf{g}_{21} \\
\mathbf{c}'_1 &= \mathbf{G} - \frac{\mu}{m_1} \mathbf{g}'_{21} \\
\mathbf{c}_2 &= \mathbf{G} + \frac{\mu}{m_2} \mathbf{g}_{21} \\
\mathbf{c}'_2 &= \mathbf{G} + \frac{\mu}{m_2} \mathbf{g}'_{21}
\end{aligned} \tag{2.113}$$

in which is a hypothetical mass quantity,  $\mu$ , named the reduced mass of the binary particle system has been introduced.

The *reduced mass* is defined as:

$$\mu = \frac{m_1 m_2}{m_1 + m_2} \tag{2.114}$$

These relations (2.113) thus show that a knowledge of  $\mathbf{G}$  and  $\mathbf{g}_{21}$  is equivalent to a knowledge of  $\mathbf{c}_1$  and  $\mathbf{c}_2$  or  $\mathbf{c}'_1$  and  $\mathbf{c}'_2$  denoting the state of motion before and after the interaction.

By experience, it proves convenient in discussing scattering events to transform the model into a frame of reference that moves along with the center of mass in which  $\mathbf{r}_c = 0$  is taken as origin. In this coordinate system, the center of mass motion is eliminated in accordance with the definition (2.105):

$$\mathbf{G}_c = \left. \frac{d\mathbf{r}_c}{dt} \right|_{\mathbf{r}_c=0} = 0 \tag{2.115}$$

Since the problem has been formulated in terms of the relative velocity vectors before and after an interaction, it is revealed that in the center of mass frame the collision process can be described by simple relationships. From (2.113), we get:

$$\mathbf{c}_{1c} = \mathbf{c}_1 - \mathbf{G} = -\frac{\mu}{m_1} \mathbf{g}_{21} \tag{2.116}$$

$$\mathbf{c}_{2c} = \mathbf{c}_2 - \mathbf{G} = \frac{\mu}{m_2} \mathbf{g}_{21} \tag{2.117}$$

$$\mathbf{c}'_{1c} = \mathbf{c}'_1 - \mathbf{G} = -\frac{\mu}{m_1} \mathbf{g}'_{21} \tag{2.118}$$

$$\mathbf{c}'_{2c} = \mathbf{c}'_2 - \mathbf{G} = \frac{\mu}{m_2} \mathbf{g}'_{21} \tag{2.119}$$

The binary particle collision presented in the center of mass frame is depicted in Fig. 2.2. The center of mass frame is 1D in the symmetric case.

**Fig. 2.2** Scattering in the center of mass frame illustrating the relative velocities of masses  $m_1$  and  $m_2$

By the definition of the center of mass frame, (2.107) might be manipulated as:

$$\mathbf{P}_c = m_c \mathbf{G}_c = m_1 \mathbf{c}_{1c} + m_2 \mathbf{c}_{2c} = m_1 \mathbf{c}'_{1c} + m_2 \mathbf{c}'_{2c} = 0 \quad (2.120)$$

By use of the relations given in (2.113), the kinetic energy equation (2.102) becomes:

$$E_c = \frac{1}{2} m_c (G_c^2 + \frac{\mu}{m_c} g^2) = \frac{1}{2} m_c (G_c^2 + \frac{\mu}{m_c} g'^2) \quad (2.121)$$

The relative velocity changes from the value  $\mathbf{g}_{21}$  before the collision to the value  $\mathbf{g}'_{21}$  after the collision. Since the collision is assumed to be elastic so that the internal energies of the molecules remain unchanged, the total kinetic energy  $E_c$  remains unchanged in a collision. It follows from (2.121) and (2.115) that the kinetic energy equation can be simplified as:

$$E_c = \frac{\mu}{m_c} g^2 = \frac{\mu}{m_c} g'^2 \quad (2.122)$$

Hence, it is revealed that the magnitude of the relative velocity is the same before and after the collision:

$$g = g' \quad (2.123)$$

This result shows that the relative velocity is changed only in direction and not in magnitude by the collision. The dynamical effect of a collision is therefore known when the change in direction of  $\mathbf{g}_{21}$  is determined.

Further knowledge on the direction of  $\mathbf{g}_{21}$  is obtained by examining the simultaneous positions (or velocities) of the two particles in the center of mass framework. The position vectors  $\mathbf{r}_{1c}$ ,  $\mathbf{r}_{2c}$  and  $\mathbf{r}'_{1c}$ ,  $\mathbf{r}'_{2c}$  of the particles relative to the center of mass are defined by:

$$\mathbf{r}_{1c} = \mathbf{r}_1 - \mathbf{r}_c = -\frac{\mu}{m_1} \mathbf{r} \quad (2.124)$$

$$\mathbf{r}_{2c} = \mathbf{r}_2 - \mathbf{r}_c = \frac{\mu}{m_2} \mathbf{r} \quad (2.125)$$

$$\mathbf{r}'_{1c} = \mathbf{r}'_1 - \mathbf{r}'_c = -\frac{\mu}{m_1} \mathbf{r}' \quad (2.126)$$

$$\mathbf{r}'_{2c} = \mathbf{r}'_2 - \mathbf{r}'_c = \frac{\mu}{m_2} \mathbf{r}' \quad (2.127)$$

in which the definition of  $\mathbf{r}_c$  is given by (2.104), p. 246.

Eliminating the relative position vectors  $\mathbf{r}$  and  $\mathbf{r}'$  from these relations, yield:

$$m_1 \mathbf{r}_{1c} = -m_2 \mathbf{r}_{2c} \quad (2.128)$$

$$m_1 \mathbf{r}'_{1c} = -m_2 \mathbf{r}'_{2c} \quad (2.129)$$

This means that in the frame of reference which moves with the center of mass, the position vectors are at all times oppositely directed along a line, and their magnitudes have a fixed ratio. Moreover, the vector  $\mathbf{r}$  joining the molecules passes always through their center of mass. The impact parameter  $b$  is now to be interpreted as the hypothetical distance of closest approach if both particles were to continue undeflected along their original trajectories ( $r_m$  is the actual distance of closest approach) [109], Chap. 8. No further information about the collision can be obtained from the laws of conservation of momentum and energy. Instead, a geometrical analysis of the interaction between molecules reveals that the direction of  $\mathbf{g}'_{21}$  depends not only on the initial velocities  $\mathbf{c}_1$  and  $\mathbf{c}_2$  (or in  $\mathbf{G}$  and  $\mathbf{g}_{21}$ ), but also on two independent geometrical variables constituting an angle  $\phi$  and a displacement  $b$ . In the center of mass system it suffices to focus on one of the molecules, due to the prior result that the other molecule always moves in the opposite direction. Thus, the problem reduces to an equivalent problem of the scattering of a molecule by a fictitious fixed center of force, represented by the point  $O$  in Figs. 2.3 and 2.4. Using (2.113), the equation of motion for particle 2 (2.99) can be expressed as:

$$m_2 \frac{d^2 \mathbf{r}_2}{dt^2} = \mu \frac{d^2 \mathbf{r}}{dt^2} = \mathbf{F}_{21} \quad (2.130)$$

It follows that the motion  $\mathbf{r}$  of molecule 2 relative to molecule 1 is the same as if the particle had a mass  $\mu$  and were acted on by the force  $\mathbf{F}_{21}$ . The discussion of the two-molecule problem is thus reduced to the solution of a simple one-molecule problem.

We naturally chose to work in a polar coordinate frame of reference where the trajectory is represented by the polar coordinates  $(r, \theta, \phi)$ . Moreover, it is convenient to define a frame of reference with  $O$  located at the origin of the coordinate system with  $z$  axis parallel to  $\mathbf{g}_{21}$ . The 2 molecule approaches  $O$  with velocity  $\mathbf{g}_{21}$ , whose perpendicular distance to  $O$  is called the impact parameter  $b$ . The polar coordinates of the point molecule 2 thus give its position relative to a fixed reference point  $O$  and a given polar axis  $z$ . The radial coordinate  $r$  is the distance from  $O$  to the molecule

**Fig. 2.3** Scattering of a molecule by a fixed center of force  $O$ . Molecule 1 is at rest with its center at the origin

**Fig. 2.4** Scattering in the frame of the relative vector  $\mathbf{r}$ . The scattering angle  $\theta$  is related to  $\psi$  through the relation  $\theta + 2\psi = \pi$

2. For elastic collisions in which  $g' = g$ , the final state after collision is specified by the two scattering angles  $\theta$  and  $\phi$ , collectively denoted by  $\Omega'$ , with  $\theta$  the angle between  $\mathbf{g}'_{21}$  and the  $z$  axis and  $\phi$  the azimuth (rotational) angle of  $\mathbf{g}'_{21}$  about the  $z$  axis, as shown in Fig. 2.4. Specifying  $\mathbf{G}$ ,  $\mathbf{g}_{21}$ , the angle  $\phi$ , and the impact parameter  $b$ , uniquely determines  $\mathbf{g}'_{21}$ . Thus, the kinetic description of the binary molecular collision is complete.

#### 2.4.2.2 Relative Velocity Difference

The main aim in this paragraph is to close the inverse collision terms in the Boltzmann equation. Consider a scattering event, as sketched in Fig. 2.4. In the following analysis the particle collision is viewed in a frame where the origin of the relative vector  $\mathbf{r}$  is fixed. This framework is also known as a fixed center of force. The line joining the

two molecules when at the points of closest approach,  $\mathbf{r}_{\min}$ , is called *the apse-line*. This apse-line passes through  $O$ , the intersection of the two asymptotes  $\mathbf{g}_{21}$  and  $\mathbf{g}'_{21}$ . The unit vector  $\mathbf{k}$  of the apse-line bisects the angle between  $-\mathbf{g}_{21}$  and  $\mathbf{g}'_{21}$ , as the orbit of the second molecule relative to the first is symmetrical about the apse-line. This symmetry is a consequence of the conservation of angular momentum [49, 90]:

$$L = \mu gb = \mu g' b' \quad (2.131)$$

Previous results revealed that the components of  $\mathbf{g}_{21}$  and  $\mathbf{g}'_{21}$  are equal in magnitude, but opposite in sign, hence from simple vector analysis it follows that:  $\mathbf{g}_{21} \cdot \mathbf{k} = -\mathbf{g}'_{21} \cdot \mathbf{k}$ . Moreover, simple vector subtraction shows that  $\mathbf{g}_{21}$  and  $\mathbf{g}'_{21}$  differ by twice the component of  $\mathbf{g}_{21}$  in the direction of  $\mathbf{k}$ , thus:

$$\mathbf{g}_{21} - \mathbf{g}'_{21} = 2(\mathbf{g}_{21} \cdot \mathbf{k})\mathbf{k} = -2(\mathbf{g}'_{21} \cdot \mathbf{k})\mathbf{k} \quad (2.132)$$

With the help of (2.132) and the relationships given in (2.113), two useful relations between the particle velocities before and after a collision are established:

$$\mathbf{c}'_1 - \mathbf{c}_1 = \frac{\mu}{m_2}(\mathbf{g}_{21} - \mathbf{g}'_{21}) = 2\frac{\mu}{m_2}(\mathbf{g}_{21} \cdot \mathbf{k})\mathbf{k} = -2\frac{\mu}{m_2}(\mathbf{g}'_{21} \cdot \mathbf{k})\mathbf{k} \quad (2.133)$$

$$\mathbf{c}'_2 - \mathbf{c}_2 = \frac{\mu}{m_1}(\mathbf{g}_{21} - \mathbf{g}'_{21}) = 2\frac{\mu}{m_1}(\mathbf{g}_{21} \cdot \mathbf{k})\mathbf{k} = -2\frac{\mu}{m_1}(\mathbf{g}'_{21} \cdot \mathbf{k})\mathbf{k} \quad (2.134)$$

Thereby it has been shown that when  $\mathbf{k}$ ,  $\mathbf{c}_1$  and  $\mathbf{c}_2$  are given, the velocities after the collision,  $\mathbf{c}'_1$  and  $\mathbf{c}'_2$ , can be determined.

These two formulas make it possible to calculate the distribution function quantities in the collision term of the Boltzmann equation associated to the inverse collisions (2.69):

$$f'_1[\mathbf{c}'_1] = f'_1[\mathbf{c}_1 + 2\frac{\mu}{m_2}(\mathbf{g}_{21} \cdot \mathbf{k})\mathbf{k}] \quad (2.135)$$

$$f'_2[\mathbf{c}'_2] = f'_2[\mathbf{c}_2 - 2\frac{\mu}{m_1}(\mathbf{g}'_{21} \cdot \mathbf{k})\mathbf{k}] \quad (2.136)$$

### 2.4.2.3 Concept of Solid Angle

The concept of solid angle, commonly used in kinetic theory, radiation and other scattering problem descriptions, is defined before the molecular scattering process is described in further details in the subsequent section. Basically, the solid angle is the three dimensional analog of an ordinary angle. A differential plane angle  $d\chi$  is defined as the ratio of the element of arc length  $dl$  on the circle to the radius  $r$  of the circle, hence  $d\chi = dl/r$ . Analogous, the differential solid angle  $d\Omega$  subtended

**Fig. 2.5** An illustration of the differential solid angle,  $d\Omega = \sin\theta d\theta d\phi$ . The solid angle has the units of the steradian (sr) or  $\text{radian}^2$  ( $\text{rad}^2$ )

by an arbitrary differential surface  $dA$  is defined as the differential surface area  $d\Omega$  of a unit sphere covered by the arbitrary surface's projection onto the unit sphere [59, 109, 131]:

$$d\Omega = \frac{\mathbf{e}_r \cdot d\mathbf{A}}{|\mathbf{r}|^2} = \frac{\mathbf{e}_r \cdot \mathbf{n} dA}{r^2} \quad (2.137)$$

where  $\mathbf{e}_r = \frac{\mathbf{r}}{|\mathbf{r}|}$  denotes a unit vector in the direction of  $\mathbf{r}$ ,  $|\mathbf{r}|$  is the distance from the origin to the arbitrary differential area  $dA$ , and  $\mathbf{n}$  is the unit normal vector of the differential surface area  $dA$  as sketched in Fig. 2.5.

In kinetic theory we are using the solid angle to indicate the direction of the outgoing particles after the collision. In principle, we can calculate the solid angle from any given surface. We chose to use the particular surface that coincides with the unit sphere making the mathematical complexity feasible. In this particular case we observe that  $\mathbf{n} = \mathbf{e}_r$  and  $|\mathbf{r}| = r = 1$ , and from (2.137) we get:  $d\Omega = \sin\theta d\theta d\phi$ . Hence, as illustrated in Fig. 2.6, in spherical coordinates the differential solid angle,  $d\Omega$ , subtended by a surface element on the sphere,  $dA = (r d\theta)(r \sin\theta d\phi)$ , can be expressed as:

$$d\Omega = \frac{\mathbf{e}_r \cdot \mathbf{e}_r dA}{r^2} = \frac{\mathbf{e}_r \cdot \mathbf{e}_r (r d\theta)(r \sin\theta d\phi)}{r^2} = \sin\theta d\theta d\phi \quad (2.138)$$

**Fig. 2.6** A sketch of the solid angle in the special case when the arbitrary surface coincides with the unit sphere. In this particular case  $\mathbf{n} = \mathbf{e}_r$ ,  $|\mathbf{r}| = r = 1$ , hence from (2.137) it follows that  $d\Omega = \sin\theta d\theta d\phi$

#### 2.4.2.4 Scattering Cross Sections and Symmetry Properties

In engineering practice we are often concerned with the scattering of a beam of identical particles incident with uniform velocity on the scattering center rather than with the deflection of a single particle. The different particles in the beam have different impact parameters and are therefore scattered through different angles. Hence, in these applications the complexity of the scattering processes involved cannot be described with the classical methods due to the prohibitive computational costs. Instead, the scattering of the particles in the incident beam are calculated in a statistical manner considering the distribution of the deflected particles to be proportional to the density of the incident beam. The corresponding proportionality factor is the *differential scattering cross section*. Due to the symmetry properties of a binary collision, it is convenient to illustrate the basic ideas considering a one body scattering problem that is concerned with the scattering of particles by a fixed center of force. We first state that as a particle approaches the center of force, its orbit will deviate from the incident straight line trajectory. After passing the center of force, the force acting on the particle will eventually diminish so that the orbit once again approaches a straight line (as sketched in Fig. 2.4). In general the final direction of motion is not the same as the incident direction, and the particle is said to be scattered. To calculate the differential scattering cross section we need to define a particular system of reference for the differential solid angle (see Chapman and Cowling [20], p. 60). For this purpose the unit vectors  $\mathbf{e}_g$  and  $\mathbf{e}_{g'}$  in the directions of  $\mathbf{g}_{21}$  and  $\mathbf{g}'_{21}$  might be defined so that  $\mathbf{g}_{21} = g\mathbf{e}_g$  and  $\mathbf{g}'_{21} = g'\mathbf{e}_{g'}$ , respectively. The element of the surface  $d\Omega_g$  includes the point in a perpendicular plane with unit normal  $\Omega \equiv \mathbf{e}_g$ , whereas the element of the surface  $d\Omega_{g'}$  includes the point in a perpendicular plane with unit normal  $\Omega' \equiv \mathbf{e}_{g'}$ , respectively. The differential scattering cross section

can then be defined in the following manner. Imagine a uniform beam of particles of energy  $E(g)$  and flux (intensity)  $\mathbf{I}$ , which is incident upon a scatterer particle denoting a scattering center of force located at the origin  $O$ . The incident flux (intensity) of this beam of particles denotes the number of molecules in the incident beam crossing a unit area normal to the beam per unit time. The number of particles scattered into the element of solid angle  $d\Omega_{g'}$  about  $\Omega'$  is proportional to the incident flux  $\mathbf{I}$  and the element of solid angle  $d\Omega_{g'}$ . The differential scattering cross section,  $\sigma_A(\Omega'; g')$ , thus represents a statistical proportionality factor, defined by:

$$\mathbf{I}\sigma_A(\Omega'; g')d\Omega_{g'} = \text{the number of molecules scattered into the solid angle element } d\Omega_{g'} \text{ about } \Omega' \text{ per unit time}(s),$$

where  $\sigma_A(\Omega'; g')d\Omega_{g'}$  denotes a surface in a plane perpendicular to the incident flux defined such that the molecules that cross this surface end up with a velocity  $\mathbf{g}'$  within the solid angle  $d\Omega_{g'}$ .

Performing a trigonometrical analysis of the particle interaction problem sketched in Fig. 2.3, it can be shown that the number of deflected molecules considered equals the number of molecules that passed through the differential cylinder collision cross section area,  $b d\phi db$ . A rigorous derivation of this relationship for rigid spheres are provided shortly (2.142)–(2.150). Hence, the number of molecules scattered into the solid angle element  $d\Omega_{g'}$  about  $\Omega'$  per unit time (s) can be expressed in terms of the differential cylinder collision cross section area  $b(\theta)db(\theta)d\phi$ :

$$\mathbf{I}\sigma_A(\Omega'; g')d\Omega_{g'} = \mathbf{I}\sigma_A(\theta; g)d\Omega = \mathbf{I}b(\theta)db(\theta)d\phi \quad (2.139)$$

The azimuthal angle  $\phi$ , which locates a section of the incident beam, is the same angle that appears in the spherical coordinate frame fixed with origin at the target particle denoting the center of force.

The relationship between  $\sigma_A(\Omega', g')$  and the deflection angle  $\theta$  is established by trigonometry since with central forces there must be complete symmetry around the axis of the incident beam. It is then observed that all the particles with an impact parameter in the range  $(b, b+db)$  are deflected in the range  $(\theta, \theta+d\theta)$ , independently of  $\phi$ , hence  $\sigma_A(\Omega', g') = \sigma_A(\theta, g')$  [117]. Henceforth the differential scattering cross section notation is simplified as  $g' = g$  from (2.123). The detailed form of  $\sigma_A(\theta; g)$  depends on the intermolecular potential.<sup>26</sup> Besides, the impact parameter  $b$  is generally considered a function of the energy and the corresponding scattering angle, thus (2.139) together with the solid angle relation in polar angles (2.138) constitute the classical formula for the differential scattering cross section,

$$\sigma_A(\theta, E(g)) = \frac{b(\theta, E(g))}{\sin \theta} \left| \frac{db(\theta, E(g))}{d\theta} \right| \quad (2.140)$$

<sup>26</sup> The differential cross section is a measurable quantity [57]. If the intermolecular potential is known,  $\sigma_A(\theta, g)$  can also be calculated using techniques from quantum mechanics. In this book we regard  $\sigma_A(\theta, g)$  as a specified property of the gas.

**Fig. 2.7** A sketch defining the geometrical variables in scattering of rigid spheres

where  $E(g) = \frac{1}{2}\mu g^2$ , and  $\theta$  is the scattering angle. The absolute signs are required as  $b$  and  $\theta$  can vary in opposite directions, thus we avoid negative particle numbers.

The *total scattering cross section* is another statistical quantity that can be derived from the differential cross section, defined as the integral of  $\sigma_A(\mathbf{\Omega}'; g)$  over all solid angle elements, hence:

$$\sigma_{AT} = \int_{4\pi} \sigma_A(\mathbf{\Omega}', g') d\mathbf{\Omega}_{g'} = \int_{2\pi} \int_{\pi} \sigma_A(\theta, g) \sin \theta d\theta d\phi \quad (2.141)$$

In other words,  $\sigma_A(\mathbf{\Omega}'; g)$  denotes the proportionality factor for the number of particles scattered into a specific direction, whereas  $\sigma_{AT}$  represents the proportionality factor for the total number of molecules scattered out of the incident beam. For example, in the particular case when the molecules are rigid elastic spheres the apse-line becomes identical with the line of center at collision. In this case the distance  $d_{12}$  between the centers of the spheres at collision is connected with their diameters  $d_1, d_2$  by the relation [109]:

$$d_{12} = \frac{1}{2}(d_1 + d_2), \quad (2.142)$$

Note also that since  $\psi$  is the angle between the  $\mathbf{g}_{21}$  and  $\mathbf{k}$ , as sketched in Fig. 2.7, it is shown that:  $\psi = \frac{1}{2}(\pi - \theta)$ .

Since the plane through  $\mathbf{k}$  and  $\mathbf{g}_{21}$  makes an angle  $\psi$  with a reference plane through  $\mathbf{g}_{21}$ ,  $\psi$  and  $\theta$  are polar coordinates specifying the direction of  $\mathbf{k}$  on the unit sphere. Thereby,

$$b = d_{12} \sin \psi = d_{12} \sin\left[\frac{1}{2}(\pi - \theta)\right] = d_{12} \cos \frac{1}{2}\theta \quad (2.143)$$

The billiard ball model is unique in that  $\theta$  depends only on  $b$ , and not on  $g$ .

From the previous result, the quantity  $b db$  can be determined:

$$b db = d_{12} \sin \psi \times d(d_{12} \sin \psi) = d_{12}^2 \sin \psi \cos \psi d\psi \quad (2.144)$$

In order to relate the differential cross section to the solid angle, some geometry and manipulation of the trigonometric functions are required. By use of standard formulas from trigonometry the following relationships are obtained [120]:

$$\begin{aligned} \cos \theta &= \cos(\pi - 2\psi) = \cos(\pi) \cos(2\psi) - \sin(\pi) \sin(2\psi) \\ &= -1[\cos^2 \psi - \sin^2 \psi] - 0[2 \sin \psi \cos \psi] = \sin^2 \psi - \cos^2 \psi \\ &= 1 - \cos^2 \psi - \cos^2 \psi = 1 - 2 \cos^2 \psi \end{aligned} \quad (2.145)$$

By differentiation of this trigonometric relationship yields:

$$\sin \theta d\theta = 4 \cos \psi \sin \psi d\psi \quad (2.146)$$

Therefore, (2.144) can be manipulated as:

$$b db = d_{12}^2 \sin \psi \cos \psi d\psi = \frac{d_{12}^2}{4} \sin \theta d\theta \quad (2.147)$$

Hence, the differential cylinder collision cross sectional area  $b db d\phi$  can be expressed in terms of the differential element of the solid angle:

$$b db d\phi = d_{12}^2 \sin \psi \cos \psi d\psi d\phi = \frac{d_{12}^2}{4} \sin \theta d\theta d\phi = \frac{d_{12}^2}{4} d\Omega \quad (2.148)$$

in which  $d\Omega = \sin \theta d\theta d\phi$  denotes the differential element of solid angle, which is the small area through which the unit vector  $\mathbf{e}_{g'}$  passes through.

The differential collision cross section is defined as a positive proportionality factor (e.g., [20], p. 60; [117], p. 81), in accordance with (2.140), hence:

$$\sigma_{A12} = \left| \frac{b db}{\sin \theta d\theta} \right| = \frac{b}{\sin \theta} \left| \frac{db}{d\theta} \right| = \frac{d_{12}^2}{4} \quad (2.149)$$

Combining (2.148) and (2.149) an important relationship between the differential cylinder collision cross sectional area  $b db d\phi$  and differential collision cross section  $\sigma_{A12}$  is obtained:

$$b db d\phi = \sigma_{A12} d\Omega_{g'} = \sigma_{A12} d\Omega \quad (2.150)$$

The corresponding total scattering cross section can be computed from (2.141):

$$\sigma_{A_{T12}} = 2\pi \int_{-1}^1 \frac{d_{12}^2}{4} d \cos \theta = \pi d_{12}^2 \quad (2.151)$$

The molecular collisions have specific symmetry properties which are consequences of the electromagnetic nature of the molecular interactions. For this reason, the differential cross section parameter must reflect the same symmetry properties. Two such collisions symmetry properties are particularly relevant in kinetic theory deriving the Boltzmann equation. In describing these symmetries, it proves convenient to speak of a collision in terms of two-particle relative velocities before  $(\mathbf{c}_1, \mathbf{c}_2)$  and after  $(\mathbf{c}'_1, \mathbf{c}'_2)$  the collision. For this purpose it is convenient to introduce the notation:

$$\sigma_A(\mathbf{c}_1, \mathbf{c}_2 | \mathbf{c}'_1, \mathbf{c}'_2) = \sigma_A(\mathbf{\Omega}_{g'}, g') = \sigma_A(\mathbf{\Omega}_g, g) \quad (2.152)$$

where  $\mathbf{\Omega}_{g'}$  denotes the angles between  $\mathbf{g}_{21}$  and  $\mathbf{g}'_{21}$ .

The relevant symmetries are outlined in the following two point paragraphs:

- Invariance Under Time Reversal:

$$\sigma_A(\mathbf{c}_1, \mathbf{c}_2 | \mathbf{c}'_1, \mathbf{c}'_2) = \sigma_A(-\mathbf{c}'_1, -\mathbf{c}'_2 | -\mathbf{c}_1, -\mathbf{c}_2) \quad (2.153)$$

The invariance of physical laws under time reversal<sup>27</sup> makes the cross sections for the original and *reverse* collisions equal [57, 115, 150]. This means that if we reverse the time each molecule will retrace its original trajectory, as sketched in Fig. 2.8.

- Invariance Under Rotation and Reflection:

$$\sigma_A(\mathbf{c}_1, \mathbf{c}_2 | \mathbf{c}'_1, \mathbf{c}'_2) = \sigma_A(\mathbf{c}^*_1, \mathbf{c}^*_2 | \mathbf{c}'^*_1, \mathbf{c}'^*_2) \quad (2.154)$$

where  $\mathbf{c}^*$  denotes the vector obtained from  $\mathbf{c}$  after performing a given rotation in space or a reflection with respect to a given plane, or a combination of both [57, 115, 150].

It is of particular interest to consider an *inverse* collision which is obtained from the original collision by interchanging the initial and final states, as sketched in Fig. 2.9. As a consequence of the symmetries outlined above, the inverse collision has the same differential cross section as the original collision [57]:

$$\sigma_A(\mathbf{c}_1, \mathbf{c}_2 | \mathbf{c}'_1, \mathbf{c}'_2) = \sigma_A(\mathbf{c}'_1, \mathbf{c}'_2 | \mathbf{c}_1, \mathbf{c}_2) \quad (2.155)$$

Prove for this relationship was given by Huang [57], p. 63, among others.

In Hamiltonian mechanics the Liouville's law for elastic collisions states that phase space volumes are conserved as it evolves in time [60, 90]. Since time-evolution is a canonical transformation, it follows that when the Jacobian is unity the differential cross sections of the original, reverse and inverse collisions are all equal. From this result, it can be concluded that [39, 115, 163]:

<sup>27</sup> From the definition of the Lagrangian function (2.6) it can be shown that the time coordinate is both homogeneous and isotropic meaning that its properties are the same in both directions [81]. For, if  $t$  is replaced by  $-t$ , the Lagrangian is unchanged, and therefore so are the equations of motion. In this sense all motions which obey the laws of classical mechanics are reversible.

**Fig. 2.8** A sketch illustrating an original collision (*left*) and an reverse collision (*right*). The scattering cross section are the same for both types of collision

**Fig. 2.9** A sketch illustrating an original collision (*left*) and an inverse collision (*right*). The scattering cross section are the same for both types of collision

$$\sigma_A(\Omega, g) = \sigma_A(\Omega', g') \quad (2.156)$$

#### 2.4.2.5 Expected Number of Molecular Collisions

To determine the rate of change of the distribution function  $f$  due to molecular collisions, an expression for the expected number of molecular collisions must be derived. In the statistical analysis of molecular collisions, it is necessary to consider small but finite ranges of the velocities,  $d\mathbf{c}_1, d\mathbf{c}_2$  rather than specific values  $\mathbf{c}_1, \mathbf{c}_2$  because the probability is about zero that at a given instant, in a finite volume of gas,  $d\mathbf{r}$ , there is any molecule whose velocity is exactly equal to any specific values  $\mathbf{c}_1, \mathbf{c}_2$  out of the whole continuous range of velocities. In a similar manner, it is necessary to consider small but finite ranges of the geometrical collision variables  $db, d\phi$  rather than specific values  $b$  and  $\phi$  because the probable number of collisions in  $d\mathbf{r}$ , during a small time-interval  $dt$ , between molecules in the velocity ranges  $d\mathbf{c}_1, d\mathbf{c}_2$  will be about zero if the geometrical collision variables  $b, \phi$  are exactly assigned at specific values. The average number of collisions of the type considered is thus proportional to the product  $d\mathbf{c}_1 d\mathbf{c}_2 db d\phi d\mathbf{r} dt$ .

The probable number of molecules of the first kind  $\mathbf{c}_1$ , in  $\mathbf{r}$ , having velocities in the small range  $d\mathbf{c}_1$ , is  $f_1 d\mathbf{c}_1 d\mathbf{r}$ , and the probable number of molecules of the second kind  $\mathbf{c}_2$ , in  $\mathbf{r}$ , having velocities within the range  $d\mathbf{c}_2$ , is  $f_2 d\mathbf{c}_2 d\mathbf{r}$ . The incident flux of particles may thus be approximated by:

$$\mathbf{I} = f_2 d\mathbf{c}_2 g \quad (2.157)$$

In order to determine the expected number of molecular collisions, consider the motion of molecules 2 relative to the center of force molecule 1 as sketched in Fig. 2.3. A collision between two molecules in which the impact parameter is in the range  $db$  about  $b$  and the azimuthal angle is in the range  $d\phi$  about  $\phi$  can occur provided that the extension of the vector  $\mathbf{g}_{21}$  cut the plane through  $O$  perpendicular to the polar axis within the area bounded by circles of radii  $db$ ,  $b + db$  and center  $O$ , and by radii from  $O$  including an angle  $d\phi$ . If such a collision is to occur in a time interval  $dt$ , then at the beginning of  $dt$  the center of molecule 2 must be within a cylinder having an area  $bd\phi db$  as base and generators equal to  $-\mathbf{g}_{21}dt$  (i.e., the length of the cylinder generators in the  $\mathbf{e}_g$  direction is given by the scalar product:  $(\mathbf{g}_{21} \cdot \mathbf{e}_g)dt = |\mathbf{g}_{21}||\mathbf{e}_g| \cos(0)dt = gdt$ ). The volume,  $dV_{\text{cylinder}} = (gdt)(bd\phi db)$ , is commonly referred to as *the collision cylinder*, as sketched in Fig. 2.10. It is imagined that such a cylinder is associated with each of the  $f_1 d\mathbf{c}_1 d\mathbf{r}$  molecules of the first kind  $\mathbf{c}_1$ , within a specific velocity range  $d\mathbf{c}_1$ , in  $\mathbf{r}$ . Moreover, if  $db$  and  $d\phi$  are small, it might be assumed that these cylinders do not overlap to any significant extent, so that the total volume  $dV_{\text{total}}$  of all the cylinders can be approximated by:

$$dV_{\text{total}} = \{f_1 d\mathbf{c}_1 d\mathbf{r}\} \times \{(gdt)(bdbd\phi)\} \quad (2.158)$$

In many of these tiny cylinders there might be no molecule of the second kind  $\mathbf{c}_2$ , having a velocity in the range  $d\mathbf{c}_2$ . If  $db$ ,  $d\phi$  and  $d\mathbf{c}_2$  are sufficiently small, the possibility that in any one cylinder there are two such molecules  $\mathbf{c}_2$  might be neglected. The total number of molecules of the second kind  $\mathbf{c}_2$ , with velocities in the range  $d\mathbf{c}_2$  about  $\mathbf{c}_2$ , in the whole combined volume  $dV_{\text{total}}$  of all the collision cylinders is  $(f_2 d\mathbf{c}_2) \times dV_{\text{total}}$ , which by the assumptions made correspond to the number of occupied cylinders in which such a molecule occurs. Moreover, it follows that each occupied cylinder corresponds to a binary collision of the specified type, occurring within  $d\mathbf{r}$  during the time  $dt$ . Inserting the above expression for  $dV_{\text{total}}$  into  $f_2 d\mathbf{c}_2 dV_{\text{total}}$ , the number of binary molecular collisions is found to be:

$$f_1 f_2 g b d b d \phi d\mathbf{c}_1 d\mathbf{c}_2 d\mathbf{r} dt = (f_2 d\mathbf{c}_2)(f_1 d\mathbf{c}_1 d\mathbf{r}) \times \{(gdt)(bdbd\phi)\} \quad (2.159)$$

On substituting  $\sigma_A(\mathbf{\Omega}, g) d\mathbf{\Omega}_g = bd\phi db$ , in accordance with (2.150), an alternative expression for the number of collisions is obtained:

$$f_1 f_2 g \sigma_A(\mathbf{\Omega}, g) d\mathbf{\Omega}_g d\mathbf{c}_1 d\mathbf{c}_2 d\mathbf{r}_1 dt \quad (2.160)$$

For completeness it is noted that these relations rely on the molecular chaos assumption (see Sect. 2.4.2), anticipating that the collisional pair distribution function can be approximated by [53, 90]:

$$f^{(2)}(\mathbf{r}, \mathbf{c}_1, \mathbf{r}, \mathbf{c}_2, t) \approx f_1(\mathbf{r}, \mathbf{c}_1, t) f_2(\mathbf{r}, \mathbf{c}_2, t) \quad (2.161)$$

There by a more general expression for the expected number of collisions is obtained:

**Fig. 2.10** Collision cylinder. Scattering in the  $\mathbf{c}_1$  molecular frame, where the  $\mathbf{c}_2$  molecules have velocity  $\mathbf{g}_{21}$

$$f^{(2)}(\mathbf{r}, \mathbf{c}_1, \mathbf{r}, \mathbf{c}_2, t) g \sigma_A(\mathbf{\Omega}, g) d\mathbf{\Omega}_{g'} d\mathbf{c}_1 d\mathbf{c}_2 d\mathbf{r} dt \quad (2.162)$$

#### 2.4.2.6 Molecular Collision Density and Frequency

The molecular collision density and frequency, that are two frequently used quantities in models deduced from kinetic theory principles, can be plainly derived from the expected number of molecular collision formula (2.160). Based on the foregoing modeling results determining the expected number of molecular collisions, different estimates of the *molecular collision density and frequency* can be deduced. Adopting the molecular billiard ball model considering molecules that are smooth and symmetric rigid elastic spheres, and requiring that the molecules are not affected by other potential field forces, the molecules interact only during the collision events. Moreover, considering such binary collisions between billiard ball molecules of masses  $m_1$  and  $m_2$  in a gas mixture at rest in a uniform steady state, the number of collisions per unit volume and time can be deduced from (2.160) after dividing by  $d\mathbf{r}$  and  $dt$ . Integrating the resulting relation over all values of  $\mathbf{\Omega}$ ,  $\mathbf{c}_1$  and  $\mathbf{c}_2$ , the *collision density* representing the total number of collisions per unit volume and time between molecules of type  $m_1$  and molecules of type  $m_2$  is obtained:

$$\begin{aligned} Z_{12} &= \int_{\mathbf{c}_2} \int_{\mathbf{c}_1} \int_{4\pi} f_1 f_2 g \sigma_A(\mathbf{\Omega}, g) d\mathbf{\Omega}_{g'} d\mathbf{c}_1 d\mathbf{c}_2 \\ &= \sigma_{A12} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_0^{2\pi} \int_0^{\pi} f_1 f_2 g \sin \theta d\theta d\phi d\mathbf{c}_1 d\mathbf{c}_2 \end{aligned} \quad (2.163)$$

where  $\sigma_{A12}$  is the differential cross section for rigid spheres defined in accordance with (2.150).

Adopting the absolute Maxwellian distribution function (anticipated at this point, it is further discussed in Sect. 2.7.2), substituting  $f_1$  and  $f_2$  by the appropriate forms

of the distribution function (2.243), p. 285:

$$\begin{aligned} f_1 &= n_1(m_1/2\pi kT)^{3/2} \times \exp(-m_1 c_1^2/2kT) \\ f_2 &= n_2(m_2/2\pi kT)^{3/2} \times \exp(-m_2 c_2^2/2kT) \end{aligned}$$

gives [20] (p. 87):

$$Z_{12} = 2n_1 n_2 d_{12}^2 \left( \frac{2\pi kT m_c}{m_1 m_2} \right)^{1/2} = 2n_1 n_2 d_{12}^2 \left( \frac{2\pi kT}{\mu} \right)^{1/2} \quad (2.164)$$

This quantity is named the *bi-molecular collision rate*. The  $\mu$  denotes the reduced mass and  $m_c = m_1 + m_2$  represents the total mass associated with the center of mass of a two particle system.

Note that the number of collisions between pairs of similar molecules  $m_1$  cannot be calculated by simply changing the suffix 2 to 1 in the given collision density relation for unlike molecules (2.164), because in this case one counts each collision between a pair of  $m_1$  molecules twice. The correct number of collisions between pairs of molecules  $m_1$  per unit volume and time is thus only half the value given by the formula for pairs of unlike molecules. Hence, for similar molecules the collision density is given by:

$$Z_{11} = 2n_1^2 d_1^2 \left( \frac{\pi kT}{m_1} \right)^{1/2} = \frac{1}{\sqrt{2}} \pi d_1^2 \langle c_1 \rangle_M n_1^2 \quad (2.165)$$

It is anticipated that the mean value of the speed of a gas which consists of molecules of type  $m_1$  in the Maxwellian state is given by  $\langle c_1 \rangle_M = \left( \frac{8kT}{\pi m_1} \right)^{1/2}$ . The derivation of this relationship is explained at page 370 in association to (2.609) and (2.610).

The *collision frequency* denotes the average number of collisions undergone by each molecule of a certain type per unit time. The frequency of collisions between any one molecule of type  $m_1$  with other  $m_1$  molecules, is:

$$Z_{1-1} = \frac{2Z_{11}}{n_1} = 4n_1 d_1^2 \left( \frac{\pi kT}{m_1} \right)^{1/2} \quad (2.166)$$

since each collision affects two molecules at once. The type of target species considered calculating the frequency is indicated by the last index of  $Z_{1-1}$  that is separated by the hyphen [157].

The frequency of collisions between any one molecule of type  $m_1$  and a  $m_2$  molecule is given by:

$$Z_{1-2} = \frac{Z_{12}}{n_1} = 2n_2 d_{12}^2 \left( \frac{2\pi kT m_c}{m_1 m_2} \right)^{1/2} \quad (2.167)$$

The collision frequency for a molecule of type  $m_1$  colliding with all kinds of molecules in the mixture is:

$$Z_1 = \frac{Z_{11} + \sum_{j=2} Z_{1j}}{n_1} = Z_{1-1} + \sum_{j=2} Z_{1-j} \quad (2.168)$$

### 2.4.2.7 The Collision Term Closure Formulation

In this section an explicit expression for the collision source term  $(\frac{\partial f}{\partial t})_{\text{Collision}}$  in the Boltzmann equation (2.67) is derived. An expression for the rate  $(\frac{\partial f}{\partial t})_{\text{Collision}} d\mathbf{r} d\mathbf{c}_1 dt$  at which the velocity distribution function  $f(\mathbf{r}, \mathbf{c}_1, t)$  is being altered by molecular collisions can be obtained by focus attention on molecules with velocity between  $\mathbf{c}_1$  and  $\mathbf{c}_1 + d\mathbf{c}_1$  located in the volume element  $d\mathbf{r}$  located between  $\mathbf{r}$  and  $\mathbf{r} + d\mathbf{r}$ , and consider the collisions which occurs there in the time between  $t$  and  $t + dt$ . In the same spatial volume there are molecules of any velocity  $\mathbf{c}_2$  that pose as an incident beam of molecules incident on the molecule  $\mathbf{c}_1$ . The volume  $d\mathbf{r}$  is taken to be large compared to the range of intermolecular forces and  $dt$  to be large compared to the duration of a collision. Nevertheless, they can be considered infinitesimally small with respect to variations in  $f$  by virtue of the assumption that the distribution function  $f(\mathbf{r}, \mathbf{c}, t)$  does not vary appreciably during a time interval of the order of the duration of a molecular collision, nor does it vary appreciably over a spatial distance of the order of the range of intermolecular forces. First, the molecules in  $d\mathbf{r}$  can be thrown out of the velocity range  $\mathbf{c}_1$  and  $\mathbf{c}_1 + d\mathbf{c}_1$  by virtue of collisions with other molecules with any velocity  $\mathbf{c}_2$ . The resulting decrease in time  $dt$  of the number of such molecules is denoted by  $(\frac{\partial f}{\partial t})_{\text{Collision}}^- d\mathbf{r} d\mathbf{c}_1 dt$ . Second, molecules in  $d\mathbf{r}$  whose velocity is originally not in the range between  $\mathbf{c}_1$  and  $\mathbf{c}_1 + d\mathbf{c}_1$  can be thrown into this velocity range by virtue of collisions with other molecules with any velocity  $\mathbf{c}_2$ . The resulting increase in time  $dt$  of the number of molecules scattered into the velocity range  $\mathbf{c}_1$  and  $\mathbf{c}_1 + d\mathbf{c}_1$  is denoted by  $(\frac{\partial f}{\partial t})_{\text{Collision}}^+ d\mathbf{r} d\mathbf{c}_1 dt$ .

To derive an approximate closure relation for the rate  $(\frac{\partial f}{\partial t})_{\text{Collision}}^- d\mathbf{r} d\mathbf{c}_1 dt$ , we need to determine the flux of incident molecules of any velocity  $\mathbf{c}_2$  that pose as an incident beam of molecules on the center of force molecule with velocity  $\mathbf{c}_1$  in the same spatial volume  $d\mathbf{r}$  about  $\mathbf{r}$ , as defined (2.139). The incident flux  $\mathbf{I}$  of this incident beam is generally approximated by:

$$\mathbf{I} = f(\mathbf{r}, \mathbf{c}_2, t) d\mathbf{c}_2 g_{21} \quad (2.169)$$

Moreover, the number of binary collisions, in which the velocities of the colliding molecules are  $\mathbf{c}_1$  and  $\mathbf{c}_2$  and the velocities of the molecules after the collision are  $\mathbf{c}'_1$  and  $\mathbf{c}'_2$ , is given by (2.139):

$$\mathbf{I} \sigma_A(\boldsymbol{\Omega}', g') d\boldsymbol{\Omega}_{g'} dt = f(\mathbf{r}, \mathbf{c}_2, t) d\mathbf{c}_2 g_{21} \sigma_A(\boldsymbol{\Omega}', g') d\boldsymbol{\Omega}_{g'} dt \quad (2.170)$$

where  $\sigma_A(\boldsymbol{\Omega}', g')$  is the differential cross section in the center of mass system and  $\boldsymbol{\Omega}'$  denotes the angles between  $\mathbf{g}_{21}$  and  $\mathbf{g}'_{21}$ .

The rate  $(\frac{\partial f}{\partial t})_{\text{Collision}}^- d\mathbf{r}d\mathbf{c}_1 dt$  is obtained by subsequent integration over all  $\mathbf{c}_2$  velocities and multiplication by the spatial density of molecules  $f(\mathbf{r}, \mathbf{c}_1, t)$  in  $d\mathbf{c}_1$ :

$$(\frac{\partial f}{\partial t})_{\text{Collision}}^- d\mathbf{r}d\mathbf{c}_1 dt = f(\mathbf{r}, \mathbf{c}_1, t) \int \int g_{21} f(\mathbf{r}, \mathbf{c}_2, t) \sigma_A(\boldsymbol{\Omega}', g') d\boldsymbol{\Omega}_g d\mathbf{r}d\mathbf{c}_2 d\mathbf{c}_1 dt \quad (2.171)$$

By arguments identical with those used above, an approximate closure relation for the rate  $(\frac{\partial f}{\partial t})_{\text{Collision}}^+ d\mathbf{r}d\mathbf{c}'_1 dt$  can be deduced examining *inverse collisions* where  $\mathbf{c}_1$  is fixed. We may first consider a molecule  $c'_1$  with a beam of molecules  $c'_2$  incident upon it. The incident flux of the beam of molecules  $\mathbf{c}'_2$  incident upon  $\mathbf{c}'_1$  can be approximated by:

$$\mathbf{I}' = f(\mathbf{r}, \mathbf{c}'_2, t) d\mathbf{c}'_2 |g'_{21}| \quad (2.172)$$

From this incident flux of molecules, we only want to consider all molecules in the same volume element  $d\mathbf{r}$  with arbitrary initial velocities  $\mathbf{c}'_1$  and  $\mathbf{c}'_2$  which are such that, after collision, one of the two molecules acquires a velocity in the range of interest between  $\mathbf{c}_1$  and  $\mathbf{c}_1 + d\mathbf{c}_1$ , while the other molecule out of the two acquires some velocity between  $\mathbf{c}_2$  and  $\mathbf{c}_2 + d\mathbf{c}_2$ . This scattering process is described by the scattering probability  $\sigma_A(\boldsymbol{\Omega}, g) = \sigma_A(c'_1, c'_2 | c_1, c_2)$ , which equals  $\sigma_A(\boldsymbol{\Omega}', g') = \sigma_A(c_1, c_2 | c'_1, c'_2)$  according to (2.155). The number of collisions of this type during  $dt$  can be approximated by:

$$\mathbf{I}' \sigma_A(\boldsymbol{\Omega}, g) d\boldsymbol{\Omega}_g dt = f(\mathbf{r}, \mathbf{c}'_2, t) d\mathbf{c}'_2 |g'_{21}| \sigma_A(\boldsymbol{\Omega}, g) d\boldsymbol{\Omega}_g dt \quad (2.173)$$

It follows that the rate  $(\frac{\partial f}{\partial t})_{\text{Collision}}^+ d\mathbf{r}d\mathbf{c}'_1 dt$  is given by:

$$(\frac{\partial f}{\partial t})_{\text{Collision}}^+ d\mathbf{r}d\mathbf{c}'_1 dt = \int \int f(\mathbf{r}, \mathbf{c}'_1, t) f(\mathbf{r}, \mathbf{c}'_2, t) |g'_{21}| \sigma_A(\boldsymbol{\Omega}, g) d\boldsymbol{\Omega}_g d\mathbf{r}d\mathbf{c}'_1 d\mathbf{c}'_2 dt \quad (2.174)$$

It is noted that the vectors  $(\mathbf{c}_1, \mathbf{c}_2)$ ,  $(\mathbf{c}'_1, \mathbf{c}'_2)$  refer to collisions that are inverse of each other, thus since  $\sigma_A(\boldsymbol{\Omega}', g') = \sigma_A(\boldsymbol{\Omega}, g)$ ,  $g_{21} = g'_{21}$ , and the transformation of the differential element  $d\boldsymbol{\Omega}_g d\mathbf{c}_1 d\mathbf{c}_2 = J \boldsymbol{\Omega}_g d\mathbf{c}'_1 d\mathbf{c}'_2$  by the Liouville theorem (e.g., [20], pp. 61–64; [39], Sect. 3.1; [57], p. 66; [90], pp. 17–18; [115], p. 52). The rate expression can be rewritten as:

$$(\frac{\partial f}{\partial t})_{\text{Collision}}^+ d\mathbf{r}d\mathbf{c} dt = \int \int f(\mathbf{r}, \mathbf{c}'_1, t) f(\mathbf{r}, \mathbf{c}'_2, t) g_{21} \sigma(\boldsymbol{\Omega}', g') d\boldsymbol{\Omega}_g d\mathbf{r}d\mathbf{c}_1 d\mathbf{c}_2 dt \quad (2.175)$$

### 2.4.2.8 Deriving the Boltzmann Equation from First Principles

Due to the approximate relation between the pair distribution function and the two associated single distribution functions (2.161) imposing the assumption of molecular chaos and the associated expression for the expected number of collisions in  $d\mathbf{r}$  (2.162), several scientists investigated the feasibility of deriving the Boltzmann equation from first principles with a higher degree of rigor. In the following paragraphs in this section, the Boltzmann equation is thus re-derived based on a more compact and mathematically formal notation. A drawback is that the numerous inherent assumptions are not easy to grasp making this analysis somewhat ad hoc.

In the formal derivation, the number of particles which is thrown out of the phase element is determined by:

$$\left(\frac{\partial f}{\partial t}\right)_{\text{Collision}}^- d\mathbf{r}d\mathbf{c}dt = \int_1 f^{(2)}(\mathbf{r}, \mathbf{c}, \mathbf{r}_1, \mathbf{c}_1, t) d\mathbf{r}_1 d\mathbf{c}_1 d\mathbf{r}d\mathbf{c}dt \quad (2.176)$$

In this model derivation it is convenient and thus common practice to divide the velocity of all particles in the gas into two groups, the small range of velocities that fall into the interval  $d\mathbf{c}$  about  $\mathbf{c}$  and all other velocities denoted by  $\mathbf{c}_1$ . Considering that the  $\mathbf{c}_1$  particles in  $d\mathbf{r}_1$  undergo a collision with the  $\mathbf{c}$  particles in  $d\mathbf{r}$  in the time  $dt$ ,  $d\mathbf{r}_1$  must be determined in terms of designable quantities. Such a model can be derived with the aid of the sketch showing a scattering event in the frame of the  $\mathbf{c}$  particles (equivalent to Fig. 2.10), revealing that all  $\mathbf{c}_1$  particles in the collision cylinder of height  $gdt$  and base area  $bd\phi db$  undergo a collision with the  $\mathbf{c}$  particles in the time  $dt$ . Hence, the volume of the collision cylinder is given by  $d\mathbf{r}_1 = gdt bd\phi db$ .

It follows that the number of particles removed in  $dt$  is determined by:

$$\begin{aligned} \left(\frac{\partial f}{\partial t}\right)_{\text{Collision}}^- d\mathbf{r}d\mathbf{c}dt &= \int_1 f^{(2)}(\mathbf{r}, \mathbf{c}, \mathbf{r}_1, \mathbf{c}_1, t) (gbd\phi db) d\mathbf{c}_1 d\mathbf{r}d\mathbf{c}dt \\ &= \int_1 f^{(2)}(\mathbf{r}, \mathbf{c}, \mathbf{r}_1, \mathbf{c}_1, t) g\sigma_A(\boldsymbol{\Omega}', g') d\boldsymbol{\Omega}_{g'} d\mathbf{c}_1 d\mathbf{r}d\mathbf{c}dt \end{aligned} \quad (2.177)$$

where  $\sigma_A(\boldsymbol{\Omega}', g') d\boldsymbol{\Omega}_{g'} = \sigma_A(\theta, g) d\boldsymbol{\Omega} = bd\phi db$  in accordance with (2.150).

Dividing by  $d\mathbf{r}d\mathbf{c}dt$  yields:

$$\left(\frac{\partial f}{\partial t}\right)_{\text{Collision}}^- = \int_1 f^{(2)}(\mathbf{r}, \mathbf{c}, \mathbf{r}_1, \mathbf{c}_1, t) g\sigma_A(\boldsymbol{\Omega}', g') d\boldsymbol{\Omega}_{g'} d\mathbf{c}_1 \quad (2.178)$$

in which the integration is over the solid angle,  $d\boldsymbol{\Omega}_{g'}$ , and  $\mathbf{c}_1$  to sum up the rate of decrease for all the collisions occurring during  $dt$ .

The number of particles injected into  $d\mathbf{c}d\mathbf{r}$  due to collisions in the interval  $dt$ ,  $\left(\frac{\partial f}{\partial t}\right)_{\text{Collision}}^+ d\mathbf{r}d\mathbf{c}dt$ , considers all the binary collisions that can send one particle into the velocity interval  $d\mathbf{c}$  about  $\mathbf{c}$ . This kind of collision is recognized as being the inverse of the original collision, hence:

$$\begin{aligned}
\left(\frac{\partial f}{\partial t}\right)_{\text{Collision}}^+ d\mathbf{r}d\mathbf{c}dt &= \int_1 f'^{(2)}(\mathbf{r}', \mathbf{c}', \mathbf{r}'_1, \mathbf{c}'_1, t) d\mathbf{r}'_1 d\mathbf{c}'_1 d\mathbf{r}d\mathbf{c}' \\
&= \int_1 f'^{(2)}(\mathbf{r}', \mathbf{c}', \mathbf{r}'_1, \mathbf{c}'_1, t) g' \sigma_A(\mathbf{\Omega}, g) d\mathbf{\Omega}_g d\mathbf{c}'_1 d\mathbf{r}d\mathbf{c}' dt
\end{aligned} \tag{2.179}$$

where the primed variables refer to the inverse collision of the un-primed variables in (2.178). That is, a collision of the type (2.155) is considered in a frame where the origin of the relative vector is fixed denoting a fixed center of force.

To express (2.179) in terms of known variables the Liouville law for elastic collisions can be adopted, as several investigators (e.g., [20], pp. 61–64; [39], Sect. 3.1; [57], p. 66; [90], pp. 17–18; [115], p. 52) have shown that by symmetry (i.e.,  $\mathbf{G} = \mathbf{G}'$  and  $d\mathbf{g}_{21} = d\mathbf{g}'_{21}$ ) the Jacobian is unity, hence:

$$d\mathbf{\Omega}_g d\mathbf{c}'_1 d\mathbf{c}' = d\mathbf{\Omega}_{g'} d\mathbf{c}_1 d\mathbf{c} \tag{2.180}$$

Note also that from the law of conservation of angular momentum (2.131), the impact parameters  $b$  and  $b'$  before and after the collisions, respectively, are equal as  $L = \mu g b = \mu g' b'$ . It follows that the number of particles added in  $dt$  is:

$$\left(\frac{\partial f}{\partial t}\right)_{\text{Collision}}^+ d\mathbf{r}d\mathbf{c}dt = \int_1 f'^{(2)}(\mathbf{r}', \mathbf{c}', \mathbf{r}'_1, \mathbf{c}'_1, t) g \sigma_A(\mathbf{\Omega}, g) d\mathbf{\Omega}_{g'} d\mathbf{c}_1 d\mathbf{r}d\mathbf{c}dt \tag{2.181}$$

Dividing by  $d\mathbf{r}d\mathbf{c}dt$  yields:

$$\left(\frac{\partial f}{\partial t}\right)_{\text{Collision}}^+ = \int_1 f'^{(2)}(\mathbf{r}', \mathbf{c}', \mathbf{r}'_1, \mathbf{c}'_1, t) g \sigma_A(\mathbf{\Omega}, g) d\mathbf{\Omega}_{g'} d\mathbf{c}_1 \tag{2.182}$$

and again the integration is over the solid angle,  $d\mathbf{\Omega}_g$ , and  $\mathbf{c}_1$ , but this time to sum up the rate of increase for all the collisions occurring during  $dt$ .

Substituting these results into (2.91), yields the net collision rate:

$$\begin{aligned}
\left(\frac{\partial f}{\partial t}\right)_{\text{Collision}} &= \int_1 f'^{(2)}(\mathbf{r}', \mathbf{c}', \mathbf{r}'_1, \mathbf{c}'_1, t) g \sigma_A(\mathbf{\Omega}') d\mathbf{\Omega}_{g'} d\mathbf{c}_1 \\
&\quad - \int_1 f^{(2)}(\mathbf{r}, \mathbf{c}, \mathbf{r}_1, \mathbf{c}_1, t) g \sigma_A(\mathbf{\Omega}') d\mathbf{\Omega}_{g'} d\mathbf{c}_1
\end{aligned} \tag{2.183}$$

Substituting all these results and the approximation of the pair distribution function (2.161) into (2.67), gives the *Boltzmann* equation:

$$\begin{aligned}
\frac{\partial f}{\partial t} + \mathbf{c} \cdot \frac{\partial f}{\partial \mathbf{r}} + \mathbf{F} \cdot \frac{\partial f}{\partial \mathbf{c}} &= \int_1 [f'(\mathbf{r}, \mathbf{c}', t) f'_1(\mathbf{r}, \mathbf{c}'_1, t) \\
&\quad - f(\mathbf{r}, \mathbf{c}, t) f_1(\mathbf{r}, \mathbf{c}_1, t)] g \sigma_A(\mathbf{\Omega}', g') d\mathbf{\Omega}_{g'} d\mathbf{c}_1
\end{aligned} \tag{2.184}$$

It is noted that this substitution is not strictly rigorous as a number of unspecified approximations are introduced as well [10].

The collision term may be further manipulated in terms of  $\mathbf{k}$  [117] (pp. 83–85), but for convenience the fundamental form is retained at this point. For denser gases and rigid spheres the collision term is normally further reformulated in terms of  $\mathbf{k}$  [117] (pp. 83–85), as outlined in Sect. 2.12.

## 2.5 Flux Vectors

In a non-equilibrium gas system there are gradients in one or more of the macroscopic properties. In a mono-atomic gas the gradients of density, fluid velocity, and temperature induce molecular transport of mass, momentum, and kinetic energy through the gas. The mathematical theory of transport processes enables the quantification of these macroscopic fluxes in terms of the distribution function on the microscopic level. It appears that the mechanism of transport of each of these molecular properties is derived by the same mathematical procedure, hence they are collectively represented by the generalized property  $\psi$ . In the gas we consider an infinitesimal element of surface area  $dA$  as sketched in Fig. 2.11. The orientation of the surface area is defined by a unit vector  $\mathbf{n}$  normal to the surface, and  $\omega$  is the angle between  $\mathbf{C}$  and  $\mathbf{n}$ . Imagine further that the element of surface area moves along with the fluid having the velocity  $\mathbf{v}(\mathbf{r}, t)$ . The collection of molecules will then move back and forth across this element area with their peculiar velocities  $\mathbf{C}$  about the mean velocity  $\mathbf{v}$ , in accordance with (2.65). Ignoring any molecular collisions the number of molecules crossing the surface area  $dA$  during the infinitesimal time interval  $(t, t + dt)$  equals the number of molecules contained within an infinitesimal cylinder volume with cross-sectional area  $dA$  and length  $|\mathbf{C}|dt$  at time  $t$ . The volume of this cylinder,  $\mathbf{n} \cdot \mathbf{C} dt dA$ , contains  $f(\mathbf{r}, \mathbf{c}, t) d\mathbf{c} (\mathbf{n} \cdot \mathbf{C} dt dA)$  molecules.

Assuming that each molecule in an average sense carries with them the physical property  $\psi(\mathbf{r}, \mathbf{c}, t)$ , the amount of  $\psi$  transported by the molecules with velocities in the range  $d\mathbf{C}$  about  $\mathbf{C}$  across the area  $dA$  in the time  $dt$  is given by  $f(\mathbf{r}, \mathbf{c}, t) d\mathbf{c} (\mathbf{n} \cdot \mathbf{C} dt dA) \psi(\mathbf{r}, \mathbf{c}, t)$ . Accordingly, the flux of  $\psi$  denoting the amount which crosses  $dA$  per unit area per unit time is expressed as  $f\mathbf{n} \cdot \mathbf{C}\psi d\mathbf{c}$ .

The total flux of  $\psi$  across the elementary surface area  $dA$  is obtained by adding the contributions from molecules within all velocity ranges<sup>28</sup>:

$$\Phi_n(\mathbf{r}, t) = \int_{-\infty}^{\infty} f\mathbf{n} \cdot \mathbf{C}\psi d\mathbf{c} \quad (2.185)$$

<sup>28</sup> The integration over  $\mathbf{c}$  is equivalent to integrating over  $\mathbf{C}$  since these two velocities differ by a constant (i.e., independent of  $\mathbf{c}$ ) only, and the integration is over the entire velocity space [55] (p. 457).

**Fig. 2.11** A cylinder containing all molecules with peculiar velocity  $\mathbf{C}$  which cross the surface element  $dA$  during the time interval  $dt$

where  $\Phi_n(\mathbf{r}, t)$  denotes the  $\mathbf{n}$ -component of the *flux vector*, thus  $\Phi_n(\mathbf{r}, t) = \mathbf{n} \cdot \Phi(\mathbf{r}, t) = n \langle C_n \psi(\mathbf{r}, t) \rangle_M$ .

The complete flux vector of the property  $\psi$  is give by:

$$\Phi(\mathbf{r}, t) = \int_{-\infty}^{\infty} f \mathbf{C} \psi d\mathbf{c} \quad (2.186)$$

The physical interpretation of this vector is that the  $\mathbf{n}$ -component of the vector equals the flux of  $\psi$  across a surface normal to  $\mathbf{n}$ .

At this point it is appropriate to introduce the particular flux vectors associated with the transport of mass, momentum, and kinetic energy.

### 2.5.1 Transport of Mass

In this case we set  $\psi = m$ :

$$\Phi(\mathbf{r}, t) = m \int_{-\infty}^{\infty} f \mathbf{C} d\mathbf{c} = mn \langle \mathbf{C} \rangle_M = 0 \quad (2.187)$$

### 2.5.2 Transport of Momentum

In this case we set  $\psi = mC_i$ , hence:

$$\Phi(\mathbf{r}, t) = m \int_{-\infty}^{\infty} f C_i \mathbf{C} d\mathbf{c} = mn \langle C_i \mathbf{C} \rangle_M = \mathbf{p}_i \quad (2.188)$$

This flux vector denotes the transport of momentum relative to  $\mathbf{v}$  in the  $i$ -direction. In a 3D system the direction index  $i$  takes three different values, so there are a total of three flux vectors associated with momentum transfer.

Together the three flux vectors constitute a symmetric second-order tensor with nine components. This tensor is usually referred to as the pressure tensor,  $\mathbf{p}$ . The pressure tensor is expressed by:

$$\mathbf{p} \equiv m \int_{-\infty}^{\infty} f \mathbf{C} \mathbf{C} d\mathbf{c} \equiv \rho \langle \mathbf{C} \mathbf{C} \rangle_M = \rho \begin{pmatrix} \langle C_x^2 \rangle_M & \langle C_x C_y \rangle_M & \langle C_x C_z \rangle_M \\ \langle C_y C_x \rangle_M & \langle C_y^2 \rangle_M & \langle C_y C_z \rangle_M \\ \langle C_z C_x \rangle_M & \langle C_z C_y \rangle_M & \langle C_z^2 \rangle_M \end{pmatrix} \quad (2.189)$$

The diagonal elements  $\langle C_i^2 \rangle_M$  represent the *normal stresses*, in general denoting the sum of the static and the viscous forces per unit area acting on a surface at an instant in time. The non-diagonal elements, denoted by  $\langle C_i C_j \rangle_M$  for  $i \neq j$ , represent the *shear stresses* or the viscous shear forces per unit area.

We define the deviatoric—or viscous stresses as the negative thermal flux, determined by the difference between the thermodynamic pressure and the pressure tensor elements, as follows:

$$\sigma_{ij} \equiv [p \delta_{ij} - \rho \langle C_i C_j \rangle_M] \quad (2.190)$$

where the  $\delta_{ij}$  is the Kronecker delta.

The *mean pressure* (or *pressure*) is defined as the mean value of the normal stresses across any three orthogonal planes. The mean pressure,  $\bar{p}$ , is thus one third of the trace of the pressure tensor:

$$\bar{p} = \frac{1}{3} \rho \langle C^2 \rangle_M = \frac{1}{3} \mathbf{p} : \mathbf{e} \quad (2.191)$$

where the  $\mathbf{e}$  is the unit tensor.

The trace of the pressure tensor can be expressed in terms of the peculiar velocity:

$$\mathbf{p} : \mathbf{e} = p_{xx} + p_{yy} + p_{zz} = nm(\langle C_x^2 \rangle_M + \langle C_y^2 \rangle_M + \langle C_z^2 \rangle_M) = \rho \langle C^2 \rangle_M \quad (2.192)$$

In particular, when the system is at equilibrium (no macroscopic gradients), the viscous stresses vanish (i.e.,  $\sigma_{ij} = 0$ ) and the pressure tensor can be expressed in terms of the mean pressure or alternatively in terms of the *thermodynamic pressure*,  $p$ , as:

$$\mathbf{p} = \bar{p} \mathbf{e} = p \mathbf{e} \quad (2.193)$$

where  $P_{xx} = P_{yy} = P_{zz} = p$ . Since these conditions are satisfied in the static case only, such a pressure system is called *static*.

In general the net macroscopic pressure tensor is determined by two different molecular effects: One pressure tensor component associated with the pressure and a second one associated with the viscous stresses.<sup>29</sup> For a fluid at rest, the system is in an equilibrium static state containing no velocity or pressure gradients so the average pressure equals the static pressure everywhere in the system. The static pressure is thus always acting normal to any control volume surface area in the fluid independent of its orientation. For a compressible fluid at rest, the static pressure may be identified with the pressure of classical thermodynamics as may be derived from the diagonal elements of the pressure tensor expression (2.189) when the equilibrium distribution function is known. On the assumption that there is local thermodynamic equilibrium even when the fluid is in motion this concept of stress is retained at the macroscopic level. For an incompressible fluid the thermodynamic, or more correctly thermostatic, pressure cannot be defined except as the limit of pressure in a sequence of compressible fluids. In this case the pressure has to be taken as an independent dynamical variable [2] (Sects. 5.13–5.24).

The macroscopic relationship between the *pressure tensor*, which includes both the *hydrostatic*- or *thermodynamic pressure* and the *viscous stresses* is expressed as:

$$\mathbf{p} = p\mathbf{e} + \boldsymbol{\sigma} \quad (2.194)$$

or in matrix notation:

$$\mathbf{p} = \begin{pmatrix} p + \sigma_{xx} & \sigma_{xy} & \sigma_{xz} \\ \sigma_{yx} & p + \sigma_{yy} & \sigma_{yz} \\ \sigma_{zx} & \sigma_{zy} & p + \sigma_{zz} \end{pmatrix} \quad (2.195)$$

In practice the local pressure variable is assumed to be independent on the state of the fluid. If the gradients in the flow field of a mono-atomic gas are sufficiently large, viscous stresses and heat conduction phenomena emerge, and the Maxwellian distribution function is no longer adequate. Therefore, when the fluid is in real motion, additional viscous normal stresses appear as denoted by  $\sigma_{ii}$ .

Adopting the Newton's viscosity law (1.77) derived from continuum mechanical principles [160] (Sect. 2-4.2), the thermodynamic pressure deviates slightly from the mean pressure. It follows that the mean pressure is approximated as:

$$\bar{p} = \frac{1}{3}(P_{xx} + P_{yy} + P_{zz}) = p - (\mu_B + \frac{2}{3}\mu)\nabla \cdot \mathbf{v} \quad (2.196)$$

---

<sup>29</sup> The viscous stresses only come into play for systems containing significant velocity gradients within the fluid. Nevertheless, very large gradients are not required as the Navier-Stokes equations can be derived from the Chapman-Enskog perturbation theory. On the other hand, for the non-equilibrium boundary layer and shock wave systems, i.e., systems which deviates considerably from equilibrium, higher order expansions are apparently needed [39]. Actually, at least for shock waves the validity of the Maxwell-Boltzmann equation becomes questionable.

This law is showing that the mean pressure in a deforming viscous fluid is not exactly equal to the thermodynamic property called pressure (i.e., apparently the constitutive relation is not consistent with the local equilibrium assumption). This distinction is rarely important, as  $\nabla \cdot \mathbf{v}$  is normally very small in typical reactor flow problems, nevertheless adopting the rigorous form of the constitutive relation (1.77) the bulk viscosity  $\mu_B$  appears as an undetermined system parameter. Stokes [144] solved this problem by introducing the novel assumption that  $\mu_B + \frac{2}{3}\mu = 0$ . Adopting this hypothesis we simply avoid the problem. Alternatively, when the incompressible flow limit  $\nabla \cdot \mathbf{v} = 0$  is applicable,  $\bar{p}$  equals  $p$ . Even for high speed compressible flows, i.e., for which  $\nabla \cdot \mathbf{v} \neq 0$ , we avoid the problem since the viscous normal stresses are normally negligible for such flows. Still a third assumption is often put forth, i.e., that the kinetic theory of gases proves that  $\mu_B + \frac{2}{3}\mu = 0$  for a mono-atomic gas<sup>30</sup> (e.g., Hirschfelder et al. [55], p. 521; Vincenti and Kruger [157], p. 391; Ferziger and Kaper [39]). However, White [160] (p. 70) states that this is a specious argument since the kinetic theory actually assumes rather than proves this relationship to be valid. The discussion reported by Truesdell [153] also states that the theory is vague on this issue, as the different perturbation methods proposed in kinetic theory for solving the Maxwell-Boltzmann equation do not give consistent results even for mono-atomic gases. For polyatomic gases no formal theory exist determining this parameter value. It appears, apparently, that there exists no exact interpretation of Newton's viscosity law.

### 2.5.3 Transport of Kinetic Energy

In this case we set  $\psi = \frac{1}{2}m\mathbf{C} \cdot \mathbf{C}$  and get:

$$\Phi(\mathbf{r}, t) = \int_{-\infty}^{\infty} f \frac{1}{2}mC^2 C d\mathbf{c} = \frac{1}{2}mn\langle C^2 \mathbf{C} \rangle_M = \mathbf{q}(\mathbf{r}, t) \quad (2.197)$$

By use of (2.65), the kinetic energy of the collection of particles may be expressed as:

$$\frac{1}{2}m\mathbf{c} \cdot \mathbf{c} = \frac{1}{2}m(\mathbf{C} + \mathbf{v}) \cdot (\mathbf{C} + \mathbf{v}) = \frac{1}{2}m(C^2 + 2\mathbf{v} \cdot \mathbf{C} + v^2) \quad (2.198)$$

The average of the second term on the RHS,  $\langle m\mathbf{v} \cdot \mathbf{C} \rangle_M$ , vanishes, whereas the average of the last term on the RHS,  $\langle \frac{1}{2}mv^2 \rangle_M$ , denotes the kinetic energy of the macroscopic

<sup>30</sup> For example, the proof given by Vincenti and Kruger [157] (p. 391) is based on a comparison between the result obtained solving the Maxwell-Boltzmann equation using the Enskog expansion method and the corresponding expressions for the stress tensor derived in continuum gas dynamics. From this inter-comparison it is seen that for mono-atomic gases the kinetic theory result does not contain any terms corresponding to the bulk viscosity, thus it is concluded that this parameter equals zero.

fluid motion. The average of the first term on the RHS,  $\langle \frac{1}{2}mC^2 \rangle_M$ , is thus interpreted as the internal energy of the gas. It follows that the *internal energy per unit mass* of the gas,  $e(\mathbf{r}, t)$ , is defined as:

$$e(\mathbf{r}, t) = \frac{1}{n(\mathbf{r}, t)} \int_{-\infty}^{\infty} \frac{1}{2}C^2 f(\mathbf{r}, \mathbf{c}, t) d\mathbf{c} = \frac{1}{\rho(\mathbf{r}, t)} \int_{-\infty}^{\infty} \frac{1}{2}mC^2 f(\mathbf{r}, \mathbf{c}, t) d\mathbf{c} \quad (2.199)$$

The translational kinetic gas *temperature*,  $T$ , is defined in terms of  $e$  by the relation:

$$\rho e = \frac{1}{2}nm\langle C^2 \rangle_M = \frac{3}{2}nkT \quad (2.200)$$

It is noted that for point particles equipartition of energy gives the relation:  $\frac{1}{2}m\langle C^2 \rangle_M = \frac{3}{2}kT$ .  $k$  is the universal Boltzmann constant,  $k = 1.380 \times 10^{-23}$  (J/K).

In classical statistical mechanics the principle of equipartition of energy states that the internal energy of a system composed of a large number of particles at thermal equilibrium will distribute itself evenly among each of the quadratic degrees of freedom allowed to the particle system [49, 150]. In particular, for any part of the internal molecular energy that can be expressed as the sum of square terms, each term contributes an average energy of  $\frac{1}{2}kT$  per molecule [100, 157]. The phrase *square term* refers to a term that is quadratic in some appropriate variable used to describe energy. It follows that for a dilute mono-atomic gas, the mean energy associated with the translational motion of the  $c$ -th molecule in each of the three space directions is  $\frac{1}{2}m\langle C_i^2 \rangle_M$ , for  $i = 1, 2, 3$ . The mean energy of the gas is obtained by adding the contributions from all the three directions:  $\frac{1}{2}m\langle C^2 \rangle_M = \langle \frac{1}{2}m(C_1^2 + C_2^2 + C_3^2) \rangle_M = \frac{3}{2}kT$ .

The equipartition principle was initially proposed by Maxwell [96] in 1867 who stated that the energy of a gas is equally divided between linear and rotational energy. The original theorem was later generalized by Boltzmann [10] in 1872 by showing that the internal energy is actually equally divided among all the independent components of motion in the system.

## 2.6 The Equation of Change in Terms of Mean Molecular Properties

The emphasis in this section is to derive an equation of change for the average property  $\langle \psi \rangle_M$ . The mean value of the property function  $\psi(\mathbf{r}, \mathbf{c}, t)$  was defined by (2.61) in Sect. 2.3.2 at p. 207, considering any property function  $\psi$  of a type of molecules that has position  $\mathbf{r}$  and velocity  $\mathbf{c}$  at time  $t$ .

The equation of change can be derived in two ways, either by analyzing the situation directly on the macroscopic moment scales, or by starting out from the

continuum microscopic Boltzmann equation (2.184) and thereafter apply a suitable averaging procedure to obtain the corresponding average—or moment equation. In this section, an analysis based on the Boltzmann equation will be given. It is noted that the translational terms on the LHS of the Boltzmann equation can be derived adopting one out of two slightly different frameworks, i.e., considering either a fixed control volume (i.e., in which  $\mathbf{r}$  and  $\mathbf{c}$  are fixed and independent of time  $t$ ) or a control volume that is allowed to move following a trajectory in phase space (i.e., in which  $\mathbf{r}(t)$  and  $\mathbf{c}(t)$  are dependent of time  $t$ ) both, of course, in accordance with the Liouville theorem. The pertinent moment equations can be derived based on either of these two frameworks. The fixed control volume approach is adopted in this book because this procedure is normally simplest mathematically and most commonly used. The alternative derivation based on the moving control volume framework is described by de Groot and Mazur [32] (pp. 167–170) among others. By virtue of the fixed control volume framework, introductory a generalized moment equation for the moment  $\langle \psi \rangle_M$  is derived. The average quantity  $\langle \psi \rangle_M$  is defined by (2.61), p. 209. To find the equation that  $\langle \psi \rangle_M$  satisfies, both sides of the Boltzmann equation (2.184) is multiplied by the property  $\psi$  and integrated over all velocities  $\mathbf{c}$ . The result is:

$$\int_{-\infty}^{\infty} \frac{\mathcal{D}f}{\mathcal{D}t} \psi d\mathbf{c} = \int_{-\infty}^{\infty} \left( \frac{\partial f}{\partial t} \right)_{\text{Collision}} \psi d\mathbf{c} \quad (2.201)$$

where

$$\int_{-\infty}^{\infty} \frac{\mathcal{D}f}{\mathcal{D}t} \psi d\mathbf{c} \equiv \underbrace{\int_{-\infty}^{\infty} \frac{\partial f}{\partial t} \psi d\mathbf{c}}_1 + \underbrace{\int_{-\infty}^{\infty} \mathbf{c} \cdot \frac{\partial f}{\partial \mathbf{r}} \psi d\mathbf{c}}_2 + \underbrace{\int_{-\infty}^{\infty} \mathbf{F} \cdot \frac{\partial f}{\partial \mathbf{c}} \psi d\mathbf{c}}_3 \quad (2.202)$$

Thereafter, all the integrals in (2.202) must be transformed into quantities which are direct averages of the density function  $f$ , i.e., into integrals which involve  $f$  itself rather than its derivatives.

Term 1 is manipulated as:

$$\int_{-\infty}^{\infty} \frac{\partial f}{\partial t} \psi d\mathbf{c} = \int_{-\infty}^{\infty} \left[ \frac{\partial}{\partial t} (f\psi) - f \frac{\partial \psi}{\partial t} \right] d\mathbf{c} = \frac{\partial}{\partial t} \int_{-\infty}^{\infty} f \psi d\mathbf{c} - \int_{-\infty}^{\infty} f \frac{\partial \psi}{\partial t} d\mathbf{c} \quad (2.203)$$

In this manipulation we have utilized that the order of differentiation with respect to  $t$  and integration over  $\mathbf{c}$  can be interchanged when the integration limits of  $\mathbf{c}$  is not a function of  $t$  (i.e., applied to the first term of the RHS as the local time differentiation acts on the whole argument of the integral). Term 1 in (2.202) thus yields:

$$\int_{-\infty}^{\infty} \frac{\partial f}{\partial t} \psi d\mathbf{c} = \frac{\partial}{\partial t} (n \langle \psi \rangle_M) - n \langle \frac{\partial \psi}{\partial t} \rangle_M \quad (2.204)$$

The integral term 2 in (2.202) can be manipulated in a similar manner, keeping in mind that  $\mathbf{r}$  and  $\mathbf{c}$  are *independent* dynamic variables:

$$\begin{aligned} \int_{-\infty}^{\infty} \mathbf{c} \cdot \frac{\partial f}{\partial \mathbf{r}} \psi d\mathbf{c} &= \int_{-\infty}^{\infty} \left[ \frac{\partial}{\partial \mathbf{r}} \cdot (f \mathbf{c} \psi) - f \mathbf{c} \cdot \frac{\partial \psi}{\partial \mathbf{r}} \right] d\mathbf{c} \\ &= \frac{\partial}{\partial \mathbf{r}} \cdot \int_{-\infty}^{\infty} f \mathbf{c} \psi d\mathbf{c} - \int_{-\infty}^{\infty} f \mathbf{c} \cdot \frac{\partial \psi}{\partial \mathbf{r}} d\mathbf{c} \\ &= \frac{\partial}{\partial \mathbf{r}} \cdot (n \langle \mathbf{c} \psi \rangle_M) - n \langle \mathbf{c} \cdot \frac{\partial \psi}{\partial \mathbf{r}} \rangle_M \end{aligned} \quad (2.205)$$

Finally, since it is imposed that the force,  $\mathbf{F}$ , is independent of the velocity  $\mathbf{c}$ , the integral term 3 in (2.202) can be manipulated as:

$$\begin{aligned} \int_{-\infty}^{\infty} \mathbf{F} \cdot \frac{\partial f}{\partial \mathbf{c}} \psi d\mathbf{c} &= \int_{-\infty}^{\infty} \left[ \frac{\partial}{\partial \mathbf{c}} \cdot (\mathbf{F} f \psi) - \mathbf{F} \cdot f \frac{\partial \psi}{\partial \mathbf{c}} \right] d\mathbf{c} \\ &= [\mathbf{F} f \psi]_{\mathbf{c}} - \mathbf{F} \cdot \int_{-\infty}^{\infty} f \frac{\partial \psi}{\partial \mathbf{c}} d\mathbf{c} \end{aligned} \quad (2.206)$$

The first term on the RHS of (2.206) vanishes, because for each direction (e.g., in Cartesian coordinates,  $i = 1, 2, 3$ ),  $f \rightarrow 0$  as  $|c_i| \rightarrow \infty$ , thus  $[F_i f \psi]_{c_i=-\infty}^{c_i=+\infty} \rightarrow 0$ . Hence, term 3 in (2.206) becomes:

$$\int_{-\infty}^{\infty} \mathbf{F} \cdot \frac{\partial f}{\partial \mathbf{c}} \psi d\mathbf{c} = -\mathbf{F} \cdot n \langle \frac{\partial \psi}{\partial \mathbf{c}} \rangle_M \quad (2.207)$$

Introducing the expressions from (2.204) through (2.206) into (2.202), the following result is achieved:

$$\begin{aligned} \int_{-\infty}^{\infty} \frac{\mathcal{D}f}{\mathcal{D}t} \psi d\mathbf{c} &= \frac{\partial}{\partial t} (n \langle \psi \rangle_M) + \frac{\partial}{\partial \mathbf{r}} \cdot (n \langle \mathbf{c} \psi \rangle_M) - \\ &\quad n \left[ \langle \frac{\partial \psi}{\partial t} \rangle_M + \langle \mathbf{c} \cdot \frac{\partial \psi}{\partial \mathbf{r}} \rangle_M + \mathbf{F} \cdot \langle \frac{\partial \psi}{\partial \mathbf{c}} \rangle_M \right] \\ &= \frac{\partial}{\partial t} (n \langle \psi \rangle_M) + \frac{\partial}{\partial \mathbf{r}} \cdot (n \langle \mathbf{c} \psi \rangle_M) - n \langle \frac{\mathcal{D}\psi}{\mathcal{D}t} \rangle_M \end{aligned} \quad (2.208)$$

in which, for convenience, a novel operator is defined:

$$\frac{\mathcal{D}\psi}{\mathcal{D}t} = \frac{\partial\psi}{\partial t} + \mathbf{c} \cdot \frac{\partial\psi}{\partial \mathbf{r}} + \mathbf{F} \cdot \frac{\partial\psi}{\partial \mathbf{c}} \quad (2.209)$$

At this point, the collision term given in (2.201) is examined. From (2.184) it is seen that the collision term takes the form:

$$\begin{aligned} \mathcal{J}(\psi(\mathbf{c})) = & \int \int \int \psi[f'(\mathbf{r}, \mathbf{c}', t) f'_1(\mathbf{r}, \mathbf{c}'_1, t) \\ & - f(\mathbf{r}, \mathbf{c}, t) f_1(\mathbf{r}, \mathbf{c}_1, t)] g \sigma_A(\mathbf{\Omega}, g) d\mathbf{\Omega}_g d\mathbf{c}_1 d\mathbf{c} \end{aligned} \quad (2.210)$$

Unfortunately, this relation is not particularly useful for a general  $\psi$  because of the very complex integrals. However, since mass ( $m$ ), momentum ( $m\mathbf{c}$ ), or kinetic energy ( $mc^2$ ) are conserved during a collision, it can be shown that:

$$\begin{aligned} \mathcal{J}(\psi(\mathbf{c})) = & \int \int \int \psi[f'(\mathbf{r}, \mathbf{c}', t) f'_1(\mathbf{r}, \mathbf{c}'_1, t) \\ & - f(\mathbf{r}, \mathbf{c}, t) f_1(\mathbf{r}, \mathbf{c}_1, t)] g \sigma_A(\mathbf{\Omega}') d\mathbf{\Omega}' d\mathbf{c}_1 d\mathbf{c} = 0 \end{aligned} \quad (2.211)$$

By use of the relation (2.211), the formulation of the general equation of change is considerably simplified. Fortunately, the fundamental gas dynamic conservation equations of continuity, momentum, and energy are thus derived from the Boltzmann equation without actually determining the form of either the collision term or the distribution function  $f$ .

It is convenient to introduce the notion of *collisional invariants* (or *summational invariants*) (e.g., [55], p. 460; [90], p. 150). The validity of (2.211) is commonly justified by the following arguments: Due to the symmetry properties of the collision term expression, interchanging variables gives the following equalities:

$$\begin{aligned} \mathcal{J}(\psi(\mathbf{c})) &= \mathcal{J}(\psi_1(\mathbf{c}_1)), \text{ for } (\mathbf{c}, \mathbf{c}_1) \rightarrow (\mathbf{c}_1, \mathbf{c}), \\ \mathcal{J}(\psi'(\mathbf{c}')) &= -\mathcal{J}(\psi(\mathbf{c})), \text{ for } (\mathbf{c}, \mathbf{c}_1) \rightarrow (\mathbf{c}', \mathbf{c}'_1), \text{ and} \\ \mathcal{J}(\psi'(\mathbf{c}')) &= \mathcal{J}(\psi'_1(\mathbf{c}'_1)), \text{ for } (\mathbf{c}'_1, \mathbf{c}') \rightarrow (\mathbf{c}', \mathbf{c}'_1) \end{aligned}$$

These symmetry properties can be combined to give the following relationship:

$$4\mathcal{J}(\psi(\mathbf{c})) = \mathcal{J}(\psi(\mathbf{c})) + \mathcal{J}(\psi_1(\mathbf{c}_1)) - \mathcal{J}(\psi'(\mathbf{c}')) - \mathcal{J}(\psi'_1(\mathbf{c}'_1))$$

The linearity of the  $\mathcal{J}$  operator allows the latter result to be manipulated as:

$$\mathcal{J}(\psi(\mathbf{c})) = \frac{1}{4} \mathcal{J} [\psi(\mathbf{c}) + \psi_1(\mathbf{c}_1) - \psi'(\mathbf{c}') - \psi'_1(\mathbf{c}'_1)]$$

In conclusion, a function  $\psi(\mathbf{c})$  is a summation invariant if:

$$\Delta\psi(\mathbf{c}) = \psi'(\mathbf{c}') + \psi'_1(\mathbf{c}'_1) - \psi(\mathbf{c}) - \psi_1(\mathbf{c}_1) = 0 \quad (2.212)$$

That is,  $\psi(\mathbf{c})$  is a property of a molecule that is preserved in a collision. Hence, for the conserved quantities mass, momentum and energy yield:

$$\mathcal{J}(m) = \mathcal{J}(m\mathbf{c}) = \mathcal{J}(mc^2) = 0 \quad (2.213)$$

Thus, a general collision invariant relationship can be expressed as:

$$\mathcal{J}(\Delta\psi = 0) = 0 \quad (2.214)$$

By substitution of the relations (2.208) and (2.210) into (2.201), the *Enskog's equation of change* is obtained:

$$\frac{\partial}{\partial t}(n\langle\psi\rangle_M) = n\langle\frac{\mathcal{D}\psi}{Dt}\rangle_M - \nabla_{\mathbf{r}} \cdot (n\langle\mathbf{c}\psi\rangle_M) + \mathcal{J}(\psi) \quad (2.215)$$

where  $\mathcal{J}(\psi)$  denotes the rate of change of  $\psi$  per unit volume due to collisions.

### 2.6.1 The Governing Equations of Gas Dynamics

In this section the conservation equations of gas dynamics are derived from the Boltzmann equation.

The equation of change, (2.215), becomes particularly simple if  $\psi$  refers to a quantity which is conserved in collisions between molecules in accordance with (2.214). Therefore, for conservative quantities (2.215) reduces to:

$$\frac{\partial}{\partial t}(n\langle\psi\rangle_M) + \nabla_{\mathbf{r}} \cdot (n\langle\mathbf{c}\psi\rangle_M) = n\langle\frac{\mathcal{D}\psi}{Dt}\rangle_M \quad (2.216)$$

By letting  $\psi$  in (2.216) be  $m$ ,  $m\mathbf{c}$ , and  $\frac{1}{2}mc^2$ , respectively, the three fundamental conservation equations that are all satisfied by the gas are established.

#### 2.6.1.1 Conservation of Mass

Let  $\psi = m$ , thus the Enskog equation of change (2.216) reduces to:

$$\frac{\partial}{\partial t}(nm) + \nabla_{\mathbf{r}} \cdot (nm\langle\mathbf{c}\rangle_M) = 0 \quad (2.217)$$

By averaging the molecular velocity  $\mathbf{c}$  yields  $\mathbf{v} = \langle\mathbf{c}\rangle_M$  which is the mean velocity of the gas (2.64) as defined in Sect. 2.3.2. Furthermore, the mass density of the gas,

given by (2.58), is defined by  $\rho(\mathbf{r}, t) = mn(\mathbf{r}, t)$ . Equation (2.217) thus becomes:

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial \mathbf{r}} \cdot (\rho \mathbf{v}) = 0 \quad (2.218)$$

This is the *equation of continuity* of gas dynamics.

### 2.6.1.2 Conservation of Momentum

Let  $\psi = m\mathbf{c}$ , thus the Enskog equation of change (2.216) reduces to:

$$\frac{\partial}{\partial t} (nm \langle \mathbf{c} \rangle_M) + \nabla_{\mathbf{r}} \cdot (nm \langle \mathbf{c} \mathbf{c} \rangle_M) = nm \langle \frac{D\mathbf{c}}{Dt} \rangle_M \quad (2.219)$$

The last term in (2.219) is defined by (2.209), and can be reduced to:

$$\frac{D\mathbf{c}}{Dt} = \mathbf{F} \cdot \frac{\partial \mathbf{c}}{\partial \mathbf{c}} = \mathbf{F} \quad (2.220)$$

because  $\mathbf{c}$  is independent of  $\mathbf{r}$  and  $t$ , and  $\frac{\partial \mathbf{c}}{\partial \mathbf{c}}$  denotes a unit tensor.

By inserting (2.220), the mean velocity (2.64), and the mass density (2.58), the momentum equation (2.219) yields:

$$\frac{\partial}{\partial t} (\rho \mathbf{v}) + \nabla_{\mathbf{r}} \cdot (\rho \langle \mathbf{c} \mathbf{c} \rangle_M) = \rho \mathbf{F} \quad (2.221)$$

The second term on the LHS of (2.221) constitutes the sum of the pressure tensor (2.189) and the convective term. By use of (2.65), the molecular velocity can be eliminated as  $\mathbf{c} = \mathbf{v} + \mathbf{C}$ , and after some manipulation the dyad  $\langle \mathbf{c} \mathbf{c} \rangle_M$  can be expressed as:

$$\begin{aligned} \langle \mathbf{c} \mathbf{c} \rangle_M &= \langle (\mathbf{v} + \mathbf{C})(\mathbf{v} + \mathbf{C}) \rangle_M = \langle \mathbf{v} \mathbf{v} + \mathbf{C} \mathbf{C} + \mathbf{v} \mathbf{C} + \mathbf{v} \mathbf{C} \rangle_M \\ &= \mathbf{v} \mathbf{v} + \langle \mathbf{C} \mathbf{C} \rangle_M \end{aligned} \quad (2.222)$$

because the average of the peculiar velocity is zero, i.e.,  $\langle \mathbf{v} \mathbf{C} \rangle_M = \mathbf{v} \langle \mathbf{C} \rangle_M = 0$ .

By use of the dyad relation (2.222) and the pressure tensor definition (2.189), the momentum equation (2.221) can be written as:

$$\frac{\partial}{\partial t} (\rho \mathbf{v}) + \nabla_{\mathbf{r}} \cdot (\rho \mathbf{v} \mathbf{v}) = -\nabla_{\mathbf{r}} \cdot \mathbf{p} + \rho \mathbf{F} \quad (2.223)$$

This equation corresponds to the *Cauchy equation of motion in gas dynamics*.

### 2.6.1.3 Conservation of Energy

Let  $\psi = \frac{1}{2}mc^2$ , thus the Enskog equation of change (2.216) reduces to:

$$\frac{\partial}{\partial t} \left( \frac{1}{2} nm \langle c^2 \rangle_M \right) + \frac{1}{2} \frac{\partial}{\partial \mathbf{r}} \cdot (nm \langle \mathbf{c} c^2 \rangle_M) = \frac{1}{2} nm \left\langle \frac{\mathcal{D}c^2}{\mathcal{D}t} \right\rangle_M \quad (2.224)$$

The last term in (2.224) is defined by (2.209), and can be reduced to:

$$\frac{\mathcal{D}(\mathbf{c} \cdot \mathbf{c})}{\mathcal{D}t} = 2\mathbf{F} \cdot \left( \frac{\partial \mathbf{c}}{\partial \mathbf{c}} \cdot \mathbf{c} \right) = 2\mathbf{F} \cdot \mathbf{c} \quad (2.225)$$

because  $\mathbf{c}$  is independent of  $\mathbf{r}$  and  $t$ , and  $\frac{\partial \mathbf{c}}{\partial \mathbf{c}}$  denotes a unit tensor.

By inserting (2.225), the mean velocity (2.64), and the mass density (2.58), the total energy equation (2.224) can be written as:

$$\frac{\partial}{\partial t} \left( \frac{1}{2} \rho \langle c^2 \rangle_M \right) + \frac{1}{2} \frac{\partial}{\partial \mathbf{r}} \cdot (\rho \langle \mathbf{c} c^2 \rangle_M) = \rho \mathbf{F} \cdot \mathbf{v} \quad (2.226)$$

Equation (2.226) may be manipulated, using the same procedure as in the treatment of the equation of motion (2.223). The first term on the LHS of (2.226) can be manipulated by use of (2.65), eliminating the molecular velocity by  $\mathbf{c} = \mathbf{v} + \mathbf{C}$ , and after some further manipulation the covariance  $\frac{1}{2} \langle c^2 \rangle_M$  can be expressed as:

$$\frac{1}{2} \langle c^2 \rangle_M = \frac{1}{2} \langle C^2 \rangle_M + \frac{1}{2} \langle v^2 \rangle_M = e + \frac{1}{2} v^2 \quad (2.227)$$

where  $e$  is defined in accordance with (2.199), p. 246.

The second term on the LHS of (2.226) also needs further manipulation. By use of (2.65) in a similar manner, the covariance  $\frac{1}{2} \rho \langle \mathbf{c} c^2 \rangle_M$  can be expressed as:

$$\begin{aligned} \frac{1}{2} \rho \langle \mathbf{c} c^2 \rangle_M &= \frac{1}{2} \rho \langle \mathbf{c} (\mathbf{c} \cdot \mathbf{c}) \rangle_M = \frac{1}{2} \rho \langle (\mathbf{C} + \mathbf{v}) (C^2 + 2\mathbf{v} \cdot \mathbf{C} + v^2) \rangle_M \\ &= \frac{1}{2} \rho \left\{ \langle \mathbf{C} C^2 \rangle_M + \langle (2\mathbf{v} \cdot \mathbf{C}) \mathbf{C} \rangle_M + \langle \mathbf{C} v^2 \rangle_M + \langle \mathbf{v} C^2 \rangle_M \right. \\ &\quad \left. + \langle \mathbf{v} (2\mathbf{v} \cdot \mathbf{C}) \rangle_M + \langle \mathbf{v} v^2 \rangle_M \right\} \\ &= \frac{1}{2} \rho \langle \mathbf{C} C^2 \rangle_M + \rho \mathbf{v} \cdot \langle \mathbf{C} \mathbf{C} \rangle_M + \frac{1}{2} \rho \mathbf{v} \langle C^2 \rangle_M + \frac{1}{2} \rho \mathbf{v} v^2 \\ &= \mathbf{q} + \mathbf{p} \cdot \mathbf{v} + \rho \mathbf{v} e + \frac{1}{2} \rho \mathbf{v} v^2 \end{aligned} \quad (2.228)$$

Examining the peculiar velocity definition (2.65), it is seen that the average peculiar velocity equals zero, thus  $\langle \mathbf{C} v^2 \rangle_M = \mathbf{v} (2\mathbf{v} \cdot \langle \mathbf{C} \rangle_M) = 0$ . Furthermore, the last line on

the RHS is obtained introducing the heat flux  $\mathbf{q}$  as defined by (2.197), the pressure tensor  $\mathbf{p}$  as defined by (2.189), and the internal energy variable  $e$  as defined by (2.199).

By use of (2.227) and (2.228), the total energy equation (2.226) can be expressed as:

$$\frac{\partial}{\partial t}(\rho[e + \frac{1}{2}v^2]) + \frac{\partial}{\partial \mathbf{r}} \cdot (\rho \mathbf{v}[e + \frac{1}{2}v^2]) = -\frac{\partial}{\partial \mathbf{r}} \cdot \mathbf{q} - \frac{\partial}{\partial \mathbf{r}} \cdot (\mathbf{p} \cdot \mathbf{v}) + \rho \mathbf{F} \cdot \mathbf{v} \quad (2.229)$$

This relation corresponds to the *total energy equation*, for which the potential energy term is expressed in terms of the external force  $\mathbf{F}$ . By use of the momentum equation (2.219) a transport equation for the mean kinetic energy can be derived. Thereafter, the mean kinetic energy part is extracted from the total energy equation (2.229) (i.e., employing a similar procedure as was used manipulating the continuum model counterpart in Chap. 1, Sect. 1.2.4). The resulting internal energy equation yields:

$$\frac{\partial}{\partial t}(\rho e) + \nabla_{\mathbf{r}} \cdot (\rho \mathbf{v} e) = -\nabla_{\mathbf{r}} \cdot \mathbf{q} - \mathbf{p} : \nabla_{\mathbf{r}} \mathbf{v} \quad (2.230)$$

This Eq. (2.230) may be manipulated and expressed in terms of temperature by use of the continuity equation (2.218) and the definitions of  $e$  (2.199) and  $T$  (2.200):

$$\rho \frac{De}{Dt} = C_v \rho \left[ \frac{\partial T}{\partial t} + \mathbf{v} \cdot \nabla_{\mathbf{r}} T \right] = -\nabla_{\mathbf{r}} \cdot \mathbf{q} - \mathbf{p} : \nabla_{\mathbf{r}} \mathbf{v} \quad (2.231)$$

For dilute mono-atomic gases, for which the thermal energy consists of translational energy only, the specific heat at constant volume is given by (see e.g., Chapman and Cowling [20], Eq. (4.43, 2)):

$$C_v = \frac{3k}{2m} \quad (2.232)$$

The corresponding specific heat at constant pressure is given by:

$$C_p = C_v + R \quad (2.233)$$

The conservation equations (2.218), (2.223) and (2.229) are rigorous (i.e., for mono-atomic gases) consequences of the Boltzmann equation (2.184). It is important to note that the governing conservation equations are derived without the exact form of the collision term, the only requirement is that only summation invariant properties of mono-atomic gases are considered. That is, only properties that are conserved in molecular collisions are considered.

Nevertheless, it is clear that, in order to obtain practically useful gas dynamic equations from the general formulations derived above, suitable closures determining explicit expressions for the unknown quantities, i.e., the pressure tensor  $\mathbf{p}$  and the heat flux  $\mathbf{q}$ , in terms of the known variables are required. Of course, (2.189) and (2.197) provide prescriptions for calculating these quantities in terms of molecular quantities, but these relations require that the actual distribution function  $f$  which is a

solution of the Boltzmann equation (2.184) is known. Moreover, the pressure tensor is generally split into the pressure and the deviatoric or viscous stresses according to (2.194). In this case, the problem is reformulated and an expression for the viscous stresses are required instead. Anyhow, using the Chapman-Enskog series approximation of the distribution function, two well known forms of the gas dynamic equations are obtained adopting the zero and first order perturbation approximations of the distribution function as will be outlined in Sects. 2.8.1 and 2.8.2, respectively.

## 2.7 The Boltzmann H-Theorem

In this section the elementary definitions and results deduced from the H-theorem are given [10]. In summary, the statistical  $H$ -theorem of kinetic theory relates to the Maxwellian velocity distribution function and thermodynamics. Most important, the Boltzmann's  $H$ -theorem provides a mechanistic or probabilistic prove for the second law of thermodynamics. In this manner, the  $H$ -theorem also relates the thermodynamic entropy quantity to probability concepts. Further details can be found in the standard references [20, 39, 55, 68, 90, 117, 150, 157]. In practice, during the process of developing novel models for the collision term, the  $H$ -theorem merely serves as a requirement for the constitutive relations in order to fulfill the second law of thermodynamics (in a similar manner as for the continuum models).

### 2.7.1 The $H$ -Theorem Formulation

Formulating the H-theorem Boltzmann considered a simple gas consisting of spherical molecules, possessing only translational energy, and are subject to no external forces. If the gas state is uniform in space, so that the velocity distribution function  $f$  is independent of  $\mathbf{r}$ , the Boltzmann equation (2.184) reduces to:

$$\frac{\partial f}{\partial t} = \int \int (f' f'_1 - f f_1) g \sigma_A(\boldsymbol{\Omega}') d\boldsymbol{\Omega}' d\mathbf{c}_1 \quad (2.234)$$

in which the notation (index 1 or no index) is employed to indicate the two sets of identical molecules having the same mass but possibly different velocities.

Moreover, Boltzmann introduced a novel function  $H(t)$ , defined in terms of a complete integral over all values of the molecular velocities:

$$H = \int f \ln f d\mathbf{c} = n \langle \ln f \rangle_M \quad (2.235)$$

The function  $H(t)$  thus depends on the mode of distribution of the molecular velocities only [20].

Multiplying the reduced form of Boltzmann equation (2.184) by  $(1 + \ln f)$  and integrating over the phase space, the results is:

$$\int (1 + \ln f) \frac{\partial f}{\partial t} d\mathbf{c} = \int \int \int (1 + \ln f) (f' f'_1 - f f_1) g \sigma_A(\mathbf{\Omega}') d\mathbf{\Omega}' d\mathbf{c} d\mathbf{c}_1 \quad (2.236)$$

By use of (2.235), Boltzmann recognized that the term on the LHS of (2.236) can be manipulated as:

$$\frac{\partial H}{\partial t} = \int \frac{\partial}{\partial t} (f \ln f) d\mathbf{c} = \int (1 + \ln f) \frac{\partial f}{\partial t} d\mathbf{c} \quad (2.237)$$

Substitution of the expression on the LHS of (2.236) by use of (2.237), and with some further manipulation of the collision term, the reduced Boltzmann equation (2.236) becomes:

$$\frac{\partial H}{\partial t} = \frac{1}{4} \int \int \int \ln(f f_1 / f' f'_1) (f' f'_1 - f f_1) g \sigma_A(\mathbf{\Omega}, g) d\mathbf{\Omega}_{g'} d\mathbf{c} d\mathbf{c}_1 \quad (2.238)$$

To reach the form of (2.238), the collision term in (2.236) was manipulated as:

$$\begin{aligned} 4\psi(1 + \ln f) &= \psi([1 + \ln f] + [1 + \ln f_1] - [1 + \ln f'] - [1 + \ln f'_1]) \\ &= \psi(\ln f + \ln f_1 - \ln f' - \ln f'_1) = \psi(\ln f f_1 - \ln f' f'_1) \quad (2.239) \\ &= \psi(\ln \frac{f f_1}{f' f'_1}) = -\psi(\ln \frac{f' f'_1}{f f_1}) \end{aligned}$$

Setting  $\mathcal{E} = f f_1$  and  $\Upsilon = f' f'_1$ , (2.238) can be rewritten as:

$$\frac{\partial H}{\partial t} = \frac{1}{4} \int \int \int (\Upsilon - \mathcal{E}) \ln(\mathcal{E}/\Upsilon) g \sigma_A(\mathbf{\Omega}, g) d\mathbf{\Omega}_{g'} d\mathbf{c} d\mathbf{c}_1 \quad (2.240)$$

with  $\mathcal{E}$  and  $\Upsilon$  positive. Examining the three cases  $\mathcal{E} = \Upsilon$ ,  $\mathcal{E} > \Upsilon$ , and  $\mathcal{E} < \Upsilon$ , it is seen that  $(\Upsilon - \mathcal{E}) \ln(\mathcal{E}/\Upsilon) \leq 0$  for all three cases.

Moreover, since  $g \sigma_A(\mathbf{\Omega}, g) d\mathbf{\Omega}_{g'} d\mathbf{c} d\mathbf{c}_1$  is a positive measure, the integral on the right hand side of (2.238) is either negative or zero, so  $H$  can never increase. The resulting relation is known as Boltzmann's *H-theorem*:

$$\frac{\partial H}{\partial t} \leq 0 \quad (2.241)$$

This theorem states that, for any initial  $f$ ,  $H$  approaches a finite minimum limit, corresponding to a state of gas in which  $\partial H / \partial t = 0$  (steady state), and this can according to (2.238) occur, only if:

$$f' f'_1 = f f_1$$

$$\ln f' + \ln f'_1 = \ln f + \ln f_1 \quad (2.242)$$

The  $H$ -theorem is thus equivalent to the second law of thermodynamics which states that the entropy cannot decrease. A formal relationship between the  $H$  quantity and the entropy  $S$  is discussed in Sect. 2.7.3. Equation (2.242) also relates  $H$  to the theory of *irreversible thermodynamics*, as it is a probabilistic confirmation of the irreversibility of physical processes.

### 2.7.2 The Maxwellian Velocity Distribution

To find the exact equilibrium distribution that is a solution to (2.242), it can be shown that the resulting equilibrium distribution is given by (see e.g., [20], p. 69; [90], p. 162; [109]):

$$f^0(\mathbf{c}) = n \left( \frac{m}{2\pi kT} \right)^{\frac{3}{2}} e^{-\frac{m\mathbf{c}^2}{2kT}} \quad (2.243)$$

where  $k$  is the Boltzmann constant. In the Maxwellian distribution the parameters  $n$ ,  $\mathbf{c}$  and  $T$  are constants in  $\mathbf{r}$  and  $t$ . This distribution formula is often referred to as the *absolute Maxwellian*.

For the imaginary equilibrium flows we assume that in the neighborhood of any point in the gas, the distribution function is locally Maxwellian, and  $\rho$ ,  $T$ , and  $\mathbf{v}$  vary slowly in space and time. It can be shown that the approximation  $f(\mathbf{r}, \mathbf{c}, t) \approx f^0(\mathbf{r}, \mathbf{c}, t)$  is also a solution to (2.242), when  $f^0(\mathbf{r}, \mathbf{c}, t)$  is defined by:

$$f^0(\mathbf{r}, \mathbf{c}, t) = n(\mathbf{r}, t) \left( \frac{m}{2\pi kT(\mathbf{r}, t)} \right)^{\frac{3}{2}} e^{-\frac{m\mathbf{c}^2(\mathbf{r}, t)}{2kT(\mathbf{r}, t)}}$$

$$= n(\mathbf{r}, t) \left( \frac{m}{2\pi kT(\mathbf{r}, t)} \right)^{\frac{3}{2}} e^{-\frac{m(\mathbf{c}-\mathbf{v}(\mathbf{r}, t))^2}{2kT(\mathbf{r}, t)}}$$
(2.244)

It is important to note that this distribution function (2.244), defined so that it resembles (2.243) but with the constant values of  $n$ ,  $\mathbf{v}$  and  $T$  in (2.243) replaced by the corresponding functions of  $\mathbf{r}$  and  $t$ , remains a solution to (2.242). This distribution function, which is called the *local Maxwellian*, makes the kinetic theory much more general and practically relevant. Both the absolute- and local Maxwellians are termed equilibrium distributions. This result relates to the local and instantaneous equilibrium assumption in continuum mechanics as discussed in Chap. 1, showing that the assumption has a probabilistic fundament. It also follows directly from the local equilibrium assumption that the pressure tensor is related to the thermodynamic pressure, as mentioned in Sect. 2.5.

### 2.7.3 The H-Theorem and Entropy

In this section a relationship between the equilibrium value of  $H$  and entropy,  $S$ , is derived [20] (p. 78). For a gas at uniform steady state, the  $H(t)$  quantity defined by (2.235) can be expressed in terms of  $n$  and  $T$ . By use of the absolute Maxwellian distribution (2.243) and the energy equipartition theorem yields:

$$\begin{aligned} \langle \ln f \rangle_M &= \left\langle \left\{ \ln n + \frac{3}{2} \ln \left( \frac{m}{2\pi kT} \right) - \frac{\frac{1}{2}mC^2}{2kT} \right\} \right\rangle_M \\ &= \left\langle \left\{ \ln n + \frac{3}{2} \ln \left( \frac{m}{2\pi kT} \right) - \frac{3}{2} \right\} \right\rangle_M \end{aligned} \quad (2.245)$$

Thus, the  $H(t)$  quantity can be expressed as:

$$H = n \left\langle \left\{ \ln n + \frac{3}{2} \ln \left( \frac{m}{2\pi kT} \right) - \frac{3}{2} \right\} \right\rangle_M \quad (2.246)$$

Considering a gas with total mass,  $M$ , the volume occupied by the gas is  $V = \frac{M}{\rho} = \frac{M}{mn}$ . Integrating  $H(t)$  over the gas volume, it follows that:

$$H_0 = \int_V H d\mathbf{r} = \frac{M}{m} \left[ \ln n + \frac{3}{2} \ln \left( \frac{m}{2\pi kT} \right) - \frac{3}{2} \right] \quad (2.247)$$

Assuming that the kinetic theory definition of temperature and the thermodynamic counterpart are consistent, the entropy variable may be considered a function of  $V$  and  $T$  as obtained combining the first and second law of thermodynamics [45]. Moreover, Boltzmann let the gas of mass  $M$  undergo a small change of state, such that the temperature increases by  $\delta T$  and the volume increases by  $\delta V$ . Furthermore, considering that the total number of molecules is constant  $\delta(nV)$ , the volume change can be expressed in terms of a change in the number concentration of molecules  $\delta V/V = -\delta n/n$ .

Hence, the small change in entropy caused by the change of state can be expressed as [20] (see p. 41 and p. 81):

$$\delta S = M \left( C_V \frac{\delta T}{T} + \frac{k}{m} \frac{\delta V}{V} \right) = \frac{Mk}{m} \left( \frac{3}{2} \frac{\delta T}{T} - \frac{\delta n}{n} \right) \quad (2.248)$$

After integration the relation can be written as:

$$S = \frac{Mk}{m} \ln \left( \frac{T^{3/2}}{n} \right) + \text{constant} = -kH_0 - \frac{3M}{2m} \left( \ln \left( \frac{2\pi k}{m} \right) + 1 \right) + \text{constant} \quad (2.249)$$

where  $\ln T$  has been eliminated using (2.247).

This relation connects  $H_0$  with the entropy when the gas is at an uniform steady state:

$$S = -kH_0 + \text{Constant}' \quad (2.250)$$

It is commonly argued that the constant reflects the arbitrariness of the zero point of entropy. Due to the statistical relationship between  $H_0$  and  $S$  expressed through (2.250), the Boltzmann's  $H$ -theorem shows that for a gas that is not in a steady state  $H_0$  must decrease and the entropy  $S$  will increase accordingly. In accordance with (2.241) the following relationship holds:

$$\frac{dH_0}{dt} = -\frac{1}{k} \frac{dS}{dt} \leq 0 \quad (2.251)$$

or

$$\frac{dS}{dt} \geq 0 \quad (2.252)$$

The  $H$ -theorem is apparently a probability theory confirmation of the 2nd law of thermodynamics stating that the entropy cannot decrease in a physical process.

## 2.8 Solving the Boltzmann Equation

Various attempts have been made to obtain approximate solutions to the Boltzmann equation. Two of these methods were suggested independently by Chapman [18, 19] and by Enskog [35] giving identical results. In this book emphasis is placed on the Enskog method, rather than the Chapman one, as most modern work follows the Enskog approach since it is more intuitive and systematic, although still very demanding mathematically.

The Enskog [35] expansion method for the solution of the Boltzmann equation provides a series approximation to the distribution function. In the zero order approximation the distribution function is locally Maxwellian giving rise to the Euler equations of change. The first order perturbation results in the Navier-Stokes equations, while the second order expansion gives the so-called Burnett equations. The higher order approximations provide corrections for the larger gradients in the physical properties like  $\rho$ ,  $T$  and  $\mathbf{v}$ . The zero order approximation to  $f$  is valid when the system is at equilibrium and the gas properties contain no or very small macroscopic gradients. In particular, when the system is at equilibrium the heat fluxes and the viscous stresses vanish. The Navier-Stokes equations are valid whenever the relative changes in  $\rho$ ,  $T$  and  $\mathbf{v}$  in the distance of the mean free path are small compared to unity. Inasmuch as the Enskog theory is rather long and involved, this book only provide a brief outline of the problem and the method of attack, and then rather discuss the important results. When the second order approximations to the pressure tensor and the heat flux vector are inserted into the general conservation equation, one obtains the set of PDEs for the density, velocity and temperature which are called

the Burnett equations. In principle, these equations are regarded as valid for non-equilibrium flows. However, the use of these equations never led to any noticeable success (e.g., [39], pp. 150–151; [55], p. 464), merely due to the severe problem of providing additional boundary conditions for the higher order derivatives of the gas properties. Thus, the second order approximation will not be considered in further details in this book. Further details of the Enskog method are given by Enskog [35] and in the standard references like Hirschfelder et al. [55], Ferziger and Kaper [39], Vincenti and Kruger [157], Chapman and Cowling [20] and Liboff [90].

### 2.8.1 Equilibrium Flow: The Euler Equations

Applying the local Maxwellian distribution function (2.244), explicit expressions can be obtained for the heat flux,  $\mathbf{q}$  and the pressure tensor  $\mathbf{p}$ . Substituting  $f^0$  into the two flux formulas (2.189) and (2.197), give:

$$\mathbf{p} = m \int f^0 \mathbf{C} \mathbf{C} d\mathbf{c} = p \mathbf{e} \quad (2.253)$$

and

$$\mathbf{q} = \frac{1}{2} m \int f^0 \mathbf{C} C^2 d\mathbf{c} = 0 \quad (2.254)$$

In the zero order solution, there is no heat flow and the pressure tensor is diagonal. The diagonal elements in the pressure tensor denote the normal stresses that are identical to the thermodynamic pressure, as defined by (2.193). These conclusions are not obvious at first sight, so a brief mathematical verification is provided. In Cartesian tensor notation, the pressure tensor (2.189) is given by:

$$P_{ij} = \rho \left( \frac{m}{2\pi kT} \right)^{3/2} \int C_i C_j \exp \left( -\frac{mC^2}{2kT} \right) dC = p \delta_{ij} \quad (2.255)$$

where  $dC = d\mathbf{c}$ , since  $\mathbf{v}$  is not a function of  $\mathbf{c}$ .

Furthermore, as the integration is over the whole velocity space, it can be proved that any integral vanishes when the integrand is odd. Inspection of the pressure tensor shows that, since  $C_i$  and  $C_j$  themselves are odd functions of  $C_i$  and  $C_j$  respectively, whereas the exponential is an even function, the integrand as a whole is odd when  $i \neq j$  and even when  $i = j$ .

The derivation of the shear and normal stress terms is examined for two representative cases, which are the odd term ( $i = 1, j = 2$ ) and the even term ( $i = j = 1$ ). The two analytical integral solutions required are taken from the literature.<sup>31</sup>

For the particular odd term ( $i = 1, j = 2$ ) yields:

---

<sup>31</sup> In the following mathematical manipulation we are solving even integrals on the form:

$$\begin{aligned}
\frac{P_{12}}{nm} &= \left(\frac{m}{2\pi kT}\right)^{3/2} \\
&\times \int_{-\infty}^{\infty} C_1 \exp\left(-\frac{mC_1^2}{2kT}\right) dC_1 \int_{-\infty}^{\infty} C_2 \exp\left(-\frac{mC_2^2}{2kT}\right) dC_2 \int_{-\infty}^{\infty} \exp\left(-\frac{mC_3^2}{2kT}\right) dC \\
&= \left(\frac{m}{2\pi kT}\right)^{3/2} \times 0 \times 0 \times 2 \left[ \frac{1}{2} \sqrt{\pi} \left(\frac{m}{2kT}\right)^{-1/2} \right] = 0,
\end{aligned} \tag{2.256}$$

and so on for the other shear stresses  $P_{13}$  and  $P_{23}$ . It is thus verified that for equilibrium flows all the viscous stresses vanish,  $\boldsymbol{\sigma} = 0$ .

For the particular even term ( $i = j = 1$ ) yields:

$$\begin{aligned}
\frac{P_{11}}{nm} &= \left(\frac{m}{2\pi kT}\right)^{3/2} \\
&\times \int_{-\infty}^{\infty} C_1^2 \exp\left(-\frac{mC_1^2}{2kT}\right) dC_1 \int_{-\infty}^{\infty} \exp\left(-\frac{mC_2^2}{2kT}\right) dC_2 \int_{-\infty}^{\infty} \exp\left(-\frac{mC_3^2}{2kT}\right) dC \\
&= \left(\frac{m}{2\pi kT}\right)^{3/2} \times 2 \left[ \frac{\sqrt{\pi}}{4} \left(\frac{m}{2kT}\right)^{-3/2} \right] \times 2^2 \left[ \frac{\sqrt{\pi}}{2} \left(\frac{m}{2kT}\right)^{-1/2} \right]^2 \\
&= p \left(\frac{1}{nkT}\right) \left(\frac{m}{2\pi kT}\right)^{3/2} (2\pi)^{3/2} \left(\frac{m}{kT}\right)^{-5/2} = \frac{p}{nm},
\end{aligned} \tag{2.257}$$

and so on for  $P_{22}$  and  $P_{33}$ . The pressure tensor becomes,  $\mathbf{p} = p\mathbf{e}$ .

The heat flux is treated in a similar manner. By substituting  $f^0$  from (2.244) into the definition of  $\mathbf{q}$  (2.197), it is seen that this expression constitutes an odd integral, hence  $\mathbf{q} = 0$  (e.g., [157], Sect. 5). Since it has been verified that both the viscous stresses and the heat conduction terms vanish for equilibrium flows, no further constitutive stress tensor or heat flux relations are required to close the governing equations. The set of equilibrium flow equations is obtained by substituting (2.253) and (2.254) into the conservation equations (2.218), (2.223) and (2.229).

The system of equations are called the *Euler* equations for isentropic flow:

---

(Footnote 31 continued)

$$\int_{-\infty}^{\infty} x^n \exp(-ax^2) dx = 2 \int_0^{\infty} x^n \exp(-ax^2) dx$$

Two even integral solutions are employed in this reformulation in which  $n = 0$  and  $n = 2$ , respectively, as listed below:

$$\int_0^{\infty} \exp(-ax^2) dx = \frac{\sqrt{\pi}}{2} a^{-1/2} \quad \text{and} \quad \int_0^{\infty} x^2 \exp(-ax^2) dx = \frac{\sqrt{\pi}}{4} a^{-3/2}$$

Further details can, for example, be found in Liboff [90] (pp. 526–527) and Chapman and Cowling [20] (Sect. 1.4).

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = 0 \quad (2.258)$$

$$\frac{\partial}{\partial t}(\rho \mathbf{v}) + \nabla \cdot (\rho \mathbf{v} \mathbf{v}) = -\nabla p + \rho \mathbf{F} \quad (2.259)$$

$$\frac{\partial}{\partial t}(\rho[e + \frac{1}{2}v^2]) + \nabla \cdot (\rho \mathbf{v}[e + \frac{1}{2}v^2]) = -\nabla \cdot (p \mathbf{v}) + \rho \mathbf{F} \cdot \mathbf{v} \quad (2.260)$$

### 2.8.2 Gradient Perturbations: Navier Stokes Equations

Applying the Enskog perturbation method, the properties of dilute gases which are only slightly deviating from equilibrium can be approximated. Only under these conditions will the flux vectors be about linear in the derivatives so that the formal definitions of the transport coefficients apply. In this limit the distribution function is still nearly Maxwellian, and the Boltzmann equation can be solved by a perturbation method. The resulting solutions are then used to obtain approximate expressions for the heat and momentum fluxes and for the corresponding transport coefficients.

The first step in the Enskog expansion is to introduce a perturbation parameter  $\varepsilon$  into the Boltzmann equation to enforce a state of equilibrium flow as the gas is dominated by a large collision term:

$$\begin{aligned} \frac{\mathcal{D}f}{Dt} &= \frac{1}{\varepsilon} \int_1 [f'(\mathbf{r}, \mathbf{c}', t) f'_1(\mathbf{r}, \mathbf{c}'_1, t) - f(\mathbf{r}, \mathbf{c}, t) f_1(\mathbf{r}, \mathbf{c}_1, t)] g \sigma_A(\boldsymbol{\Omega}') d\boldsymbol{\Omega}' d\mathbf{c}_1 \\ &= \frac{1}{\varepsilon} J(ff) \end{aligned} \quad (2.261)$$

where the perturbation parameter factor  $\varepsilon^{-1}$  measures the frequency of collisions. It is assumed that if  $\varepsilon \ll 1$ , the collisions are so frequent that the gas behaves like a continuum being in local equilibrium at every point.

Thereafter, the distribution function is expanded in a series in  $\varepsilon$ :

$$f = f^0 + \varepsilon f^1 + \varepsilon^2 f^2 + \dots \quad (2.262)$$

In a similar manner the time derivative is expanded as:

$$\frac{\partial}{\partial t} = \frac{\partial_0}{\partial t} + \varepsilon \frac{\partial_1}{\partial t} + \varepsilon^2 \frac{\partial_2}{\partial t} + \dots \quad (2.263)$$

stipulating that the time dependence of  $f$  is solely dependent on the gas dynamic variables  $\rho$ ,  $T$ , and  $\mathbf{v}$ , and expressed in terms of an exact differential.

The physical meaning of the expansion in time is that the lowest order terms vary most rapidly, whereas higher order terms are more slowly varying. If these series expansions are introduced into the modified Boltzmann equation (2.261), and the coefficients of equal powers of  $\varepsilon$  equated, the distribution function can be uniquely

determined to a specified order provided that  $f$  still satisfies the moment relations defining the physical properties like density, gas velocity and temperature.

Following this procedure, the result is:

$$0 = J(f^0 f^0) \quad (2.264)$$

$$\frac{D_{c,0} f^0}{D_c t} = J(f^0 f^1) \quad (2.265)$$

The solution of (2.264) gives rise to the absolute Maxwellian,  $f^0$ , as discussed in Sect. 2.7.2. Considering the first order approximation, (2.265) is supposedly solved for  $f^1$ . It is then required that the physical properties ( $\rho, \mathbf{v}, T$ ) are determined by the zero order approximation,  $f^0$ , whereas the higher order terms in the expansion contribute to  $\mathbf{q}$  and  $\sigma$  only.

Next, in the first order perturbation solution  $f^1$  is written in terms of the perturbation function  $\Phi$ . Hence,

$$f \approx f^0 + f^1 \approx f^0 + \Phi f^0 = f^0(1 + \Phi) \quad (2.266)$$

where  $\varepsilon$  is set to unity.

After (2.265) has been solved for  $\Phi$  (i.e., instead of  $f^1$ ),  $f$  is known to second order  $f = f^0(1 + \Phi)$ . Note that when the perturbation function  $\Phi \neq 0$  but still  $\Phi \ll 1$ , the system is only slightly different from equilibrium as prerequisites. When the first order approximation is introduced through (2.266), (2.265) is said to be an inhomogeneous linear integral equation for  $\Phi$ . The form of  $\Phi$  is then established without actually obtaining a complete solution. Instead, by functional analysis a partial solution is written in the form (e.g., Chapman and Cowling [20], Sect. 7.3; Hirschfelder et al. [55], Chap. 7, Sect. 3):

$$\Phi = -\frac{1}{n} \left[ \sqrt{\frac{2kT}{m}} \mathbf{A} \cdot \frac{\partial}{\partial \mathbf{r}} (\ln T) + 2\mathbf{B} : \frac{\partial}{\partial \mathbf{r}} \mathbf{v} \right] \quad (2.267)$$

where  $\mathbf{A}$  is a vector function of  $\mathcal{C} = \sqrt{\frac{m}{2kT}} \mathbf{C}$ ,  $n$  and  $T$ , whereas  $\mathbf{B}$  is a tensor function of  $\mathcal{C}$ ,  $n$  and  $T$ .

To determine the form of the two functions  $\mathbf{A}$  and  $\mathbf{B}$  the solution for  $\Phi$  (2.267) is substituted into the linearized Boltzmann equation (2.265), and thereafter the coefficients of the different components of  $\nabla T$  and  $\nabla \mathbf{v}$  in the resulting relation are equated. The only vectors that can be formed from these quantities are products of  $\mathcal{C}$  itself and scalar functions  $A(\mathcal{C}, n, T)$ , expressed as:

$$\mathbf{A} = A(\mathcal{C}, n, T) \mathcal{C} \quad (2.268)$$

$\mathbf{B}$  can be shown to be a symmetrical, traceless and non-divergent tensor [20, 39, 90]. The only second order symmetrical traceless tensors that can be formed from  $\mathcal{C}$ ,  $n$  and  $T$  are products of  $\overline{\mathcal{C}\mathcal{C}}$ <sup>32</sup> and scalar functions  $B(\mathcal{C}, n, T)$ .

Hence, it follows that:

$$\mathbf{B} = \overline{\mathcal{C}\mathcal{C}} B(\mathcal{C}, n, T) \quad (2.269)$$

Finally, solutions to the integral flux equations like (2.189) and (2.197) are then obtained by expressing the scalar functions  $A(\mathcal{C}, n, T)$  and  $B(\mathcal{C}, n, T)$  in terms of certain polynomials<sup>33</sup> (i.e., Sonine polynomials). However, without showing all the lengthy details of the method by which the two scalar functions are determined, we briefly sketch the problem definition in which the partial solution (2.267) is used to determine expressions for the viscous-stress tensor  $\sigma$  and the heat flux vector  $\mathbf{q}$ .

Introducing the expressions for the first order approximation of the distribution function (2.266) and thereafter the partial solution for  $\Phi$  (2.267) into the pressure tensor definition (2.189), the pressure tensor approximation is given by [55]:

$$\begin{aligned} p &= m \int f \mathbf{C} \mathbf{C} d\mathbf{c} = m \int f^0 (1 + \Phi) \mathbf{C} \mathbf{C} d\mathbf{c} \\ &= \underbrace{m \int f^0 \mathbf{C} \mathbf{C} d\mathbf{c}}_1 + \underbrace{m \int f^0 \Phi \mathbf{C} \mathbf{C} d\mathbf{c}}_2 \end{aligned} \quad (2.270)$$

where the parameter  $\varepsilon$  has been set equal to one.

From the previous section, it is recognized that term 1 on the RHS of (2.270) equals the pressure term,  $p\mathbf{e}$ , as for equilibrium systems. It can be shown by kinetic theory that term 2 on the RHS corresponds to the viscous stress tensor  $\sigma$  as defined by the pressure tensor (2.194). In order to determine the stress tensor term 2 in (2.270), the perturbation function  $\Phi$  in the integrand is substituted by the partial solution (2.267). Omitting integrals of odd functions of the components of  $\mathcal{C}$  or  $\mathbf{C}$ , only the term containing the  $\mathbf{B}$  remains. After some lengthy manipulations, the result is:

$$\sigma = -\mu \left( \nabla \mathbf{v} + (\nabla \mathbf{v})^T - \frac{2}{3} (\nabla \cdot \mathbf{v}) \mathbf{e} \right) \quad (2.271)$$

Note that the viscosity parameter  $\mu$  has been introduced as a pre-factor in front of the tensor functions by substitution of the kinetic theory transport coefficient expression after comparing the kinetic theory result with the definition of the viscous stress tensor  $\sigma$ , (2.194). In other words, this model inter-comparison defines the viscosity parameter in accordance with the Enskog theory.

<sup>32</sup> This notation is used denoting a symmetrical, traceless and non-divergent tensor [20, 39, 90].

<sup>33</sup> The detailed mathematical analysis needed determining these integrals are omitted in this book as it is rather lengthy and involved, instead the reader being interested in these pure mathematics are referred to the formal mathematical procedures given in the standard references (e.g., Enskog [35]; Hirschfelder et al. [55]; Chapman and Cowling [20], p. 126; Liboff [90], p. 187).

An analytical expression for the heat flux vector can be derived in a similar manner using the Enskog approach. That is, introducing the first order approximation of the distribution function from (2.266) into the heat flux definition (2.197) and thereafter substitute the partial solution for  $\Phi$ , as defined by (2.267), into the resulting flux vector integrand as follows [55]:

$$\mathbf{q} = \frac{1}{2}m \int f^0(1 + \Phi)C^2 \mathbf{C} d\mathbf{C} = -k\nabla T \quad (2.272)$$

Hence, the conductivity  $k$  in (2.272) is determined by model inter-comparison in accordance with the Enskog method. In general, it is important to recognize that both the Newton viscosity law and Fourier's law of heat conduction are automatically generated from the approximate kinetic theory solution of Enskog.

In conclusion, when these first order expressions for the pressure tensor and the heat flow vector are substituted into the general conservation equations (2.218), (2.223) and (2.229), the following set of partial differential equations are obtained:

$$\frac{1}{\rho} \frac{D\rho}{Dt} = -\nabla \cdot \mathbf{v} \quad (2.273)$$

$$\rho \frac{D\mathbf{v}}{Dt} = -\nabla p - \nabla \cdot \boldsymbol{\sigma} + \rho \mathbf{F} \quad (2.274)$$

$$\rho \frac{D}{Dt} \left( e + \frac{1}{2} v^2 \right) = -\nabla \cdot \mathbf{q} - \nabla \cdot (p\mathbf{v}) - \nabla \cdot (\boldsymbol{\sigma} \cdot \mathbf{v}) + \rho \mathbf{F} \cdot \mathbf{v} \quad (2.275)$$

where  $\boldsymbol{\sigma}$  and  $\mathbf{q}$  are given by (2.271) and (2.272), respectively.

The resulting set of conservation equations derived by kinetic theory corresponds to the governing equations of gas dynamics (sometimes referred to as the Navier-Stokes equations).

## 2.9 Multicomponent Mixtures

In this section we briefly discuss some of the important issues that arise when the kinetic gas theory is extended to gas mixtures. For a more detailed study of kinetic theory of mixtures the reader is referred to Hirschfelder et al. [55], Williams [162] (app D) and Ferziger and Kaper [39].

### 2.9.1 The Boltzmann Equations for a Mixture of Chemical Species

It is first necessary to generalize the definitions of the important functions. If we denote the chemical species in a gas mixture by  $s$ , then  $n_s$ ,  $m_s$ ,  $f_s$ ,  $\mathbf{c}_s$ ,  $\mathbf{C}_s$ ,  $\mathbf{F}_s$ , etc. will in general be different for each species.

The starting point for the kinetic theory of low density, non-reacting mixtures of mono-atomic gases is the knowledge of the distribution function  $f_s(\mathbf{r}, \mathbf{c}_s, t)$ .  $f_s(\mathbf{r}, \mathbf{c}_s, t)$  is defined in such a way that the quantity  $f_s(\mathbf{r}, \mathbf{c}_s, t)d\mathbf{c}_s d\mathbf{r}$  represents the probable number of molecules of the  $s$ -th species which at the time  $t$  lie in a unit volume element  $d\mathbf{r}$  about the point  $\mathbf{r}$  and which have velocities within the range  $d\mathbf{c}_s$  about  $\mathbf{c}_s$ . It is emphasized that  $\mathbf{c}_s$  denotes the molecular velocity of a species  $s$  with respect to a coordinate system fixed in space.

The total number of molecules of species  $s$  per unit spatial volume yields:

$$n_s(\mathbf{r}, t) = \int f_s(\mathbf{r}, \mathbf{c}_s, t)d\mathbf{c}_s \quad (2.276)$$

For the mixture as a whole we have:

$$n(\mathbf{r}, t) = \sum_s \int f_s(\mathbf{r}, \mathbf{c}_s, t)d\mathbf{c}_s = \sum_s n_s \quad (2.277)$$

and

$$\rho(\mathbf{r}, t) = \sum_s m_s \int f_s(\mathbf{r}, \mathbf{c}_s, t)d\mathbf{c}_s = \sum_s m_s n_s = \sum_s \rho_s \quad (2.278)$$

The mean (number average) values of any function  $\psi_s(\mathbf{c}_s)$  over all the molecules of a particular species,  $s$ , yield:

$$\langle \psi \rangle_{M,s} = \frac{1}{n_s} \int \psi_s(\mathbf{c}_s) f_s(\mathbf{r}, \mathbf{c}_s, t)d\mathbf{c}_s \quad (2.279)$$

The corresponding mean (number average) values of any function  $\psi_s(\mathbf{c}_s)$  over all the species  $n$  in the mixture are:

$$\langle \psi \rangle_{M,n} = \frac{1}{n} \sum_s \int \psi_s(\mathbf{c}_s) f_s(\mathbf{r}, \mathbf{c}_s, t)d\mathbf{c}_s = \frac{1}{n} \sum_s n_s \langle \psi \rangle_{M,s} \quad (2.280)$$

The corresponding mixture mass average value of any function  $\psi_s(\mathbf{c}_s)$  is defined by:

$$\langle \psi \rangle_{M,m} = \frac{1}{\rho} \sum_s m_s \int \psi_s(\mathbf{c}_s) f_s(\mathbf{r}, \mathbf{c}_s, t)d\mathbf{c}_s = \frac{1}{\rho} \sum_s n_s m_s \langle \psi \rangle_{M,s} \quad (2.281)$$

In particular, the mass average velocity  $\mathbf{v}_m$  of the mixture is given by:

$$\mathbf{v}_m = \langle \mathbf{c}_s \rangle_{M,m} = \frac{1}{\rho} \sum_s \rho_s \langle \mathbf{c}_s \rangle_{M,s} \quad (2.282)$$

It is recognized that the mass average velocity for a mixture,  $\mathbf{v}_m$ , is not equal to the number or molar average velocity  $\langle \mathbf{c}_s \rangle_{M,n}$ .

The number average velocity for a particular species,  $s$ , is defined by:

$$\begin{aligned}\langle \mathbf{c}_s \rangle_{M,s} &= \frac{1}{n_s} \int \mathbf{c}_s f_s(\mathbf{r}, \mathbf{c}_s, t) d\mathbf{c}_s \\ &= \frac{1}{n_s m_s} \int m_s \mathbf{c}_s f_s(\mathbf{r}, \mathbf{c}_s, t) d\mathbf{c}_s = \mathbf{v}_s(\mathbf{r}, t)\end{aligned}\quad (2.283)$$

Note that for each species the molecular number and mass average velocities are equal, as all the molecules have the same mass.

The peculiar velocity of a molecule of species  $s$  is defined in terms of the mass average velocity:

$$\mathbf{C}_s(\mathbf{r}, \mathbf{c}_s, t) = \mathbf{c}_s - \mathbf{v}_m(\mathbf{r}, t) \quad (2.284)$$

The species  $s$  diffusion velocity denotes the average velocity of the particular type of species with respect to a reference frame moving with the mass average velocity of the gas mixture:

$$\mathbf{v}_{d,s} = \langle \mathbf{C}_s \rangle_{M,s} - \mathbf{v}_m = \mathbf{v}_s - \mathbf{v}_m \quad (2.285)$$

Thus, the diffusion velocity for a given species equals the average of the corresponding peculiar velocity and can be written in the form:

$$\mathbf{v}_{d,s} = \frac{1}{n_s} \int (\mathbf{c}_s - \mathbf{v}_m) f_s(\mathbf{r}, t) d\mathbf{c}_s \quad (2.286)$$

Hence, from the definitions of the diffusion and mass average velocities it follows that:

$$\begin{aligned}\sum_s n_s m_s \mathbf{v}_{d,s} &= \sum_s m_s \int (\mathbf{c}_s - \mathbf{v}_m) f_s(\mathbf{r}, t) d\mathbf{c}_s \\ &= \sum_s m_s n_s (\langle \mathbf{c}_s \rangle_{M,s} - \mathbf{v}_m) = 0\end{aligned}\quad (2.287)$$

The kinetic theory temperature is defined in terms of the mean (number average) peculiar kinetic energy:

$$\begin{aligned}\frac{1}{2} \sum_s m_s \int (\mathbf{c}_s - \mathbf{v}_m)^2 f_s d\mathbf{c}_s &= \frac{1}{2} \sum_s m_s n_s \langle (\mathbf{c}_s - \mathbf{v}_m)^2 \rangle_M \\ &= \frac{1}{2} \sum_s m_s n_s \langle C_s^2 \rangle_M = \frac{3}{2} n k T\end{aligned}\quad (2.288)$$

The rigorous development of the kinetic theory of gases is based upon the Boltzmann equation for the velocity distribution function  $f_s$ . An extended Boltzmann equation, similar to (2.184), describes how  $f_s$  evolves in time and space:

$$\frac{\partial f_s}{\partial t} + \mathbf{c}_s \cdot \nabla f_s + \mathbf{F}_s \cdot \frac{\partial f_s}{\partial \mathbf{c}_s} = \sum_{r=1}^q \left( \frac{\partial f_s}{\partial t} \right)_{\text{Collision}} (f_s | f_r) \quad (2.289)$$

where the generalized multicomponent form of the collision term is approximated as:

$$\left( \frac{\partial f_s}{\partial t} \right)_{\text{Collision}} (f_s | f_r) = \int \int (f'_s f'_r - f_s f_r) g_{sr} \sigma_{A_{sr}}(\Omega', g_{sr}) d\Omega'_{g',sr} d\mathbf{c}_s \quad (2.290)$$

in which  $f'_s = f'_s(\mathbf{r}, \mathbf{c}'_s, t)$ , the magnitude of the relative velocities is  $g_{sr} = |\mathbf{c}_s - \mathbf{c}_r| = |\mathbf{c}'_s - \mathbf{c}'_r|$ , and  $\sigma_{A_{sr}}(\Omega', g_{sr})$  is the differential cross section between particles  $s$  and  $r$ . The external force per unit mass acting on a molecules of species  $s$  is denoted by  $\mathbf{F}_s$ .

The set of  $q$  coupled equations on the form (2.289), with the generalized collision term defined by (2.290), comprises the generalization of the Boltzmann equation for mono-atomic molecules to  $q$  species. In each of these equations, the distribution functions for all the species appear on the RHS of the equation under the integration sign. Moreover, the sum of integrals describes the entry and exit of particles of  $s$  in or out of the phase element.

### 2.9.2 The Diffusive Flux Vectors for a Mixture of Chemical Species

The collective flux vector associated with the property  $\psi_s(\mathbf{c}_s)$  is given by:

$$\Phi_s = \int \psi_s f_s \mathbf{C}_s d\mathbf{c}_s = \int \psi_s f_s \mathbf{C}_s d\mathbf{C}_s \quad (2.291)$$

It is noted that, as for simple systems computing average quantities, integration over  $\mathbf{C}_s$  is equivalent to integration over  $\mathbf{c}_s$  since the two velocities differ by a constant, and the integration is over the entire range of velocities.

The specific species mass, heat and momentum fluxes can now be expressed by substituting the individual conservative properties for the function  $\psi_s$ .

The diffusive mass flux vector is obtained if  $\psi_s = m_s$ :

$$\mathbf{j}_s = m_s \int (\mathbf{c}_s - \mathbf{v}_m) f_s d\mathbf{c}_s = m_s \int \mathbf{C}_s f_s d\mathbf{C}_s = n_s m_s \langle \mathbf{C}_s \rangle_{M,s} = n_s m_s \mathbf{v}_{d,s}, \quad (2.292)$$

As shown earlier by (2.287), the sum of all the species mass flux vectors equals zero:

$$\sum_s \mathbf{j}_s = 0 \quad (2.293)$$

The three flux vectors associated with the species momentum transport in the  $x$ ,  $y$  and  $z$ -directions are obtained from (2.291) when  $\psi_s = m_s C_{s,x}$ ,  $\psi_s = m_s C_{s,y}$  and  $\psi_s = m_s C_{s,z}$ , respectively.

The nine components of these three vectors form a symmetric pressure tensor,  $\mathbf{p}_s$ , hence the mixture pressure yields:

$$\begin{aligned} \mathbf{p} &= \sum_s \mathbf{p}_s = \sum_s m_s \int (\mathbf{c}_s - \mathbf{v}_m)(\mathbf{c}_s - \mathbf{v}_m) f_s d\mathbf{c}_s = \sum_s m_s \int \mathbf{C}_s \mathbf{C}_s f_s d\mathbf{C}_s \\ &= \sum_s m_s n_s \langle \mathbf{C}_s \mathbf{C}_s \rangle_{M,s} \end{aligned} \quad (2.294)$$

where the thermodynamic pressure is given by  $p = \frac{1}{3} \text{tr}(\mathbf{p}) = \frac{1}{3} \mathbf{p} : \mathbf{e} = \sum_s p_s = nkT$ , and the viscous stresses yield:  $\boldsymbol{\sigma} = \mathbf{p} - p\mathbf{e}$ .

The species  $s$  heat flux vector associated with the transport of kinetic energy is obtained if we let  $\psi_s = \frac{1}{2} m_s C_s^2$ , hence the mixture heat flux vector is determined by the sum over all the components:

$$\begin{aligned} \mathbf{q} &= \sum_s \mathbf{q}_s = \frac{1}{2} \sum_s m_s \int (\mathbf{c}_s - \mathbf{v}_m)^2 (\mathbf{c}_s - \mathbf{v}_m) f_s d\mathbf{c}_s = \frac{1}{2} \sum_s m_s \int C_s^2 \mathbf{C}_s f_s d\mathbf{C}_s \\ &= \frac{1}{2} \sum_s m_s n_s \langle C_s^2 \mathbf{C}_s \rangle_M \end{aligned} \quad (2.295)$$

Analytical expressions for the multicomponent flux vectors can be derived using the Enskog [35] perturbation method as sketched for one component mono-atomic gases in Sect. 2.8.

### 2.9.3 The Enskog's Equation for a Mixture of Chemical Species

If the species  $s$  Boltzmann equation (2.289) is multiplied by the molecular property  $\psi_s(\mathbf{c}_s)$  and thereafter integrated over all molecular velocities, the general Enskog's equation of change is achieved:

$$\frac{\partial}{\partial t} \int \psi_s f_s d\mathbf{c}_s + \nabla \cdot \int \mathbf{c}_s \psi_s f_s d\mathbf{c}_s + \int \mathbf{F}_s \cdot \frac{\partial \psi_s}{\partial \mathbf{c}_s} f_s d\mathbf{c}_s = \int \psi_s \left( \frac{\partial f_s}{\partial t} \right)_{\text{Collision}} d\mathbf{c}_s \quad (2.296)$$

### 2.9.4 The Equation of Change for a Mixture of Chemical Species

To derive the species equations of change we let  $\psi_s$  denote successively the mass  $m_s$ , the momentum  $m_s \mathbf{c}_s$ , and the energy  $\frac{1}{2} m_s (\mathbf{C}_s \cdot \mathbf{C}_s)$ . Thereafter, the corresponding

mixture equations are obtained simply by adding all the specific species  $s$  equations. The governing equations are given by [55] (Sect. 7-2):

$$\frac{\partial \rho_s}{\partial t} + \nabla \cdot (\rho_s \mathbf{v}_m) + \nabla \cdot \mathbf{j}_s = 0, \quad (2.297)$$

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}_m) = 0, \quad (2.298)$$

$$\frac{\partial}{\partial t}(\rho \mathbf{v}_m) + \nabla \cdot (\rho \mathbf{v}_m \mathbf{v}_m) = -\nabla p - \nabla \cdot \boldsymbol{\sigma}_m + \sum_s \rho_s \mathbf{F}_s \quad (2.299)$$

$$\frac{\partial}{\partial t}(\rho[e + \frac{1}{2}v_m^2]) + \nabla \cdot (\rho \mathbf{v}_m[e + \frac{1}{2}v_m^2]) = -\nabla \cdot \mathbf{q} - \nabla \cdot (\mathbf{p} \cdot \mathbf{v}_m) + \rho \mathbf{F} \cdot \mathbf{v}_m \quad (2.300)$$

where the internal energy per unit volume is defined by  $\rho e = \frac{3}{2}nkT = \frac{1}{2} \sum_s m_s \int (\mathbf{c}_s - \mathbf{v}_m)^2 f_s d\mathbf{c}_s$ .

### 2.9.5 Mass Diffusion Fluxes for Mixtures of Chemical Species

It is possible to justify several alternative definitions of the multicomponent diffusivities. The multicomponent mass flux vectors themselves are expressed in either of two mathematical forms or frameworks referred to as the generalized Fick's- and Maxwell-Stefan equations. In this subsection, the mass diffusion flux models for mixtures of chemical species are examined. The bulk diffusion flux models considered are the Fick's first law for binary mixtures, the approximate Fickian Wilke model, the generalized Fick's first law, and the rigorous Maxwell-Stefan model. For the combined bulk and Knudsen diffusion fluxes, the Fickian Wilke-Bosanquet and dusty gas models are considered. The dusty gas model designate an extended Maxwell-Stefan model. In this survey of the mass diffusion flux models, emphasis is placed on the first principles derivation of the governing flux equations, the physical interpretations of the terms in the resulting models, the consistency with Fick's first law for binary systems, and the relationships between the molar and mass based fluxes. The conventional modeling practice considers the mass average mixture velocity as a primitive variable instead of the number or molar averaged mixture velocity. The mass averaged velocity is the natural and most convenient basis for the laws of conservation of mixture mass, momentum and energy. It is noticed that the total number of moles of the molecules in a mixture is not necessarily conserved in reactive systems, whereas the elements and the mixture mass are preserved quantities. Separate equations of motion and energy for each species  $s$  can be derived by continuum arguments [9]. However, for mixtures containing a large number of different species the resulting sets of separate species mole, momentum and energy equations are neither feasible nor needed for solving transport problems. Besides, the species

momentum and energy fluxes are not measurable quantities. Therefore, for the calculation of multicomponent problems containing convective transport phenomena the mass average velocity based description of the diffusion has an essential advantage. If this description is chosen, then all the conservation equations contain only mass average velocities, while in the molar description of the diffusion the equations of motion and energy contain mass average velocities whereas the species mass balance equations contain number or mole average velocities. The two velocities are equal only when all the components of the system have the same molar mass, hence the mass average velocity based diffusion flux formulation is recommended for reactor simulations.

### 2.9.5.1 The Fick's First Law for Binary Mixtures

The Fick's first law of binary diffusion [40], proposed by Fick in 1855, expresses the mass flux as a negative function of the driving force, is defined by:

$$\mathbf{j}_s = -\rho D_{sr} \nabla \omega_s, \quad \text{where } s, r = 1, 2. \quad (2.301)$$

This mass diffusion flux relation serves as basis for the generalized Fickian multicomponent formulations.

### 2.9.5.2 Generalized Fick's First Law Based on Kinetic Theory

Numerous generalized Fickian mass diffusion flux models have been proposed based on the concept of kinetic theory. Four such models are outlined in this subsection.

The Enskog series solution to the species  $s$  Boltzmann equation can be obtained in the same manner as sketched for the simple systems in Sect. 2.8. Near equilibrium the perturbation function  $\Phi_s$  can be expressed as a linear function of the various gradients (Curtiss and Hirschfelder [24], p. 551; Hirschfelder et al. [55], p. 469; Curtiss [25], p. 2918):

$$\Phi_s = -(\mathbf{A}_s \cdot \frac{\nabla T}{T}) - (\mathbf{B}_s : \nabla \mathbf{v}_m) + n \sum_{r=1}^N (\mathcal{C}_{s,r} \cdot \mathbf{d}_r) \quad (2.302)$$

where  $s = 1, 2, 3, \dots, N$ . The vector  $\mathbf{A}_s$ , the tensor  $\mathbf{B}_s$ , and the vectors  $\mathcal{C}_{s,r}$  are functions of  $\mathbf{c}_s$ ,  $\mathbf{r}$ , and  $t$ .

By inserting this expression for  $\Phi_s$  into the integrals for the flux vectors, Hirschfelder et al. [55] obtained expressions for the mass diffusion vector, the pressure tensor, and the heat flux vector. In particular, the integral for the diffusion flux vector can be expressed in terms of  $\Phi_s$ .

Hence, for a  $N$  component gas mixture the multicomponent mass flux vector was expressed as (Hirschfelder et al. [55], p. 478, p. 516):

$$\begin{aligned}
\mathbf{j}_s &= n_s m_s \mathbf{v}_{d,s} = m_s \int \mathbf{C}_s f_s d\mathbf{C}_s \approx m_s \int \mathbf{C}_s f_s^0 \Phi_s d\mathbf{C}_s \\
&= m_s \int \left[ -(\mathbf{A}_s \cdot \frac{\nabla T}{T}) + n \sum_r \mathcal{C}_{s,r} \cdot \mathbf{d}_r \right] \mathbf{C}_s f_s^0 d\mathbf{C}_s \quad (2.303) \\
&\approx \frac{n^2}{\rho} \sum_{r=1}^N m_s m_r \mathcal{D}_{sr} \mathbf{d}_r - D_s^T \frac{\nabla T}{T}
\end{aligned}$$

where the  $\mathcal{D}_{sr}$  are the generalized multicomponent diffusion coefficients, and the  $D_s^T$  are the generalized multicomponent thermal diffusion coefficients, respectively. It is noted that the term involving  $\mathbf{B}_s$  vanishes on integration (see Hirschfelder et al. [55], p. 478). The given relations correspond to Eqs. (7.4-1)–(7.4-3) in the book of Hirschfelder et al. [55], pp. 478–479.

The multicomponent thermal diffusion coefficients  $D_s^T$ , have the property:

$$\sum_{s=1}^N D_s^T = 0. \quad (2.304)$$

The multicomponent thermal diffusion coefficients serve as reminders that the kinetic theory predicts the cross effects like the transport of mass resulting from a temperature gradient (thermal diffusion). It can also be shown that the theory predicts transport of energy resulting from a concentration gradient (the diffusion-thermo effects). These second-order effects are often referred to as the Soret—and Dufour effects. It is noted that these terms do not appear when applying simple kinetic theory, only the more rigorous solution methods resolve these properties.

For dilute mono-atomic gases the generalized diffusional driving force vector,  $\mathbf{d}_s$ , that includes the composition gradients, the pressure gradient, and the external force differences, is defined<sup>34</sup> by (Curtiss and Hirschfelder [24], p. 551; Bird et al. [9]):

$$\begin{aligned}
\mathbf{d}_s &= \nabla x_s + (x_s - \omega_s) \frac{\nabla p}{p} - \frac{\rho_s}{p} \left[ \mathbf{g}_s - \sum_{r=1}^N \omega_r \mathbf{g}_r \right] \\
&= \frac{1}{cRT} \left[ (\nabla p_s - \rho_s \mathbf{g}_s) - \omega_s \left( \nabla p - \sum_{r=1}^N \rho_r \mathbf{g}_r \right) \right] \quad (2.305)
\end{aligned}$$

where  $x_s$  and  $\omega_s$  are the mole fraction and mass fraction, respectively.

It can be shown that  $\sum_s \mathbf{d}_s = 0$  by simple summation. This diffusional driving force vector, valid for a mixture of dilute mono-atomic gases, can be generalized for other gases using principles of irreversible thermodynamics. The generalized diffusional driving force vector is given in (2.382), p. 282.

<sup>34</sup> It is noted that the external force difference driving force defined in Hirschfelder et al. [55] at p 516, contains a couple of misprints.

By analysis of the model equations, i.e., (2.303) and (2.305), Hirschfelder et al. [55] concluded that these diffusion coefficients  $\mathcal{D}_{sr}$  are not uniquely defined. In the development of the kinetic theory of multicomponent mixtures, Hirschfelder et al. [55] resolved this lack of uniqueness by arbitrarily taking the diagonal coefficient  $\mathcal{D}_{ii}$  to be zero. However, this convention did lead to coefficients which are not symmetric. Moreover, Hirschfelder et al. [55] did relate the diffusion transport coefficients occurring in the mass diffusion flux model resulting from kinetic theory (2.303) with a corresponding set of phenomenological coefficients occurring in an alternative mass diffusion flux model derived from the principles of irreversible thermodynamics (2.313). The irreversible thermodynamics relation is examined at page 304. By comparison of the two model formulations, the generalized thermal diffusion coefficients were related to the phenomenological coefficients by:  $D_s^T = \alpha_{s0}$ . The diffusion coefficients,  $\mathcal{D}_{sr}$ , were related to the phenomenological coefficients,  $\alpha_{sr}$ , in the following manner (Curtiss and Hirschfelder [24], p. 552; Hirschfelder et al. [55], p. 479 and p. 715):

$$\mathcal{D}_{sr} = -\frac{\rho p}{n^2 m_s m_r} \left( \frac{\alpha_{sr}}{n_r m_r} + \frac{1}{n_s m_s} \sum_{\substack{k=1 \\ k \neq s}}^N \alpha_{sk} \right) \quad (2.306)$$

Fifty years later, Curtiss and Bird [26] proposed that the multicomponent diffusion coefficient relations can be written in simpler form by using the quantities  $\check{D}_{sr} = (\omega_i \omega_j / x_i x_j) \mathcal{D}_{sr}$ , rather than  $\mathcal{D}_{sr}$  from (2.305). The modified diffusion coefficients  $\check{D}_{sr}$  are thus related to  $\alpha_{sr}$  by:

$$\check{D}_{sr} = -\frac{cRT}{\rho} \left( \frac{\alpha_{sr}}{n_r m_r} + \frac{1}{n_s m_s} \sum_{\substack{k=1 \\ k \neq s}}^N \alpha_{sk} \right) \quad (2.307)$$

The  $\check{D}_{sr}$  have the properties  $\check{D}_{ss} = \sum_{k=1}^N (\check{D}_{ks} - \check{D}_{rk}) = 0$ , for  $s, r = 1, 2, 3, \dots, N$ . For this choice of multicomponent diffusivities, the mass diffusion flux vectors can be expressed as:

$$\mathbf{j}_s = -\rho \sum_{r=1}^N \check{D}_{sr} \mathbf{d}_r - D_s^T \frac{\nabla T}{T} \quad (2.308)$$

It is noted that neither of these two sets of generalized Fickian diffusivities are symmetric, i.e.,  $\mathcal{D}_{sr} \neq \mathcal{D}_{rs}$  and  $\check{D}_{sr} \neq \check{D}_{rs}$ . These diffusion coefficients are thus not practical because the number of parameters to fit is very large requiring numerous costly experimentally determined data sets.

In response to the disadvantageous lack of symmetry argument, Curtiss [25] made an alternative generalized Fickian diffusion coefficient definition proposal in 1968:

$$\hat{D}_{sr} = \frac{cRT\alpha_{sr}}{\rho_s\rho_r} \quad (2.309)$$

These multicomponent Fickian diffusivities,  $\hat{D}_{sr}$ , are symmetric [25], i.e.,  $\hat{D}_{sr} = \hat{D}_{rs}$ , and they obey the relations  $\sum_{s=1}^N \omega_s \hat{D}_{sr} = 0$  for  $s, r = 1, 2, 3, \dots, N$ . In terms of these symmetric diffusivity coefficients, the species mass flux was expressed as [26]:

$$\mathbf{j}_s = \rho_s \mathbf{v}_{d,s} = -\rho_s \sum_{r=1}^N \hat{D}_{sr} \mathbf{d}_r - D_s^T \frac{\nabla T}{T} \quad (2.310)$$

Comparing the generalized Fickian flux formulations of Curtiss and Bird [26] and Curtiss [25], it is noted that in (2.308) there is a  $\rho$  in front of the summation sign, whereas in (2.310) there is a  $\rho_s$ .

In the second edition of the textbook by Bird et al. [9] from 2002, a third alternative definition of the Fickian multicomponent mass diffusion coefficients was proposed, deviating from relation (2.309) by the sign convention only. These diffusion coefficients were thus defined by:

$$\mathbb{D}_{sr} = -\frac{cRT\alpha_{sr}}{\rho_s\rho_r} \quad (2.311)$$

These diffusivities are also symmetric ( $\mathbb{D}_{sr} = \mathbb{D}_{rs}$ ) and they obey the relations  $\sum_{s=1}^N \omega_s \mathbb{D}_{sr} = 0$  for  $s, r = 1, 2, 3, \dots, N$ . In terms of these symmetric diffusivity coefficients, the species mass flux was expressed as [26]:

$$\mathbf{j}_s = \rho_s \sum_{r=1}^N \mathbb{D}_{sr} \mathbf{d}_r - D_s^T \frac{\nabla T}{T} \quad (2.312)$$

Comparing the latter two symmetric Fickian flux formulations, it is noted that in (2.310) there is a minus sign in front of the summation sign, whereas in (2.312) there is a plus sign.

It is remarked that even though the latter two Fickian diffusivity proposals, i.e., (2.309) and (2.311), are symmetric, the multicomponent Fickian diffusivities  $\hat{D}_{sr}$  and  $\mathbb{D}_{sr}$  do not correspond to the approximately concentration independent binary diffusivities, i.e.,  $D_{sr}$ , which are available from binary diffusion experiments or kinetic theory determined by the inter-molecular forces between  $s - r$  pair of gases. Instead, these generalized multicomponent Fickian diffusion coefficients are strongly composition dependent. For these reasons, the generalized Fickian diffusivities are hardly used in practice because of the large number of costly experimental data sets that are required for parameter fitting.

### 2.9.5.3 Generalized Fick's First Law and Generalized Driving Forces Based on Irreversible Thermodynamics Principles

The principles of irreversible thermodynamics may be used to study the species mass and heat conduction transport. In this approach, the diffusion coefficients are defined in terms of the Onsager [102, 103] phenomenological coefficients. For a  $q$  component gas mixture, the linearity postulate in irreversible thermodynamics can be employed to obtain the multicomponent mass flux vectors (Hirschfelder et al. [55], p. 714; Curtiss and Bird [26, 27]):

$$\mathbf{j}_s = n_s m_s \mathbf{v}_{d,s} = -p \sum_{r=1}^N \frac{\alpha_{sr}}{n_r m_r} \mathbf{d}_r - \alpha_{s0} \frac{\nabla T}{T} \quad (2.313)$$

where  $s = 1, 2, 3, \dots, N$ . The coefficients,  $\alpha_{sr}$ , correspond to the phenomenological coefficients of Onsager which satisfy the reciprocal relations considering the processes of diffusion and thermal conduction. One of the phenomenological coefficient indices refers to the temperature variable, whereas the other indices refer to the species in the mixture. The flux equations in irreversible thermodynamics describe the coupling among the fluxes of the various system properties. The linearity postulate states that the fluxes are linear functions of all the driving forces [9, 26, 32, 55, 91].

In the derivation of (2.313) the original Onsager phenomenological coefficients were redefined as:

$$\alpha_{kr} - \sum_{\substack{k=1 \\ k \neq s}}^N \alpha_{sk} = 0 \quad \text{and} \quad \alpha_{rk} = \alpha_{kr} = - \sum_{\substack{s=1 \\ s \neq k}}^N \alpha_{rs} = 0 \quad (2.314)$$

for  $r = 1, 2, 3, \dots, N$ . That is, the new  $\alpha_{sr}$  are symmetric and also satisfy the relations  $\sum_{s=1}^N \alpha_{sr} = \sum_{s=1}^N \alpha_{rs} = 0$ .

A comparison with the results of the kinetic theory of dilute gases with those from the irreversible thermodynamics also shows that  $D_s^T = \alpha_{s0}$ . By use of (2.314) it is concluded that the generalized thermal diffusion coefficients  $D_s^T$ , have the property (2.304). Moreover, it was shown in the previous subsection that the various generalized Fickian diffusivities  $\mathcal{D}_{sr}$ ,  $\check{D}_{sr}$ ,  $\hat{D}_{sr}$  and  $\mathbb{D}_{sr}$  derived from kinetic theory can be related to the phenomenological coefficients by the following relations (2.306), (2.307), (2.309) and (2.311).

The *multicomponent generalization of Fick's first law of binary diffusion* is a second mass flux formulation on the Fickian form derived based on irreversible thermodynamics principles. This empirical formulation was first proposed by Onsager [104]. The generalized Fick's first law is defined by<sup>35</sup> [28, 32, 91, 104, 148]:

<sup>35</sup> In the chemical engineering literature the generalized or multicomponent form of Fick's first law of binary diffusion is normally written on a molar basis.

$$\mathbf{j}_s = -\rho \sum_{r=1}^{N-1} \dot{D}_{sr} \nabla \omega_r \quad s = 1, 2, 3, \dots, N-1 \quad (2.315)$$

This law is restricted to multicomponent systems, i.e.,  $N > 2$ . The diffusivities,  $\dot{D}_{sr}$ , defined by this relation may take negative values and are not, in general, symmetric ( $\dot{D}_{sr} \neq \dot{D}_{rs}$ ). The vector form of this mass flux is given by (2.316):

$$\mathbf{j} = -\rho[\text{diag}(\dot{\mathbf{D}})]\nabla(\boldsymbol{\omega}) \quad (2.316)$$

A multicomponent Fickian diffusion flux on this form was first suggested in irreversible thermodynamics and has no origin in kinetic theory of dilute gases. Hence, basically, these multicomponent flux equations represent a purely empirical generalization of Fick's first law and define a set of empirical multicomponent diffusion coefficients.

In retrospect the irreversible thermodynamics community did somewhat rationalize the origin of these equations and buttress this rationale with more fundamental principles [28]. Three basic postulates were required in order to derive the generalized Fick's law equations (2.316). The first postulate states that the thermodynamic properties such as entropy, chemical potential, and temperature can be correctly defined in a differential volume of a system that is not at equilibrium. The second postulate states that a linear relation exists between the forces and fluxes. The third postulate is that the Onsager phenomenological coefficients are symmetric. With these three postulates, it was possible to relate the generalized Fick's first law multicomponent diffusivities in (2.316) to the original Onsager phenomenological coefficients determining the basis for (2.313). That is, in the literature surveys by de Groot and Mazur [32] (Chap. 11), Taylor and Krishna [148] and Cussler [28] it was concluded that not all of the generalized Fick's law multicomponent diffusion coefficients are independent but are subject to certain constraints. However, these theoretical constraints are not very useful in practice, since they require detailed thermodynamic information that is rarely available. Anyhow, the thermodynamic theory does not provide any values for (quantification of) the multicomponent diffusion coefficients,  $\dot{D}_{sr}$ , so in practice all of them have to be determined from experiments. Hence, these coefficients cannot be interpreted simply, and there is therefore no fundamental theory predicting any formal relationships between the multicomponent—and the Fick first law binary diffusivities even for dilute gases in this particular diffusion model formulation.

An extension of the generalized diffusional driving force flux vector derived for dilute gases in kinetic theory (2.305) has been deduced based on principles of irreversible thermodynamics (e.g., Bird et al. [9], p. 766):

$$cRT\mathbf{d}_s = c_s \nabla \bar{g}_s + c_s \bar{s}_s \nabla T - \omega_s \nabla p - \rho_s \mathbf{g}_s - \omega_s \sum_{r=1}^N \rho_r \mathbf{g}_r \quad (2.317)$$

This extended form of the generalized diffusional driving force flux vector is valid for dilute gases, as well as dense gases and liquids. Moreover, it can be shown that  $\sum_s \mathbf{d}_s = 0$  by making use of the properties of partial molal quantities and the Gibbs-Duhem relation. In order to develop a more rigorous expression for the *driving forces in mass transfer* valid also for dense gases and liquids, use is normally made of physical laws and postulates taken from irreversible thermodynamics. For multicomponent systems it is advantageous to relate the diffusion fluxes to the activity rather than number—or mass fractions, since the activity formulation is valid for ideal as well as non-ideal systems. Notwithstanding, the binary diffusivities,  $D_{sr}$ , and the Maxwell-Stefan diffusivities,  $\tilde{D}_{sr}$ , are almost identical for ideal gas mixtures solely. For non-ideal gas mixtures and liquids the multi-component diffusivities are empirical parameters only. However, the generalized driving force formulation is claimed to be more useful in describing the inter-diffusion in dense gases and liquids (e.g., Curtiss and Bird [26, 27]; Taylor and Krishna [148]).

The Gibbs-Duhem equation is derived from the Euler and Gibbs equations (e.g., Prausnitz et al. [108], app D; Slattery [132], p. 443). The mass based form of the Gibbs-Duhem equation is outlined next. The total differential of the Gibbs free energy  $\hat{G}$  in terms of the natural variables (i.e.,  $T$ ,  $p$ ,  $m_s$ ) is:

$$d\hat{G} = \left( \frac{\partial \hat{G}}{\partial p} \right)_{T,m} dp + \left( \frac{\partial \hat{G}}{\partial T} \right)_{p,m} dT + \sum_{r=1}^N \left( \frac{\partial \hat{G}}{\partial m_r} \right)_{T,p,m_{r \neq s}} dm_r \quad (2.318)$$

With the substitution of the Maxwell relations and the definition of chemical potential, the total derivative expression is transformed into:

$$d\hat{G} = V dp - \hat{S} dT + \sum_{r=1}^N \mu_r dm_r \quad (2.319)$$

The partial mass chemical potential of the  $s$ -th species is defined as:

$$\mu_s = \check{G}_s = \left( \frac{\partial \hat{G}}{\partial m_s} \right)_{T,p,m_{r \neq s}} \quad (2.320)$$

The Gibbs free energy can also be computed from:

$$\hat{G} = \sum_{r=1}^N \mu_r m_r \quad (2.321)$$

The total differential of this expression is:

$$d\hat{G} = \sum_{r=1}^N \mu_r dm_r + \sum_{r=1}^N m_r d\mu_r \quad (2.322)$$

Considering that  $d\hat{G} = 0$  at thermodynamic equilibrium, and by combining the two relations for the total differential of the Gibbs free energy gives the Gibbs-Duhem equation:

$$\hat{S}dT - Vdp + \sum_{r=1}^N m_r d\mu_r = 0 \quad (2.323)$$

This relation implies that changes in the intensive quantities are not independent.

In fluid mechanics it might be natural to employ mass based thermodynamic properties whereas the classical thermodynamics convention is to use mole based variables. It follows that the extensive thermodynamic functions (e.g., internal energy, Gibbs free energy, Helmholtz energy, enthalpy, entropy, and specific volume) can be expressed in both ways, either in terms of mass or mole. The two forms of the Gibbs-Duhem equation are:

$$mSdT - Vdp + \sum_{s=1}^N m\omega_s d\mu_s = 0 \quad (2.324)$$

using specific variables, and

$$n\hat{S}dT - Vdp + \sum_{s=1}^N nx_s d\bar{G}_s = 0 \quad (2.325)$$

in terms of specific molar variables.

The thermodynamic notation is defined using one thermodynamic property as an example. It is postulated that the Gibbs free energy is a function of pressure, temperature and composition, hence we can write:

$$\hat{G} = \hat{G}(T, p, m_1, m_2, m_3, \dots, m_N) \quad (2.326)$$

in terms of mass, and

$$\hat{G} = \hat{G}(T, p, n_1, n_2, n_3, \dots, n_N) \quad (2.327)$$

in terms of mole.

In irreversible thermodynamics it is more convenient to use intensive or specific variables instead. Again we have two possible ways of defining the specific functions, either using molar specific variables which are given per mole or specific variables which are given per unit mass. Hence,

$$G = \frac{\hat{G}}{m} = G(T, p, \omega_1, \omega_2, \omega_3, \dots, \omega_{N-1}) \quad (2.328)$$

and

$$\underline{G} = \frac{\hat{\diamond} G}{n} = \underline{G}(T, p, x_1, x_2, x_3, \dots, x_{N-1}) \quad (2.329)$$

In thermodynamics partial variables are also used intensively. Accordingly, two sets of partial variables can be defined. The *partial mass variable* yields<sup>36</sup>:

$$\mu_s = \check{G}_s = \left( \frac{\partial \hat{G}}{\partial m_s} \right)_{T, p, m_r \neq s}, \quad s, r = 1, 2, \dots, N. \quad (2.330)$$

This quantity is related to the corresponding intensive variables in the following way (Slattery [132], Sect. 8.4):

$$\left( \frac{\partial \hat{G}}{\partial m_s} \right)_{T, p, m_r \neq s} - \left( \frac{\partial \hat{G}}{\partial m_q} \right)_{T, p, m_r \neq q} = \left( \frac{\partial G}{\partial \omega_s} \right)_{T, p, \omega_r \neq q, s} \quad (2.331)$$

The corresponding *partial molar variable* is written as:

$$\bar{G}_s = \left( \frac{\partial \hat{\diamond} G}{\partial n_s} \right)_{T, p, n_r \neq s}, \quad s, r = 1, 2, \dots, N. \quad (2.332)$$

which is related to the corresponding intensive variables:

$$\left( \frac{\partial \hat{\diamond} G}{\partial n_s} \right)_{T, p, n_r \neq s} - \left( \frac{\partial \hat{\diamond} G}{\partial n_q} \right)_{T, p, n_r \neq q} = \left( \frac{\partial G}{\partial x_s} \right)_{T, p, x_r \neq q, s} \quad (2.333)$$

The partial mass and the partial molar variables are simply related by:

$$\bar{G}_s = M_{w_s} \mu_s \quad (2.334)$$

Finally, we relate the intensive variables to the partial variables in the following manner:

$$G(T, p, \omega_1, \omega_2, \omega_3, \dots, \omega_{N-1}) = \sum_{s=1}^N \left( \frac{\partial \hat{G}}{\partial m_s} \right)_{T, p, m_r \neq s} \omega_s \quad (2.335)$$

and

---

<sup>36</sup> In this book the partial mass and molar variables are defined employing the same notation as used by Slattery [132]

$$\underline{G}(T, p, x_1, x_2, x_3, \dots, x_{N-1}) = \sum_{s=1}^N \left( \frac{\partial \hat{G}}{\partial n_s} \right)_{T, p, n_{r \neq s}} x_s \quad (2.336)$$

The starting point for the rigorous derivation of the diffusive fluxes in terms of the activity is the entropy equation as given by (1.174), wherein the entropy flux vector is defined by (1.175) and the rate of entropy production per unit volume is written (1.176) as discussed in Sect. 1.2.4. To eliminate  $S$  from the Gibbs-Duhem relation formulated in terms of specific quantities (2.324) we need the definitions of  $\hat{H} = mH$  and  $\hat{G} = mG$ :

$$mG = mH - TmS = \sum_{s=1}^N m\omega_s \mu_s \quad (2.337)$$

$$mH = mE + pV = \sum_{s=1}^N m\omega_s \check{H}_s \quad (2.338)$$

where  $\check{H}_s = \left( \frac{\partial \hat{H}}{\partial m_s} \right)_{T, p, m_{r \neq s}}$ , and  $H(T, p, \omega_1, \omega_2, \dots, \omega_{N-1})$  denotes the intensive or specific enthalpy.

By use of (2.337) and (2.338), an expression for  $MS$  can be obtained:

$$mS = \frac{mH - mG}{T} = \frac{mE + pV - \sum_{s=1}^N m\omega_s \mu_s}{T} \quad (2.339)$$

Hence, by substitution of the given expressions for  $MS$  (2.339) into the mass form of the Gibbs-Duhem equation (2.324) yields:

$$\left( \frac{mH - mG}{T} \right) dT - Vdp + \sum_{s=1}^N m\omega_s d\mu_s = 0 \quad (2.340)$$

After division by the volume and the temperature, this equation can be put in a form useful to manipulate the entropy production term. Thus, introducing the partial mass quantities from (2.337) and (2.338) into (2.339), the result is:

$$\frac{1}{T^2} \left( \sum_{s=1}^N \rho_s \check{H}_s dT - \sum_{s=1}^N \rho_s \mu_s dT \right) - \frac{1}{T} dp + \frac{1}{T} \sum_{s=1}^N \rho_s d\mu_s = 0 \quad (2.341)$$

By minor manipulation of the terms:

$$\frac{1}{T^2} \sum_{s=1}^N \rho_s \check{H}_s dT + \sum_{s=1}^N \rho_s d \left( \frac{\mu_s}{T} \right) - \frac{1}{T} dp = 0 \quad (2.342)$$

Assuming that this relation is valid at the state of local equilibrium, the differentiation can be exchanged by the  $\nabla$ -operator (Curtiss and Bird [26, 27]):

$$\frac{1}{T^2} \sum_{s=1}^N \rho_s \check{h}_s \nabla T + \sum_{s=1}^N \rho_s \nabla \left( \frac{\mu_c}{T} \right) - \frac{1}{T} \nabla p = 0 \quad (2.343)$$

With the aim of expressing the rate of entropy production  $\Phi_{\text{total}}$  due to mass diffusion in terms of a convenient driving force,  $\frac{cRT}{\rho_s} \mathbf{d}_s$ , we add some extra terms in the third term on the RHS of (1.176) in such a way that the entropy production term remains unaltered utilizing the property that  $\sum_s \mathbf{j}_s = 0$ . The form of the terms that are added is guided by the terms in the Gibbs-Duhem equation (2.343).

The modified entropy production rate (1.176) is commonly written as [26, 27]:

$$\begin{aligned} \Phi_{\text{total}} = & -\frac{1}{T^2} (\mathbf{q} \cdot \nabla T) - \frac{1}{T} (\boldsymbol{\sigma} : \nabla \mathbf{v}) - \frac{1}{T} \sum_{r=1}^N A_r r_r \\ & - \sum_{s=1}^N \left( \frac{\mathbf{j}_s}{\rho_s} \cdot \left[ \rho_s \nabla \left( \frac{\mu_s}{T} \right) - \frac{\rho_s}{\rho T} \nabla p + \frac{\rho_s \check{h}_s}{T^2} \nabla T - \frac{\rho_s \check{h}_s}{T^2} \nabla T - \frac{\rho_s \mathbf{g}_s}{T} + \frac{\rho_s}{\rho T} \sum_{r=1}^N \rho_r \mathbf{g}_r \right] \right) \end{aligned} \quad (2.344)$$

The entropy production term has been written as a sum of products of fluxes and forces. However, there are only  $N - 1$  independent mass fluxes  $\mathbf{j}_s$ , and the Gibbs-Duhem equation (2.343) tells us that there are only  $N - 1$  independent forces as well [9].

Furthermore, it is noted that the first three terms in the brackets on the RHS of (2.344) are similar to the terms in the Gibbs-Duhem relation (2.343). However, two of these three terms do not contribute to the sum. The pressure term vanishes because  $\sum_s \mathbf{j}_s = 0$ . The two enthalpy terms obviously cancel because they are identical with opposite signs. Moreover, the last term in the brackets on the RHS of (2.344), involving the sum of external forces, is zero as  $\sum_s \mathbf{j}_s = 0$ . One of the two remaining terms, i.e., the one containing the enthalpy, we combine with the  $\mathbf{q}$  term. Hence, the modified entropy flux vector (1.175) and production terms (1.176) become:

$$\mathbf{J}_s = \frac{1}{T} \left( \mathbf{q} - \sum_{r=1}^N \mathbf{j}_r \check{h}_r \right) + \sum_{r=1}^N \check{s}_r \mathbf{j}_r \quad (2.345)$$

and

$$T \Phi_{\text{total}} = -\frac{1}{T} \left[ \mathbf{q} - \sum_{r=1}^N \mathbf{j}_r \check{h}_r \right] \cdot \nabla T - \sum_{r=1}^N \mathbf{j}_r \cdot \frac{cRT}{\rho_r} \mathbf{d}_r - \boldsymbol{\sigma} : \nabla \mathbf{v} - \sum_{r=1}^N A_r r_r \quad (2.346)$$

where

$$\frac{cRT}{\rho_s} \mathbf{d}_s = T \nabla \left( \frac{\mu_s}{T} \right) + \frac{\check{h}_s}{T} \nabla T - \frac{1}{\rho} \nabla p - \mathbf{g}_s + \frac{1}{\rho} \sum_{r=1}^N \rho_r \mathbf{g}_r \quad (2.347)$$

Due to the linearity postulate in irreversible thermodynamics, each vector flux must depend linearly on all the vector forces in the system. We may thus rewrite the fluxes as [26, 27]:

$$\mathbf{q} - \sum_{r=1}^N \mathbf{j}_r \check{h}_r = -\frac{1}{T} \alpha_{00} \nabla T - \sum_{r=1}^N \left( \frac{cRT \alpha_{0r}}{\rho_r} \right) \mathbf{d}_r \quad (2.348)$$

$$\mathbf{j}_s = -\frac{1}{T} \alpha_{s0} \nabla T - \rho_s \sum_{r=1}^N \left( \frac{cRT \alpha_{sr}}{\rho_s \rho_r} \right) \mathbf{d}_r \quad (2.349)$$

where  $s = 1, 2, \dots, N$ . The  $\alpha_{sr}$  are the symmetric phenomenological coefficients according to the Onsager reciprocal relations. Henceforth, the thermal diffusion coefficients are denoted by  $D_s^T = \alpha_{s0} = \alpha_{0s}$  and the Fickian diffusivities are given by  $\hat{D}_{sr} = \frac{cRT \alpha_{sr}}{\rho_s \rho_r}$  as foreseen in the preceding paragraphs.

The generalized diffusional driving forces  $\mathbf{d}_s$  either in terms of mass or molar functions, can be extended to a more rigorous form valid for dense gases and liquids using the partial mass Gibbs free energy definition,  $\check{G}_s = \check{h}_s - T \check{s}_s$ , and the chain rule of partial differentiation assuming that the chemical potential (i.e.,  $\mu_s = \check{G}_s$ ) is a function of temperature, pressure and concentration (Slattery [132], Sect. 8.4).  $\mathbf{d}_s$  can then be expressed in several useful forms as listed below. Expressing the thermodynamic functions on a mass basis yields:

$$\begin{aligned} \mathbf{d}_s &= \frac{\rho_s}{cRT} \left( \check{s}_s \nabla T + \nabla \mu_s - \frac{1}{\rho} \nabla p - \mathbf{g}_s + \frac{1}{\rho} \sum_{r=1}^N \rho_r \mathbf{g}_r \right) \\ &= \frac{\rho_s}{cRT} \left[ \sum_{\substack{r=1 \\ r \neq s}}^N \left( \frac{\partial \mu_s}{\partial \omega_r} \right)_{T, p, \omega_k \neq r, s} \nabla \omega_r + \left( \check{V}_s - \frac{1}{\rho} \right) \nabla p - \mathbf{g}_s + \frac{1}{\rho} \sum_{r=1}^N \rho_r \mathbf{g}_r \right] \\ &= \frac{\rho_s}{cRT} \left[ \nabla_{T, p} \mu_s + \left( \check{V}_s - \frac{1}{\rho} \right) \nabla p - \mathbf{g}_s + \frac{1}{\rho} \sum_{r=1}^N \rho_r \mathbf{g}_r \right] \end{aligned} \quad (2.350)$$

These relations may also be reformulated on a mole basis:

$$\begin{aligned}
\mathbf{d}_s &= \frac{c_s M_{w_s}}{c R T} \left( \frac{\bar{s}_s}{M_{w_s}} \nabla T + \nabla \left( \frac{\bar{g}_s}{M_{w_s}} \right) - \frac{1}{\rho} \nabla p - \mathbf{g}_s + \frac{1}{\rho} \sum_{r=1}^N \rho_r \mathbf{g}_r \right) \\
&= \frac{x_s}{R T} \left[ \sum_{\substack{r=1 \\ r \neq s}}^N \left( \frac{\partial \bar{g}_s}{\partial x_r} \right)_{T, p, x_{k \neq r, s}} \nabla x_r + \bar{V}_s \nabla p \right] \\
&\quad + \frac{x_s M_{w_s}}{R T} \left( -\frac{1}{\rho} \nabla p - \mathbf{g}_s + \frac{1}{\rho} \sum_{r=1}^N \rho_r \mathbf{g}_r \right) \\
&= \frac{x_s}{R T} \nabla_{T, p} \bar{g}_s + \frac{x_s M_{w_s}}{R T} \left[ \left( \check{V}_s - \frac{1}{\rho} \right) \nabla p - \mathbf{g}_s + \frac{1}{\rho} \sum_{r=1}^N \rho_r \mathbf{g}_r \right]
\end{aligned} \tag{2.351}$$

The transformations of the thermodynamic quantities like the partial mass Gibbs free energy might need further explanation. By use of the chain rule of partial differentiation the chemical potential on a mass basis is expanded considering that the chemical potential,  $\mu_s$ , is a function of  $T$ ,  $p$  and  $\omega_s$ :

$$d\mu_s = \left( \frac{\partial \mu_s}{\partial T} \right)_{p, \omega} dT + \left( \frac{\partial \mu_s}{\partial p} \right)_{T, \omega} dp + \sum_{\substack{r=1 \\ r \neq s}}^N \left( \frac{\partial \mu_s}{\partial \omega_r} \right)_{T, p, \omega_{k \neq r, s}} d\omega_r \tag{2.352}$$

where the partial derivatives with respect to  $T$  and  $p$  are eliminated by the thermodynamic relations,

$$\left( \frac{\partial \mu_s}{\partial T} \right)_{p, x} = -\check{S}_s \tag{2.353}$$

and

$$\left( \frac{\partial \mu_s}{\partial p} \right)_{T, \omega} = \check{V}_s \tag{2.354}$$

where  $\check{V}_s$  is the partial mass volume.

Alternatively, expressing the chemical potential on a molar basis we get:

$$d\bar{G}_s = \left( \frac{\partial \bar{G}_s}{\partial T} \right)_{p, x} dT + \left( \frac{\partial \bar{G}_s}{\partial p} \right)_{T, x} dp + \sum_{\substack{r=1 \\ r \neq s}}^N \left( \frac{\partial \bar{G}_s}{\partial x_r} \right)_{T, p, x_{k \neq r, s}} dx_r \tag{2.355}$$

where the partial derivatives with respect to  $T$  and  $p$  are substituted by the thermodynamic relations,

$$\left( \frac{\partial \bar{G}_s}{\partial T} \right)_{p, x} = -\bar{S}_s \tag{2.356}$$

and

$$\left(\frac{\partial \bar{G}_s}{\partial p}\right)_{T,x} = \bar{V}_s \quad (2.357)$$

where  $\bar{V}_s$  is the partial molar volume.

Hence, from (2.352) and (2.355) we may define the following short notations:

$$d_{T,p}\mu_s = \sum_{\substack{r=1 \\ r \neq s}}^N \left(\frac{\partial \mu_s}{\partial \omega_r}\right)_{T,p,\omega_k \neq r,s} d\omega_r = RT \sum_{\substack{r=1 \\ r \neq s}}^N \left(\frac{\partial \ln a_s}{\partial \omega_r}\right)_{T,p,\omega_k \neq r,s} d\omega_r \quad (2.358)$$

and

$$d_{T,p}\bar{G}_s = \sum_{\substack{r=1 \\ r \neq s}}^N \left(\frac{\partial \bar{G}_s}{\partial x_r}\right)_{T,p,x_k \neq r,s} dx_r = RT \sum_{\substack{r=1 \\ r \neq s}}^N \left(\frac{\partial \ln a_s^m}{\partial x_r}\right)_{T,p,x_k \neq r,s} dx_r \quad (2.359)$$

in which we are keeping the temperature  $T$  and pressure  $p$  constant.

It is postulated that the given relations are valid for a system at local equilibrium, the differential 'd' may thus be substituted by the  $\nabla$ -operator in the forthcoming derivations.

For the description of inter-diffusion in dense gases and liquids the expression for  $\mathbf{d}_s$  is further modified introducing a fugacity (i.e., a corrected pressure) or an activity (i.e., a corrected mole fraction) function [108]. The activity  $a_s(T, \omega_1, \omega_2, \omega_3, \omega_{N-1})$  for species  $s$  is defined by:

$$\mu_s = \mu_s^0 + RT \ln \frac{\hat{f}_s}{f_s^0} = \mu_s^0 + RT \ln a_s \quad (2.360)$$

where the auxiliary fugacity and activity functions are related by  $a_s = \hat{f}_s / f_s^0$ .  $\mu_s^0$  denotes the chemical potential at some reference state. While either  $\mu_s^0$  or  $f_s^0$  is arbitrary, both may not be chosen independently, since when one is chosen the other is fixed.

For liquids it is convenient to choose a particular reference state, a *standard state*, that can be defined by the Gibbs free energy of 1 mole of pure  $s$  at the mixture temperature,  $T$ , and a specified pressure, say 1 bar. Hence, in this case  $\mu_s^0$  is a function of temperature only,  $\mu_s^0 = \mu_s^0(T, p = 1 \text{ bar}, \omega \rightarrow 1)$ . Alternatively,  $\mu_s^0$  may be chosen as the chemical potential for pure species  $s$  at the system temperature and pressure in which  $\mu_s^0 = \mu_s^0(T, p)$ . That is, numerous reference states are possible, which one to be chosen matters little provided that the model formulation is consistent. Henceforth, we are using the given standard state as defined above.

For dense gases it is often more convenient to use the fugacity,  $\hat{f}_s$ , defined by:

$$\mu_s = \mu_s^* + RT \ln \frac{\hat{f}_s}{f_s^*} \quad (2.361)$$

where  $\mu_s^*$  denotes a reference state being an ideal gas state at the system temperature and a standard pressure state (e.g.,  $p^* = 1$  bar). However, in either case using fugacities or activities the model derivation is very similar so we proceed considering the activity formulation only.

Introducing the mass based activity variable, the first term on the RHS of (2.347) is rewritten by use of the chain rule of partial differentiation considering that the chemical potential is a function of temperature, pressure and composition. The mass based chain rule of partial differentiation of the chemical potential function is given by (2.352).

It follows that the first term on the RHS of the mass based expression (2.347) can be written as:

$$\begin{aligned} \rho_s T \nabla \left( \frac{\mu_s}{T} \right) &= \rho_s T \nabla \left( \frac{\mu_s^0}{T} \right) + \rho_s RT \nabla \ln a_s = \rho_s \nabla \mu_s^0 - \rho_s \mu_s^0 \nabla \ln T + \rho_s RT \nabla \ln a_s \\ &= -\rho_s \check{s}_s^0 \nabla T - \rho_s \mu_s^0 \nabla \ln T + \rho_s RT \nabla \ln a_s \\ &= -\rho_s (T \check{s}_s^0 + \mu_s^0) \nabla \ln T + \rho_s RT \nabla \ln a_s \\ &= -\rho_s \check{h}_s^0 \nabla \ln T + \rho_s RT \nabla \ln a_s \end{aligned} \quad (2.362)$$

In (2.362) the relation:

$$\nabla \mu_s^0 = \left( \frac{d\mu_s^0}{dT} \right) \nabla T = -\check{s}_s^0 \nabla T \quad (2.363)$$

holds because  $\mu_s^0(T)$  is a function of temperature only.

The Gibbs free energy definition is employed in order to express the standard state chemical potential  $\mu_s^0$  and entropy  $\check{s}_s^0$  potentials and introduce the entropy potential  $\check{h}_s^0$ :

$$\mu_s = \check{g}_s = \check{h}_s - T \check{s}_s \quad (2.364)$$

Substitution of (2.362) into (2.347), the extended generalized diffusional driving force vector relation can be manipulated as:

$$\frac{cRT}{\rho_s} \mathbf{d}_s = RT \nabla \ln a_s + (\check{h}_s - \check{h}_s^0) \nabla \ln T - \frac{1}{\rho} \nabla p - \mathbf{g}_s + \frac{1}{\rho} \sum_{r=1}^N \rho_r \mathbf{g}_r \quad (2.365)$$

The chain rule of partial differentiation of  $\mu_s$  (2.352), in which the partial derivatives therein are eliminated by (2.353) and (2.354), is employed in order to rewrite the first term on the RHS of (2.365):

$$RT \nabla \ln a_s = RT \sum_{\substack{r=1 \\ r \neq s}}^N \left( \frac{\partial \ln a_s}{\partial \omega_r} \right)_{T,p,\omega_{k \neq r,s}} \nabla \omega_r + \check{V}_s \nabla p - (\check{h}_s - \check{h}_s^0) \nabla \ln T \quad (2.366)$$

in which  $\check{V}_s$  denotes the partial mass volume which can be related to the volume fraction of species  $s$  by:  $\phi_s = \rho_s \check{V}_s = c_s \bar{V}_s$ .

Inserting (2.366) into (2.365), gives:

$$\begin{aligned} cRT \mathbf{d}_s &= \rho_s RT \sum_{\substack{r=1 \\ r \neq s}}^N \left( \frac{\partial \ln a_s}{\partial \omega_r} \right)_{T,p,\omega_{k \neq r,s}} \nabla \omega_r + \rho_s \left( \check{V}_s - \frac{1}{\rho} \right) \nabla p - \rho_s \mathbf{g}_s + \omega_s \sum_{r=1}^N \rho_r \mathbf{g}_r \\ &= \rho_s RT \nabla_{T,p} \ln a_s + \rho_s \left( \check{V}_s - \frac{1}{\rho} \right) \nabla p - \rho_s \mathbf{g}_s + \omega_s \sum_{r=1}^N \rho_r \mathbf{g}_r \end{aligned} \quad (2.367)$$

A problem related to the use of thermodynamic quantities on a mass basis instead of molar basis is that all the existing thermodynamic models naturally are expressed in terms of molar quantities. For example, in the case of concentrated non-ideal liquid mixtures the thermodynamic quantities can be calculated from the existing models of the excess Gibbs energy  $G^E$  which are normally expressed in terms of specific molar functions. There are numerous models for  $G^E$  available, e.g., NRTL, UNIQUAC and UNIFAC, all providing thermodynamic properties on the molar basis [108].

The modeling problems related to the mass based formulation of the thermodynamic relations are illustrated next considering a binary mixture. For flowing systems it is natural to seek an expression for the driving force in terms of mass fractions using (2.350) and (2.360). For a binary mixture the result is:

$$\begin{aligned} \mathbf{d}_1 &= \frac{\rho_1}{cRT} \left[ \left( \frac{\partial \mu_1}{\partial \omega_2} \right)_{T,p} \nabla \omega_2 + \left( \check{V} - \frac{1}{\rho} \right) \nabla p - \omega_2 (\mathbf{g}_1 - \mathbf{g}_2) \right] \\ &= \frac{\rho}{c} \left( \frac{\partial \ln a_1}{\partial \ln \omega_1} \right)_{T,p} \nabla \omega_1 + \frac{\rho_1}{cRT} \left[ \left( \check{V} - \frac{1}{\rho} \right) \nabla p - \omega_2 (\mathbf{g}_1 - \mathbf{g}_2) \right] \end{aligned} \quad (2.368)$$

where we have introduced an activity on a mass basis.

However, this mass based activity property is an unconventional variable and there exists no model for it yet. In addition, a principal disadvantage of working in terms of mass based activities like  $a_1$  is that for ideal solutions  $M_w \left( \frac{\partial \ln a_1}{\partial \ln \omega_1} \right)_{T,p} \neq 1$  in general. Instead, the driving force is usually rewritten on a molar basis using (2.350), (2.351) and (2.370). Hence, we obtain:

$$\begin{aligned} \mathbf{d}_1 &= \frac{\rho_1}{cRT} \left[ \left( \frac{\partial \mu_1}{\partial \omega_2} \right)_{T,p} \nabla \omega_2 + \left( \check{V} - \frac{1}{\rho} \right) \nabla p - \omega_2 (\mathbf{g}_1 - \mathbf{g}_2) \right] \\ &= \frac{x_1}{RT} \left( \frac{\partial \bar{G}_1}{\partial x_2} \right)_{T,p} \nabla x_2 + \frac{x_1 M_{w1}}{RT} \left[ \left( \check{V} - \frac{1}{\rho} \right) \nabla p - \omega_2 (\mathbf{g}_1 - \mathbf{g}_2) \right] \\ &= \left( \frac{\partial \ln a_1^m}{\partial \ln x_1} \right)_{T,p} \nabla x_1 + \frac{x_1 M_{w1}}{RT} \left[ \left( \check{V} - \frac{1}{\rho} \right) \nabla p - \omega_2 (\mathbf{g}_1 - \mathbf{g}_2) \right] \end{aligned} \quad (2.369)$$

The principal advantages of working in terms of  $a_1^m$  is that there exist thermodynamics models for this property and for ideal solutions  $(\frac{\partial \ln a_1^m}{\partial \ln x_1})_{T,p} = 1$ .

The important partial mass properties in (2.365) are easily transformed into molar basis as the partial mass and partial molar variables of species  $s$  are related by the molecular weight. The activity for species  $s$  is redefined by:

$$\bar{G}_s = \bar{G}_s^0 + RT \ln a_s^m \quad (2.370)$$

where  $a_s^m = a_s^m(T, x_1, x_2, x_3, \dots, x_{N-1})$ . This mole based activity variable  $a_s^m$  (2.370) is introduced into the first term on the RHS of (2.347).

The standard state Gibbs free energy potential is eliminated by use of the following relation:

$$\nabla \bar{g}_s^0 = (\frac{d\bar{g}_s^0}{dT}) \nabla T = -\bar{s}_s^0 \nabla T \quad (2.371)$$

This relationship holds because  $\bar{G}_s^0(T)$  is a function of temperature only.

The Gibbs free energy definition is employed in order to express the standard state chemical potential  $\bar{g}_s^0$  and entropy  $\bar{s}_s^0$  potentials and introduce the entropy potential  $\bar{h}_s^0$ .

$$\bar{g}_s = \bar{h}_s - T \bar{s}_s \quad (2.372)$$

Substitution of (2.370), (2.371) and (2.372) into (2.347), the first term on the RHS of the expression (2.347) can be written as:

$$\begin{aligned} c_s T \nabla \left( \frac{\bar{g}_s}{T} \right) &= c_s T \nabla \left( \frac{\bar{g}_s^0}{T} \right) + c_s RT \nabla \ln a_s^m = c_s \nabla \bar{g}_s^0 - c_s \bar{g}_s^0 \nabla \ln T + \rho_s RT \nabla \ln a_s^m \\ &= -c_s \bar{s}_s^0 \nabla T - c_s \bar{g}_s^0 \nabla \ln T + c_s RT \nabla \ln a_s^m \\ &= -c_s (T \bar{s}_s^0 + \bar{g}_s^0) \nabla \ln T + c_s RT \nabla \ln a_s^m \\ &= -c_s \bar{h}_s^0 \nabla \ln T + c_s RT \nabla \ln a_s^m \end{aligned} \quad (2.373)$$

Substitution of (2.373) into the expression (2.347), the extended diffusional driving force vector can be manipulated as:

$$c RT \mathbf{d}_s = c_s RT \nabla \ln a_s^m + (\bar{h}_s - \bar{h}_s^0) \nabla \ln T - \omega_s \nabla p - \rho_s \mathbf{g}_s + \omega_s \sum_{r=1}^N \rho_r \mathbf{g}_r \quad (2.374)$$

The chain rule of partial differentiation of  $\bar{G}_s$ , in which the partial derivatives therein are eliminated by use of (2.356) and (2.357), is employed in order to rewrite the first term on the RHS of (2.374):

$$\nabla \bar{g}_s = -\bar{s}_s \nabla T + \bar{V}_s \nabla p + \nabla_{T,p} \bar{g}_s \quad (2.375)$$

where the last term is written in the compact form (2.359).

By substitution of (2.370), (2.371) and (2.372), the LHS and RHS of (2.375) become:

$$\nabla \bar{g}_s^0 + R \ln a_s^m \nabla T + RT \nabla \ln a_s^m = -\bar{s}_s^0 \nabla T + R \ln a_s^m \nabla T + RT \nabla \ln a_s^m \quad (2.376)$$

$$\begin{aligned} \frac{(\bar{g}_s^0 + RT \ln a_s^m - \bar{h}_s)}{T} \nabla T + \bar{V}_s \nabla p + \nabla_{T,p} \bar{g}_s &= R \ln a_s^m \nabla T \\ &+ (\bar{g}_s^0 - \bar{h}_s) \nabla \ln T \\ &+ \bar{V}_s \nabla p + \nabla_{T,p} \bar{g}_s \end{aligned} \quad (2.377)$$

Substitution of these two relations into (2.375) gives an expression for the first term on the RHS of (2.374):

$$c_s RT \nabla \ln a_s^m = -c_s (\bar{h}_s - \bar{h}_s^0) \nabla \ln T + c_s \bar{V}_s \nabla p + c_s \nabla_{T,p} \bar{g}_s \quad (2.378)$$

The molar form of the driving force (2.374) becomes:

$$\begin{aligned} c RT \mathbf{d}_s &= c_s RT \nabla_{T,p} \ln a_s^m + (c_s \bar{V}_s - \omega_s) \nabla p - \rho_s \mathbf{g}_s + \omega_s \sum_{r=1}^N \rho_r \mathbf{g}_r \\ &= c_s RT \sum_{\substack{r=1 \\ r \neq s}}^N \left( \frac{\partial \ln a_s^m}{\partial x_r} \right)_{T,p,x_{k \neq s,r}} \nabla x_r + (c_s \bar{V}_s - \omega_s) \nabla p \\ &\quad - \rho_s \mathbf{g}_s + \omega_s \sum_{r=1}^N \rho_r \mathbf{g}_r \end{aligned} \quad (2.379)$$

This is the most frequently used mole based form of the extended generalized diffusional driving force vector formulation, that can be employed for dilute gases as well as dense gases and liquids.

For ideal solutions:

$$\sum_{\substack{r=1 \\ r \neq s}}^N \left( \frac{\partial \ln a_s^m}{\partial \ln x_r} \right)_{T,p,x_{k \neq s,r}} = 1 \quad (2.380)$$

The ratio of activity and mole fraction defines the activity coefficient,  $a_s^m = x_s \gamma_s$  [108]. For an ideal mixture, the activity is equal to the mole fraction since the activity coefficient equals unity. That is, we may expand the first term on the RHS in a convenient manner, excluding  $x_N$  (i.e., for a solvent containing several solutes it might be convenient to label the solvent as species  $N$ ):

$$\begin{aligned}
x_s \sum_{r=1}^{N-1} \left( \frac{\partial \ln a_s^m}{\partial x_r} \right)_{T,p,x} \nabla x_r &= x_s \sum_{r=1}^{N-1} \left( \frac{\partial \ln(\gamma_s^m x_s)}{\partial x_r} \right)_{T,p,x} \nabla x_r \\
&= x_s \sum_{r=1}^{N-1} \left( \frac{1}{\gamma_s^m x_s} \frac{\partial \gamma_s^m x_s}{\partial x_r} \right)_{T,p,x} \nabla x_r \\
&= x_s \sum_{r=1}^{N-1} \left( \frac{\partial \ln x_s}{\partial x_r} + \frac{\partial \ln \gamma_s^m}{\partial x_r} \right)_{T,p,x} \nabla x_r \quad (2.381) \\
&= \sum_{r=1}^{N-1} \left( \delta_{sr} + x_s \frac{\partial \ln \gamma_s^m}{\partial x_r} \right)_{T,p,x} \nabla x_r
\end{aligned}$$

For ideal solutions  $\gamma_s^m = 1$ , hence the  $N - 1$  independent driving forces yield:

$$\mathbf{d}_s = \nabla x_s + \frac{1}{cRT} (c_s \bar{V}_s - \omega_s) \nabla p - \frac{\rho_s}{cRT} \mathbf{g}_s + \frac{\omega_s}{cRT} \sum_{r=1}^N \rho_r \mathbf{g}_r \quad (2.382)$$

This reduced form of the extended generalized diffusional driving force vector corresponds to (2.305) which was derived from the kinetic theory of dilute gases.

#### 2.9.5.4 The Maxwell-Stefan Multicomponent Diffusion Flux Model

For dilute gases, the generalized multicomponent Fickian diffusion coefficients are strongly composition dependent. It follows that these diffusion coefficients do not correspond to the approximately concentration independent binary diffusivities,  $D_{sr}$ , which are available from binary diffusion experiments or kinetic theory since  $\tilde{D}_{sr} \approx D_{sr}$ . In response to this Fickian model limitation it has been proposed to transform the Fickian diffusion flux model, in which the mass-flux vector,  $\mathbf{j}_s$ , is expressed in terms of the driving force,  $\mathbf{d}_s$ , into the corresponding Maxwell-Stefan form [95, 97, 142, 143] where  $\mathbf{d}_s$  is given as a linear function of  $\mathbf{j}_s$ . The key idea is to rewrite the Fickian diffusion flux in terms of an alternative set of diffusivities (i.e., preferably the known binary diffusivities) which are less concentration dependent than the Fickian diffusivities.

The proposed transformation can be done using the method suggested by Curtiss and Bird [26, 27] which is in accordance with the work of Merk [101]. To shorten the notation they temporary define a modified diffusion velocity,  $\mathbf{v}'_{d,s}$ , by:

$$\rho_s \mathbf{v}'_{d,s} = \mathbf{j}_s + D_s^T \nabla \ln T \quad (2.383)$$

Thereafter, the modified diffusion velocity is expressed in terms of the driving forces using (2.310). For species  $s$  and  $k$  the resulting relationships are given by:

$$\mathbf{v}'_{d,s} = - \sum_{r=1}^N \hat{D}_{sr} \mathbf{d}_r \quad (2.384)$$

$$\mathbf{v}'_{d,k} = - \sum_{r=1}^N \hat{D}_{kr} \mathbf{d}_r \quad (2.385)$$

Next, each of the two relations is multiplied by the multicomponent inverse diffusivities,  $\hat{C}_{sk}$  with  $k \neq s$ , and if the first equation is subtracted from the second one, the result is:

$$\hat{C}_{sk}(\mathbf{v}'_{d,k} - \mathbf{v}'_{d,s}) = - \sum_{r=1}^N \hat{C}_{sk}(\hat{D}_{kr} - \hat{D}_{sr}) \mathbf{d}_r \quad (2.386)$$

Then, the sum on  $k$  is performed:

$$\sum_{\substack{k=1 \\ k \neq s}}^N \hat{C}_{sk}(\mathbf{v}'_{d,k} - \mathbf{v}'_{d,s}) = - \sum_{r=1}^N \left[ \sum_{\substack{k=1 \\ k \neq s}}^N \hat{C}_{sk}(\hat{D}_{kr} - \hat{D}_{sr}) \right] \mathbf{d}_r \quad (2.387)$$

where  $s = 1, 2, 3, \dots, N$ .

Curtiss and Bird [26, 27] and Slattery [132] (Sect. 8.4.4) state that from kinetic theory of dilute gas mixtures, it appears that the coefficients  $\hat{C}_{sk}$  are determined in such a way that the following relations are satisfied:

$$\sum_{\substack{k=1 \\ k \neq s}}^N \hat{C}_{sk}(\hat{D}_{kr} - \hat{D}_{sr}) = -\delta_{sr} + \omega_s \quad (2.388)$$

Accordingly, by use of the property  $\sum_{s=1}^q \omega_s \hat{D}_{sr} = 0$ , the RHS of (2.387) reduces to  $+\mathbf{d}_s$ . The modified diffusion velocity (2.383) can thus be related to the standard diffusion velocity (2.310), and expressed by:

$$\mathbf{v}'_{d,s} = \frac{\mathbf{j}_s}{\rho_s} + \frac{D_s^T}{\rho_s} \nabla \ln T = \mathbf{v}_{d,s} + \frac{D_s^T}{\rho_s} \nabla \ln T \quad (2.389)$$

Hence, the diffusion problem (2.387) can be expressed in terms of the actual diffusion velocities:

$$\sum_{\substack{k=1 \\ k \neq s}}^N \hat{C}_{sk}(\mathbf{v}_{d,k} - \mathbf{v}_{d,s}) = \mathbf{d}_s - \sum_{\substack{k=1 \\ k \neq s}}^N \hat{C}_{sk} \left( \frac{D_k^T}{\rho_k} - \frac{D_s^T}{\rho_s} \right) \nabla \ln T \quad (2.390)$$

where  $s = 1, 2, 3, \dots, N$ .

These relations are called *the generalized Maxwell-Stefan equations* and are the inverted counterparts of the Fick diffusion equations (2.310). These two descriptions contain the same information and are interrelated as proven by Curtiss and Bird [26, 27] for dilute mono-atomic gas mixtures. Finally, the Maxwell-Stefan diffusivities are defined by:

$$\hat{C}_{sk} = \frac{x_s x_k}{\tilde{D}_{sk}} \quad (2.391)$$

Thereby, the generalized Maxwell-Stefan equations can be expressed several ways:

$$\begin{aligned} \mathbf{d}_s - \sum_{\substack{k=1 \\ k \neq s}}^N \frac{x_s x_k}{\tilde{D}_{sk}} \left( \frac{D_k^T}{\rho_k} - \frac{D_s^T}{\rho_s} \right) \frac{\nabla T}{T} &= \sum_{\substack{k=1 \\ k \neq s}}^N \frac{x_s x_k}{\tilde{D}_{sk}} (\mathbf{v}_{d,k} - \mathbf{v}_{d,s}) \\ &= \sum_{\substack{k=1 \\ k \neq s}}^N \frac{x_s x_k}{\tilde{D}_{sk}} (\{\mathbf{v}_k - \mathbf{v}_m\} - \{\mathbf{v}_s - \mathbf{v}_m\}) = \sum_{\substack{k=1 \\ k \neq s}}^N \frac{x_s x_k}{\tilde{D}_{sk}} (\mathbf{v}_k - \mathbf{v}_s) \\ &= \sum_{\substack{k=1 \\ k \neq s}}^N \frac{x_s x_k}{\tilde{D}_{sk}} \left( \frac{\mathbf{n}_k}{\rho_k} - \frac{\mathbf{n}_s}{\rho_s} \right) = \sum_{\substack{k=1 \\ k \neq s}}^N \frac{x_s x_k}{\tilde{D}_{sk}} \left( \frac{\mathbf{j}_k}{\rho_k} - \frac{\mathbf{j}_s}{\rho_s} \right) \\ &= \sum_{\substack{k=1 \\ k \neq s}}^N \frac{1}{c \tilde{D}_{sk}} (x_s \mathbf{N}_k - x_k \mathbf{N}_s) = \sum_{\substack{k=1 \\ k \neq s}}^N \frac{1}{c \tilde{D}_{sk}} (x_s \mathbf{J}_k^* - x_k \mathbf{J}_s^*) \end{aligned} \quad (2.392)$$

where  $s = 1, 2, 3, \dots, N$ .

The combined molar flux with respect to stationary axes is defined by:

$$\mathbf{N}_s = c_s \mathbf{v}_s = c x_s \mathbf{v}_s = c_s \mathbf{v}_m^* + \mathbf{J}_s^*, \quad (2.393)$$

The corresponding combined mass flux is defined by:

$$\mathbf{n}_s = \rho_s \mathbf{v}_s = \rho \omega_s \mathbf{v}_s = \rho_s \mathbf{v}_m + \mathbf{j}_s \quad (2.394)$$

For multicomponent diffusion in gases and liquids, the generalized Maxwell-Stefan forms (2.392) and the extended generalized diffusional driving force vector (2.379) gives:

$$\begin{aligned}
\sum_{s=1}^N \frac{x_s x_r}{\tilde{D}_{sr}} (\mathbf{v}_s - \mathbf{v}_r) = & -x_s \nabla_{T,p} \ln a_s^m \\
& - \frac{1}{cRT} \left[ (c_s \bar{V}_s - \omega_s) \nabla p - \rho_s \mathbf{g}_s + \omega_s \sum_{r=1}^N \rho_r \mathbf{g}_r \right] \\
& + \sum_{\substack{k=1 \\ k \neq s}}^N \frac{x_s x_k}{\tilde{D}_{sk}} \left( \frac{D_k^T}{\rho_k} - \frac{D_s^T}{\rho_s} \right) \frac{\nabla T}{T}
\end{aligned} \tag{2.395}$$

where  $s = 1, 2, \dots, N$ . This equation has been written in terms of the difference of molecular velocities,  $\mathbf{v}_s - \mathbf{v}_r$ . Equations (2.392) may then be used to write this equation in terms of any desired mass or molar fluxes. In the case of employing the mass based model form, it might be convenient to convert the mole fractions to mass fractions by use of (2.519).

It is seen from (2.397), or maybe easier from the Fickian formulation (2.310), that when the driving force (2.305) is approximated by the mole fraction gradients, there is an important difference between binary diffusion and multicomponent diffusion fluxes (e.g., Toor [152]; Taylor and Krishna [148]). In binary systems the movement of species  $s$  is always proportional to the negative of the concentration gradient of species  $s$ . In multicomponent diffusion, however, we may also experience *reverse diffusion* in which a species moves against its own concentration gradient, *osmotic diffusion* in which a species diffuses even though its concentration gradient is zero, and *diffusion barrier* when a species does not diffuse even though its concentration gradient is nonzero.

#### Mole based Maxwell-Stefan model forms

For dilute gas mixtures, a set of simplifying assumptions is normally considered very good approximations for ordinary mass transport problems. That is, the thermal diffusion mechanism is assumed negligible compared to the other mass transport phenomena for ordinary temperature gradients, the body force per unit mass is the same on each species when gravity is the only body force acting on the gas mixture, and either the pressure is constant or the molecular weights of all the species in the mixture are about the same. For such system operating conditions, the driving force (2.305) reduces to:

$$\mathbf{d}_s \approx \nabla x_s \tag{2.396}$$

The resulting set of Maxwell-Stefan equations, i.e., using the first expression in last line on the RHS of (2.392), is given by:

$$\nabla x_s = \sum_{r=1}^N \frac{x_i x_j}{\tilde{D}_{sr}} (\mathbf{v}_r - \mathbf{v}_s) = - \sum_{r=1}^N \frac{1}{c \tilde{D}_{sr}} (x_r \mathbf{N}_s - x_s \mathbf{N}_r) \tag{2.397}$$

where  $s = 1, 2, 3, \dots, N$ .

This relation is referred to as the original Maxwell-Stefan model equations, since Maxwell [95, 97] was the first to derive diffusion equations in a form analogous to (2.397) for dilute binary gas mixtures using kinetic theory arguments (i.e., Maxwell's seminal idea was that concentration gradients result from the friction between the molecules of different species, hence the proportionality coefficients,  $\hat{C}_{sk}$ , were interpreted as inverse friction or drag coefficients), and Stefan [142, 143] extended the approach to ternary dilute gas systems. It is emphasized that the original model equations were valid for ordinary diffusion only and did not include thermal, pressure, and forced diffusion. It is sometimes convenient to cast the governing set of equations into a  $N - 1$  dimensional matrix form.

Starting out from the diffusive molar fluxes, as given by the last term on the RHS of (2.392), yield:

$$\mathbf{d}_s = - \sum_{r=1}^N \frac{x_r \mathbf{J}_s^* - x_s \mathbf{J}_r^*}{c \tilde{D}_{sr}} \quad (2.398)$$

where  $s = 1, 2, 3, \dots, N$ .

However, only  $N - 1$  of the diffusion fluxes are independent, hence:

$$\mathbf{J}_N^* = - \sum_{r=1}^{N-1} \mathbf{J}_r^* \quad (2.399)$$

Using the latter relation, (2.398) may be rewritten as:

$$\begin{aligned} \mathbf{d}_s &= - \sum_{r=1}^N \frac{x_r \mathbf{J}_s^* - x_s \mathbf{J}_r^*}{c \tilde{D}_{sr}} = - \sum_{r=1}^{N-1} \frac{x_r \mathbf{J}_s^* - x_s \mathbf{J}_r^*}{c \tilde{D}_{sr}} - \left( \frac{x_N \mathbf{J}_s^* - x_s \mathbf{J}_N^*}{c \tilde{D}_{sN}} \right) \\ &= - \sum_{r=1}^{N-1} \frac{x_r \mathbf{J}_s^* - x_s \mathbf{J}_r^*}{c \tilde{D}_{sr}} - \left( \frac{x_N \mathbf{J}_s^* - x_s \left( - \sum_{r=1}^{N-1} \mathbf{J}_r^* \right)}{c \tilde{D}_{sN}} \right) \\ &= - \sum_{r=1}^{N-1} \left( - \frac{x_s \mathbf{J}_r^*}{c \tilde{D}_{sr}} + \frac{x_s \mathbf{J}_r^*}{c \tilde{D}_{sN}} \right) - \sum_{r=1}^{N-1} \frac{x_r \mathbf{J}_s^*}{c \tilde{D}_{sr}} - \frac{x_N \mathbf{J}_s^*}{c \tilde{D}_{sN}} \\ &= - \sum_{r=1}^{N-1} \left( - \frac{x_s \mathbf{J}_r^*}{c \tilde{D}_{sr}} + \frac{x_s \mathbf{J}_r^*}{c \tilde{D}_{sN}} \right) - \sum_{r=1}^N \frac{x_r \mathbf{J}_s^*}{c \tilde{D}_{sr}} \quad (2.400) \\ &= - \sum_{\substack{r=1 \\ r \neq s}}^{N-1} \left( - \frac{x_s}{c \tilde{D}_{sr}} + \frac{x_s}{c \tilde{D}_{sN}} \right) \mathbf{J}_r^* - \sum_{\substack{k=1 \\ k \neq s}}^N \frac{x_k}{c \tilde{D}_{sk}} \mathbf{J}_s^* - \frac{x_s}{c \tilde{D}_{sN}} \mathbf{J}_s^* \\ &= \frac{1}{c} \left\{ - \sum_{\substack{r=1 \\ r \neq s}}^{N-1} B_{sr} \mathbf{J}_r^* - B_{ss} \mathbf{J}_s^* \right\} \end{aligned}$$

where the coefficients  $B_{ss}$  and  $B_{sr}$  are defined by:

$$B_{sr} = -x_s \left( \frac{1}{\tilde{D}_{sr}} - \frac{1}{\tilde{D}_{sN}} \right) \quad (2.401)$$

and

$$B_{ss} = \frac{x_s}{\tilde{D}_{sN}} + \sum_{\substack{k=1 \\ k \neq s}}^N \frac{x_k}{\tilde{D}_{sk}} \quad (2.402)$$

Let  $\mathbf{d}$  and  $\mathbf{J}^*$  denote, respectively, the vectors of independent driving forces  $\mathbf{d}_1, \mathbf{d}_2, \mathbf{d}_3, \dots, \mathbf{d}_{N-1}$  and independent diffusion fluxes  $\mathbf{J}_1^*, \mathbf{J}_2^*, \mathbf{J}_3^*, \dots, \mathbf{J}_{N-1}^*$ , thus the  $N - 1$  equations can be written in the  $N - 1$  dimensional matrix form as:

$$c\mathbf{d} = -[B]\mathbf{J}^* \quad (2.403)$$

where  $[B]$  is a square matrix of order  $N - 1$ .

Then, to find an explicit expression for  $\mathbf{J}^*$  the previous relation is pre-multiplied by the inverse of  $[B]$ . The result is:

$$c[B]^{-1}\mathbf{d} = -[B]^{-1}[B]\mathbf{J}^* = -\mathbf{J}^* \quad (2.404)$$

or, more conveniently, the diffusive flux vector can be defined in terms of the driving force vector:

$$\mathbf{J}^* = -c[B]^{-1}\mathbf{d} \quad (2.405)$$

In particular cases it is desired to work with an explicit expression for the mole flux of a single species type  $s$ ,  $\mathbf{J}_s^*$ , avoiding the matrix form given above. Such an explicit model can be derived manipulating the original Maxwell-Stefan model (2.398), with the approximate driving force (2.396), assuming that the mass fluxes for all the other species are known:

$$\begin{aligned} \mathbf{J}_s^* &= \frac{-c\nabla x_s + \sum_{\substack{r=1 \\ r \neq s}}^N \frac{\mathbf{J}_r^* x_s}{\tilde{D}_{sr}}}{\sum_{\substack{r=1 \\ r \neq s}}^N \frac{x_r}{\tilde{D}_{sr}}} \\ &= D_s \left( -c\nabla x_s + \sum_{\substack{r=1 \\ r \neq s}}^N \left( \frac{\mathbf{J}_r^* x_s}{\tilde{D}_{sr}} \right) \right) \end{aligned} \quad (2.406)$$

in which  $D_s$  is given by:

$$D_s = \left( \sum_{\substack{r=1 \\ r \neq s}}^N \frac{x_r}{\tilde{D}_{sr}} \right)^{-1} \quad (2.407)$$

where  $s = 1, 2, 3, \dots, N$ . It is noted that Datta and Vilekar [30] outlined a more rigorous procedure deriving an explicit expression for the Maxwell-Stefan diffusion fluxes into the Fickian form.

A rigorous derivation of these relations were given by Curtiss and Hirschfelder [24] extending the Enskog theory to multicomponent systems. One important result of the Curtiss and Hirschfelder [24] theory of dilute mono-atomic gas mixtures is that it did show that the Maxwell-Stefan diffusivities are to a very good approximation equal to the binary diffusivities,  $\tilde{D}_{sr} \approx D_{sr}$ . On the other hand, Curtiss and Bird [26, 27] did show that for dense gases and liquids the Maxwell-Stefan equations are still valid, but the strongly concentration dependent diffusivities appearing therein are not the binary diffusivities but merely empirical parameters. It is thus noted that for these two types of systems (i.e., dense gases and liquids), the practical application of the generalized Fick's first law diffusivities and the Maxwell-Stefan diffusivities are equivalent in that both sets of coefficients require numerous costly experimentally determined data sets to enable proper parameter fitting.

#### *Mass based Maxwell-Stefan model forms*

The corresponding combined mass flux form of the Maxwell-Stefan relation can be expressed as:

$$\mathbf{d}_s = - \sum_{r=1}^N \frac{x_s x_r (\mathbf{v}_s - \mathbf{v}_r)}{\tilde{D}_{sr}} = - \sum_{r=1}^N \frac{x_s x_r \left( \frac{\mathbf{n}_s}{\omega_s} - \frac{\mathbf{n}_r}{\omega_r} \right)}{\rho \tilde{D}_{sr}} \quad (2.408)$$

The combined flux variable in the Maxwell-Stefan equation given above is then eliminated using the definition (2.394), thus:

$$\mathbf{d}_s = - \sum_{r=1}^N \frac{x_s x_r \left( \frac{\mathbf{j}_s + \rho \omega_s \mathbf{v}_m}{\omega_s} - \frac{\mathbf{j}_r + \rho \omega_r \mathbf{v}_m}{\omega_r} \right)}{\rho \tilde{D}_{sr}} = - \sum_{r=1}^N \frac{x_s x_r \left( \frac{\mathbf{j}_s}{\omega_s} - \frac{\mathbf{j}_r}{\omega_r} \right)}{\rho \tilde{D}_{sr}} \quad (2.409)$$

By use of (2.519), the Maxwell-Stefan equation can be manipulated as:

$$\begin{aligned}
\mathbf{d}_s &= - \sum_{r=1}^N \left( \frac{x_s x_r \frac{\mathbf{j}_s}{\omega_s} - x_s x_r \frac{\mathbf{j}_r}{\omega_r}}{\rho \tilde{D}_{sr}} \right) \\
&= - \sum_{r=1}^N \frac{\left( \frac{\omega_s M_w}{M_{w_s}} \right) \left( \frac{\omega_r M_w}{M_{w_r}} \right) \frac{\mathbf{j}_s}{\omega_s} - \left( \frac{\omega_s M_w}{M_{w_s}} \right) \left( \frac{\omega_r M_w}{M_{w_r}} \right) \frac{\mathbf{j}_r}{\omega_r}}{\rho \tilde{D}_{sr}} \\
&= - \frac{M_w^2}{\rho M_{w_s}} \sum_{r=1}^N \frac{\omega_r \mathbf{j}_s - \omega_s \mathbf{j}_r}{M_{w_r} \tilde{D}_{sr}}
\end{aligned} \tag{2.410}$$

However, only  $N - 1$  of the diffusion fluxes are independent, hence:

$$\mathbf{j}_N = - \sum_{r=1}^{N-1} \mathbf{j}_r \tag{2.411}$$

Eliminating the diffusive flux  $\mathbf{j}_N$  from (2.410), by use of (2.411), yields:

$$\begin{aligned}
\mathbf{d}_s \frac{\rho M_{w_s}}{M_w^2} &= - \sum_{r=1}^{N-1} \frac{\omega_r \mathbf{j}_s - \omega_s \mathbf{j}_r}{M_{w_r} \tilde{D}_{sr}} - \left( \frac{\omega_N \mathbf{j}_s - \omega_s \mathbf{j}_N}{M_{w_N} \tilde{D}_{sN}} \right) \\
&= - \sum_{r=1}^{N-1} \frac{\omega_r \mathbf{j}_s - \omega_s \mathbf{j}_r}{M_{w_r} \tilde{D}_{sr}} - \left( \frac{\omega_N \mathbf{j}_s - \omega_s \left( - \sum_{r=1}^{N-1} \mathbf{j}_r \right)}{M_{w_N} \tilde{D}_{sN}} \right) \\
&= - \sum_{r=1}^{N-1} \left( - \frac{\omega_s \mathbf{j}_r}{M_{w_r} \tilde{D}_{sr}} + \frac{\omega_s \mathbf{j}_r}{M_{w_N} \tilde{D}_{sN}} \right) - \sum_{r=1}^{N-1} \left( \frac{\omega_r \mathbf{j}_s}{M_{w_r} \tilde{D}_{sr}} \right) - \left( \frac{\omega_N \mathbf{j}_s}{M_{w_N} \tilde{D}_{sN}} \right) \\
&= - \sum_{r=1}^{N-1} \left( - \frac{\omega_s \mathbf{j}_r}{M_{w_r} \tilde{D}_{sr}} + \frac{\omega_s \mathbf{j}_r}{M_{w_N} \tilde{D}_{sN}} \right) - \sum_{r=1}^N \left( \frac{\omega_r \mathbf{j}_s}{M_{w_r} \tilde{D}_{sr}} \right) \\
&= - \sum_{\substack{r=1 \\ r \neq s}}^{N-1} \left( - \frac{\omega_s \mathbf{j}_r}{M_{w_r} \tilde{D}_{sr}} + \frac{\omega_s \mathbf{j}_r}{M_{w_N} \tilde{D}_{sN}} \right) - \left( - \frac{\omega_s \mathbf{j}_s}{M_{w_s} \tilde{D}_{ss}} + \frac{\omega_s \mathbf{j}_s}{M_{w_N} \tilde{D}_{sN}} \right) \\
&\quad - \sum_{\substack{r=1 \\ r \neq s}}^N \left( \frac{\omega_r \mathbf{j}_s}{M_{w_r} \tilde{D}_{sr}} \right) - \left( \frac{\omega_s \mathbf{j}_s}{M_{w_s} \tilde{D}_{ss}} \right) \\
&= - \sum_{\substack{r=1 \\ r \neq s}}^{N-1} \left( - \frac{\omega_s}{M_{w_r} \tilde{D}_{sr}} + \frac{\omega_s}{M_{w_N} \tilde{D}_{sN}} \right) \mathbf{j}_r - \left( \frac{\omega_s}{M_{w_N} \tilde{D}_{sN}} + \sum_{\substack{k=1 \\ k \neq s}}^N \left( \frac{\omega_k}{M_{w_k} \tilde{D}_{sk}} \right) \right) \mathbf{j}_s
\end{aligned} \tag{2.412}$$

A more compact notation is achieved introducing two coefficient matrices:

$$\mathbf{d}_s = -\frac{M_w^2}{\rho M_{w_s}} \left( \sum_{\substack{r=1 \\ r \neq s}}^{N-1} B'_{sr} \mathbf{j}_r + B'_{ss} \mathbf{j}_s \right) \quad (2.413)$$

where the coefficient matrices  $B_{sr}$  and  $B_{ss}$  are defined by:

$$B'_{sr} = -\omega_s \left( \frac{1}{M_{w_r} \tilde{D}_{sr}} - \frac{1}{M_{w_N} \tilde{D}_{sN}} \right) \quad (2.414)$$

and

$$B'_{ss} = \frac{\omega_s}{M_{w_N} \tilde{D}_{sN}} + \sum_{\substack{k=1 \\ k \neq s}}^N \frac{\omega_k}{M_{w_k} \tilde{D}_{sk}} \quad (2.415)$$

The diffusion flux can then be written on the vector form:

$$\mathbf{j} = -\frac{\rho(\mathbf{M}_w)}{M_w^2} [B']^{-1} \mathbf{d} \quad (2.416)$$

For the particular cases in which the model for the driving force reduces to the mole fraction gradient, an explicit relation for  $\mathbf{j}_s$  can be expressed in terms of the other unknown fluxes  $\mathbf{j}_r$ . This nonlinear model must thus be solved by an iteration procedure. Besides, when the mass based formulation is used, it is convenient to rewrite the driving force in terms of the corresponding mass fraction gradient:

$$\mathbf{d}_s \approx \nabla x_s = \nabla \left( \frac{\omega_s M_w}{M_{w_s}} \right) = \frac{1}{M_{w_s}} \nabla (\omega_s M_w) = \frac{1}{M_{w_s}} (\omega_s \nabla M_w + M_w \nabla \omega_s) \quad (2.417)$$

By inserting (2.417) into (2.410), gives:

$$\frac{1}{M_{w_s}} (\omega_s \nabla M_w + M_w \nabla \omega_s) = -\frac{M_w^2}{\rho M_{w_s}} \sum_{r=1}^N \frac{\omega_r \mathbf{j}_s - \omega_s \mathbf{j}_r}{M_{w_r} \tilde{D}_{sr}} \quad (2.418)$$

After multiplication by  $M_{w_s}/M_w$ , this expression can be manipulated as:

$$\omega_s \nabla \ln(M_w) + \nabla \omega_s = \frac{M_w}{\rho} \sum_{r=1}^N \frac{\omega_s \mathbf{j}_r - \omega_r \mathbf{j}_s}{M_{w_r} \tilde{D}_{sr}} \quad (2.419)$$

The RHS of the relation can be further manipulated, as the terms for  $r = s$  cancel out. The result is given by:

$$\omega_s \nabla \ln(M_w) + \nabla \omega_s = \frac{M_w}{\rho} \left( \sum_{\substack{r=1 \\ r \neq s}}^N \frac{\omega_s \mathbf{j}_r}{M_{w_r} \tilde{D}_{sr}} - \mathbf{j}_s \sum_{\substack{r=1 \\ r \neq s}}^N \frac{\omega_r}{M_{w_r} \tilde{D}_{sr}} \right) \quad (2.420)$$

An explicit relation for the diffusive flux of species  $s$ ,  $\mathbf{j}_s$ , can be obtained with minor manipulation:

$$\mathbf{j}_s = D'_s \left( -\rho \omega_s \nabla \ln(M_w) - \rho \nabla \omega_s + M_w \omega_s \sum_{\substack{r=1 \\ r \neq s}}^N \frac{\mathbf{j}_r}{M_{w_r} \tilde{D}_{sr}} \right) \quad (2.421)$$

where the effective mass based diffusion coefficient is defined by:

$$D'_s = \left( M_w \sum_{\substack{r=1 \\ r \neq s}}^N \frac{\omega_r}{M_{w_r} \tilde{D}_{sr}} \right)^{-1} \quad (2.422)$$

The relation (2.421) can be used to solve the set of Maxwell-Stefan equations iteratively.

Kleijn [65] used this Maxwell-Stefan formulation simulating chemical vapor deposition reactors. One advantage of this explicit formula is that the multicomponent flux is relatively easy to implement as user defined functions in commercial flow codes. However, the conventional matrix form probably enables the design of more efficient solution strategies.

#### *Maxwell-Stefan model consistency with Fick's first law*

The consistency with Fick's first law for binary systems (2.301) is examined comparing the generalized Fickian mass flux vectors (2.310), including the Maxwell-Stefan diffusivity (2.391), the Bird et al. [9] generalized Fickian diffusivity (2.311), and the binary diffusivity. For binary systems, i.e.,  $s, r = 1, 2$ , the Fickian mass flux vector (2.310) reduces to:

$$\begin{aligned} \mathbf{j}_1 &= -D_1^T \nabla \ln T - \rho_1 (\hat{D}_{11} \mathbf{d}_1 + \hat{D}_{12} \mathbf{d}_2) = -D_1^T \nabla \ln T + \rho \hat{D}_{12} \mathbf{d}_1 \\ &= -D_1^T \nabla \ln T + \rho \left\{ -\tilde{D}_{12} \frac{\omega_1 \omega_2}{x_1 x_2} \right\} \mathbf{d}_1 \approx -D_1^T \nabla \ln T + \rho \left\{ -D_{12} \frac{\omega_1 \omega_2}{x_1 x_2} \right\} \mathbf{d}_1 \\ &= -D_1^T \nabla \ln T - \rho \mathbb{D}_{12} \mathbf{d}_1 = -D_1^T \nabla \ln T - \rho \left\{ \tilde{D}_{12} \frac{\omega_1 \omega_2}{x_1 x_2} \right\} \mathbf{d}_1 \end{aligned} \quad (2.423)$$

where we have used the additional requirements that  $\mathbf{j}_1 + \mathbf{j}_2 = 0$  in accordance with (2.293),  $\mathbf{d}_1 + \mathbf{d}_2 = 0$  due to the properties specified for the generalized driving force (2.305). For binary mixtures, the current diffusivities (2.310) have the following

properties  $\omega_1 \hat{D}_{11} + \omega_2 \hat{D}_{21} = \omega_1 \hat{D}_{12} + \omega_2 \hat{D}_{22} = 0$ , and  $\hat{D}_{12} = \hat{D}_{21}$ . For dilute gases the multicomponent Fickian diffusivities  $\tilde{D}_{12}$  are also related to the Maxwell-Stefan and Fick's first law diffusivities as shown by Curtiss [25] and tabulated by Curtiss and Bird [26, 27] and Bird et al. [9], i.e.,  $\hat{D}_{11} = -\frac{\omega_2 \omega_2}{x_1 x_2} \tilde{D}_{12}$  and  $\hat{D}_{12} = -\frac{\omega_1 \omega_2}{x_1 x_2} \tilde{D}_{12}$ . It is further noticed that for gases at low density the Maxwell-Stefan diffusivities are approximately equal to the Fick first law binary diffusivities, i.e.  $\tilde{D}_{12} \approx D_{12}$ .

Comparing the binary diffusivities  $\hat{D}_{12}$  and the Maxwell-Stefan diffusivity  $\tilde{D}_{12}$  and the Fick's first law diffusivity  $D_{12}$ , it is revealed that these coefficients differ by a factor that is a function of the composition. Moreover, these diffusivities do not even have the same sign. It is noted, however, that for binary mixtures the alternative Fickian binary diffusivity  $\mathbb{D}_{12}$  do have the same sign as the Maxwell-Stefan and thus the Fick's first law binary diffusivities. This explains why the plus sign was chosen in (2.311). The binary form of the generalized Maxwell-Stefan equation (2.423) might also be combined with the extended generalized diffusional driving force vector (2.369).

The result is:

$$\begin{aligned}
 \mathbf{j}_1 &= -D_1^T \nabla \ln T + \rho \left\{ -\tilde{D}_{12} \frac{\omega_1 \omega_2}{x_1 x_2} \right\} \mathbf{d}_1 = -D_1^T \nabla \ln T - \left( \frac{c^2}{\rho} \right) M_{\omega_1} M_{\omega_2} \tilde{D}_{12} \mathbf{d}_1 \\
 &= -D_1^T \nabla \ln T - \left( \frac{c^2}{\rho} \right) M_{\omega_1} M_{\omega_2} \tilde{D}_{12} \\
 &\quad \times \left[ \frac{x_1}{RT} \left( \frac{\partial \tilde{G}_1}{\partial x_2} \right)_{T,P} \nabla x_2 + \frac{x_1 M_{w_1}}{RT} \left[ \left( \check{V} - \frac{1}{\rho} \right) \nabla p - \omega_2 (\mathbf{g}_1 - \mathbf{g}_2) \right] \right] \\
 &= -D_1^T \nabla \ln T - \left( \frac{c^2}{\rho} \right) M_{\omega_1} M_{\omega_2} \tilde{D}_{12} \\
 &\quad \times \left[ \left( \frac{\partial \ln a_1^m}{\partial \ln x_1} \right)_{T,P} \nabla x_1 + \frac{x_1 M_{w_1}}{RT} \left[ \left( \check{V} - \frac{1}{\rho} \right) \nabla p - \omega_2 (\mathbf{g}_1 - \mathbf{g}_2) \right] \right] \quad (2.424)
 \end{aligned}$$

If the pressure-, thermal-, and forced-diffusion terms are dropped, the binary diffusivities can be expressed as:

$$\mathbf{j}_1 = -\frac{c^2}{\rho} M_{w_1} M_{w_2} \left\{ \tilde{D}_{12} \left( \frac{\partial \ln a_1^m}{\partial \ln x_1} \right)_{T,P} \right\} \nabla x_1 \quad (2.425)$$

The driving force can also be expressed in terms of the mass fraction gradient using (2.524):

$$\begin{aligned}
 \mathbf{j}_1 &= -\frac{c^2}{\rho} M_{\omega_1} M_{\omega_2} \left\{ \tilde{D}_{12} \left( \frac{\partial \ln a_1^m}{\partial \ln x_1} \right)_{T,P} \right\} \left[ \left( \frac{\rho}{c} \right)^2 \frac{1}{M_{\omega_1} M_{\omega_2}} \nabla \omega_1 \right] \\
 &= -\rho \left\{ \tilde{D}_{12} \left( \frac{\partial \ln a_1^m}{\partial \ln x_1} \right)_{T,P} \right\} \nabla \omega_1 = -\rho D_{12} \nabla \omega_1 \quad (2.426)
 \end{aligned}$$

where we have used the relation (2.524) between mole and mass fraction gradients;  $\nabla x_1 = M_\omega^2 \nabla \omega_1 / (M_{\omega_1} M_{\omega_2})$ . This result confirms that for binary systems the Maxwell-Stefan model reduces to the Fick's first law (2.301). Moreover, it follows that for dilute gas systems  $D_{12} \approx \tilde{D}_{12}$ . Similarly, it can be shown that the Fick's first law diffusivity is the same whether this law is formulated on a mass or molar basis.

It is informative to express the overall binary mass diffusion flux (2.424) as a linear sum of the four terms [7, 9, 55, 132] and examine the importance of each of the mass diffusion flux vector contributions in chemical reactor analysis:

$$\mathbf{j}_1 = \mathbf{j}_1^o + \mathbf{j}_1^p + \mathbf{j}_1^g + \mathbf{j}_1^T \quad (2.427)$$

The relative importance of the various contributions to the overall mass diffusion flux in chemical reactor analysis is discussed in Sect. 1.2.2.

The *ordinary diffusion flux*, which is normally significant in reactor analysis, is expressed as:

$$\mathbf{j}_1^o = -\rho \left\{ \tilde{D}_{12} \left( \frac{\partial \ln a_1^m}{\partial \ln x_1} \right)_{T,p} \right\} \nabla \omega_1 = -\rho D_{12} \nabla \omega_1 \quad (2.428)$$

where  $\nabla x_1 = M_\omega^2 \nabla \omega_1 / (M_{\omega_1} M_{\omega_2})$ .

For non-ideal mixtures, the Fick first law binary diffusivity,  $D_{12}$ , can thus be expressed in terms of the Maxwell-Stefan diffusivity,  $\tilde{D}_{12}$ , by:

$$D_{12} = \tilde{D}_{12} \left( \frac{\partial \ln a_1^m}{\partial \ln x_1} \right)_{T,p} \quad (2.429)$$

The *pressure diffusion* is given by:

$$\mathbf{j}_1^p = \frac{M_{w_1} x_1}{RT} \left( \check{V} - \frac{1}{\rho} \right) \nabla p \quad (2.430)$$

This term is significant in systems where there are very large pressure gradients [91]. However, the operating pressure gradients in chemical reactors are usually not large enough so this term is not significant in reactor models.

The *forced diffusion* is expressed as:

$$\mathbf{j}_1^g = -\frac{M_{w_1} x_1 \omega_2}{RT} (\mathbf{g}_1 - \mathbf{g}_2) \quad (2.431)$$

which may be of importance describing aqueous electrolytes [91]. If gravity is the only external force, as in most chemical reactors, then  $\mathbf{g}_1 = \mathbf{g}_2 = \mathbf{g}$  and  $\mathbf{j}_1^{(g)}$  vanishes.

The *thermal diffusion* term is written as:

$$\mathbf{j}_1^T = -D_1^T \nabla \ln T \quad (2.432)$$

This term is usually not important in reactor modeling, since sufficiently large temperature gradients are not common in chemical process plants.

*Application of the Maxwell-Stefan model to dense gases and liquids*

For non-ideal systems the Maxwell-Stefan diffusivities for multicomponent dense gases and liquids deviate from the Fick first law binary coefficients derived from kinetic theory and are thus merely empirical parameters [26]. Hence, for non-ideal systems either  $D_{12}$  or  $\tilde{D}_{12}$  must be fitted to experimental data. In the first approach the actual diffusivities  $D_{12}$  are measured directly, thus this procedure requires no additional activity data. In the second approach the non-ideal effects are divided from the Maxwell-Stefan diffusivities. These are the binary Maxwell-Stefan coefficients,  $\tilde{D}_{12}$ , that are fitted to experimental diffusivity data. The non-ideality corrections may be computed from a suitable thermodynamic model. These thermodynamic models generally contains numerous model parameters that have to be fitted to suitable thermodynamic data. This type of simulations were performed extensively by Taylor and Krishna [148]. The various forms of the multicomponent diffusion flux formulations are all of limited utility in describing multicomponent diffusion in non-ideal systems as they all contain a large number of empirical parameters that have to be determined experimentally.

### 2.9.5.5 The Approximate Wilke Multicomponent Diffusion Flux Model

Wilke [161] proposed a simpler model for calculating the effective diffusion coefficients for diffusion of a species  $s$  into a multicomponent mixture of stagnant gases. For dilute gases the Maxwell-Stefan diffusion equation is reduced to a multicomponent diffusion flux model on the binary Fick's law form in which the binary diffusivity is substituted by an effective multicomponent diffusivity. The Wilke model derivation is examined in the sequel.

*Approximate mole based Wilke diffusion model*

The combined molar flux of species  $s$  in a binary mixture is defined in accordance with (2.393), using Fick's law:

$$\mathbf{N}_s = c_s \mathbf{v}_m^* + \mathbf{J}_s^* = x_s c \mathbf{v}_m^* - c D_{sr} \nabla x_s = x_s (\mathbf{N}_s + \mathbf{N}_r) - c D_{sr} \nabla x_s \quad (2.433)$$

in which  $c \mathbf{v}_m^* = \mathbf{N}_s + \mathbf{N}_r$  for binary mixtures.

Wilke [161], among others, postulated that an analogous equation for the combined molar flux of species  $s$  in a multicomponent mixture can be written as [7] (p. 571):

$$\mathbf{N}_s = x_s \sum_{r=1}^N \mathbf{N}_r - c D_{sm} \nabla x_s \quad (2.434)$$

where  $D_{sm}$  represents the effective diffusion coefficient of component  $s$  with respect to the composition of the multicomponent gas mixture.

To express the effective diffusion coefficient in terms of the known binary diffusivities Wilke invoked the Maxwell-Stefan equation. From the last line on the RHS of (2.392) a particular form of the Maxwell-Stefan equation is given:

$$\nabla x_s = \sum_{\substack{r=1 \\ r \neq s}}^N \frac{1}{c \tilde{D}_{sr}} (x_s \mathbf{N}_r - x_r \mathbf{N}_s) \quad (2.435)$$

For dilute systems all gases except the species  $s$  molecules are being stagnant, hence all the fluxes denoted by  $\mathbf{N}_r$ , for  $r \neq s$ , are zero. Thus, the Wilke relation (2.434) reduces to:

$$\mathbf{N}_s = -\frac{c D_{sm}}{1 - x_s} \nabla x_s, \quad (2.436)$$

and the Maxwell-Stefan equation (2.435) yields:

$$\nabla x_s = -\sum_{\substack{r=1 \\ r \neq s}}^N \frac{1}{c \tilde{D}_{sr}} x_r \mathbf{N}_s \quad (2.437)$$

Then, by solving (2.436) for  $\nabla x_s$  and equating the result to the simplified driving force (2.396) in the Maxwell-Stefan equations (2.435), we get (see [7], p. 571 and [34]):

$$\frac{1}{D_{sm}} = \frac{1}{(1 - x_s)} \sum_{\substack{r=1 \\ r \neq s}}^N \frac{x_r}{\tilde{D}_{sr}} \quad (2.438)$$

The diffusion of species  $s$  in a multicomponent mixture can then be written in the form of Fick's law of binary diffusion, using the effective diffusion coefficient  $D_{sm}$  instead of the binary diffusivity. The Wilke equation is defined by:

$$\mathbf{J}_s^* = -c D_{sm} \nabla x_s \quad (2.439)$$

However, the Wilke equation does not in general satisfy the constraint that the species mole fractions must sum to 1 [22].

A similar model often used by reaction engineers is derived for the limiting case in which all the convective fluxes can be neglected. Consider a dilute component  $s$  that diffuses into a homogeneous mixture, then  $\mathbf{J}_r^* \approx 0$  for  $r \neq s$ . To describe this molecular transport the Maxwell-Stefan equations given by the last line in (2.392) are adopted. With the given restrictions, the model reduces to:

$$\nabla x_s = \sum_{\substack{r=1 \\ r \neq s}}^N \frac{1}{c \tilde{D}_{sr}} (x_s \mathbf{J}_r^* - x_r \mathbf{J}_s^*) \approx -\sum_{\substack{r=1 \\ r \neq s}}^N \frac{1}{c \tilde{D}_{sr}} x_r \mathbf{J}_s^* \quad (2.440)$$

By solving the effective multicomponent diffusion flux, as postulated by Wilke (2.439), for  $\nabla x_s$  and equating the result to the simplified driving force (2.396) in the Maxwell-Stefan equations (2.440), the result is:

$$\frac{1}{D_{sm}} = \sum_{\substack{r=1 \\ r \neq s}}^N \frac{x_r}{\tilde{D}_{sr}} \quad (2.441)$$

This simple relation provides fair approximations of the molecular fluxes for several multicomponent systems in which  $s$  is a trace component [114] (p. 597).

*Approximate mass based Wilke diffusion model*

The corresponding mass based Wilke approximate formulation [161] is outlined next. In this model the diffusion of species  $s$  in a multicomponent mixture is written in the form of Fick's law with an effective diffusion coefficient  $D'_{sm}$  instead of the conventional binary molecular diffusion coefficient. Following the ideas of Wilke [161] we postulate that an equation for the combined mass flux of species  $s$  in a multicomponent mixture can be written as:

$$\mathbf{n}_s = \omega_s \sum_{r=1}^N \mathbf{n}_r - \rho D'_{sm} \nabla \omega_s \quad (2.442)$$

where  $D'_{sm}$  represents the effective diffusion coefficient of component  $s$  with respect to the mass based composition of the multicomponent gas mixture.

From the second last line on the RHS of (2.392) a particular form of the Maxwell-Stefan equation is given:

$$\nabla x_s = \sum_{\substack{r=1 \\ r \neq s}}^N \frac{x_s x_r (\frac{\mathbf{n}_r}{\omega_r} - \frac{\mathbf{n}_s}{\omega_s})}{\rho \tilde{D}_{sr}} \quad (2.443)$$

For dilute systems all gases except the species  $s$  molecules are being stagnant, hence all the fluxes denoted by  $\mathbf{n}_r$ , for  $r \neq s$ , are zero. Hence, the Wilke relation (2.442) reduces to:

$$\mathbf{n}_s = - \frac{\rho D'_{sm}}{1 - \omega_s} \nabla \omega_s, \quad (2.444)$$

The Maxwell-Stefan equation (2.443) reduces to:

$$\nabla x_s \approx - \sum_{\substack{r=1 \\ r \neq s}}^N \frac{x_s x_r \frac{\mathbf{n}_s}{\omega_s}}{\rho \tilde{D}_{sr}} \quad (2.445)$$

Noting that the driving force can be expressed in terms of mass fractions instead of mole fractions in according to (2.417), and by transforming the mole fractions on the RHS into mass fractions, the relation above can be written as:

$$\omega_s \nabla M_w + M_w \nabla \omega_s \approx -\frac{M_w^2 \mathbf{n}_s}{\rho} \sum_{\substack{r=1 \\ r \neq s}}^N \frac{\omega_r}{M_{w_r} \tilde{D}_{sr}} \quad (2.446)$$

With minor manipulation this relation can be written as:

$$\nabla \omega_s \approx -\frac{M_w \mathbf{n}_s}{\rho} \sum_{\substack{r=1 \\ r \neq s}}^N \frac{\omega_r}{M_{w_r} \tilde{D}_{sr}} - \omega_s \frac{\nabla M_w}{M_w} \quad (2.447)$$

For dilute mixtures consisting of species having about the same molecular weight, the last term on the RHS of (2.447) might be neglected:

$$\nabla \omega_s \approx -\frac{M_w \mathbf{n}_s}{\rho} \sum_{\substack{r=1 \\ r \neq s}}^N \frac{\omega_r}{M_{w_r} \tilde{D}_{sr}} \quad (2.448)$$

By solving (2.444) for  $\nabla \omega_s$  and equating the result to the same gradient as derived from the simplified Maxwell-Stefan equations (2.448), we obtain an expression for the effective mass based diffusivity:

$$\frac{1}{D'_{sm}} \approx \frac{M_w}{1 - \omega_s} \sum_{\substack{r=1 \\ r \neq s}}^N \frac{\omega_r}{M_{w_r} \tilde{D}_{sr}} \quad (2.449)$$

This effective diffusivity expression is consistent with the multicomponent diffusive flux written on the Fick's law form:

$$\mathbf{j}_s = -\rho D'_{sm} \nabla \omega_s, \quad (2.450)$$

which might be applied when the given restrictions are fulfilled.

### 2.9.5.6 Combined Bulk and Knudsen Diffusion Fluxes: The Wilke-Bosanquet and Dusty Gas Models

To describe the combined bulk and Knudsen diffusion fluxes in the transition gas transport regime, the simple Wilke-Bosanquet model [11, 70, 151] and the more rigorous *dusty gas model* [62, 70, 71, 94] can be used either on the mass or molar forms. Knudsen diffusion refers to a gas transport regime where the mean free

path between particle-particle collisions is significantly larger than the characteristic spatial dimension of the system considered. The transition region between Knudsen and bulk diffusion is of considerable importance because many processes involving gas transport in restricted geometries lies in this region.

From the classic Knudsen formula the value of the Knudsen diffusion transport coefficient,  $D_{i,K}$ , can be computed [46, 66, 67]:

$$D_{s,K} = \frac{d_{\text{pore}}}{3} \sqrt{\frac{8RT}{\pi M_s}} = \frac{2}{3} \sqrt{\frac{8R}{\pi}} \frac{d_{\text{pore}}}{2} \sqrt{\frac{T}{M_s}} \approx 97.0 \frac{d_{\text{pore}}}{2} \left( \frac{T}{M_s} \right)^{1/2} \quad (2.451)$$

where  $R = 8.3143 \times 10^3$  [Nm/(kg mol K)].

The Knudsen formula (2.451) was originally verified [66, 67] in macro-pores, i.e. pore size in the range of 50 nm to 50  $\mu\text{m}$ , but is widely applied at the meso-pore scale with adsorption effects neglected [6]. Because of the assumption that every gas-wall collision is purely diffusive, the computed Knudsen diffusion coefficient by (2.451) is considered to be an ideal upper limit [61]. The adsorption effect (van der Waals interactions) lowers the Knudsen diffusivities because adsorption causes the molecules to “stick” to the wall, and perhaps hop to a neighboring adsorption site, rather than return to the bulk after collision. Hence, the trajectory of a weakly adsorbed gas molecule strikes the pore wall and return to the bulk largely in keeping with the diffusive reflection scenario prescribed by the Knudsen theory. On the other hand, the trajectory of strongly adsorbed species are largely influenced by the hopping of the molecules to neighboring positions along the surface, rather than being reflected into the “core” of the pore. The validity of the Knudsen formula (2.451) is thus based on the requirement that the time during which the molecules are in the free space (i.e., under the influence of the uniform potential of the gas phase) significantly exceeds the time during which the molecules experience the attractive forces of the surface. This is equivalent to the requirement that the number of molecules in “bulk” notably exceed the number of molecules closer to the surface [74]. Because equation (2.451) holds in the limiting case of purely diffusive collision, i.e. when the molecules does not adsorb at pore walls, the validity of the correlation is debated in the literature. The results of the studies of [6, 72–75] cast doubts on the validity of the Bosanquet—and dusty gas models when applied to mixtures in which at least one of the species has strong adsorption characteristics, because of the neglect of van der Waals interactions between the wall and the diffusing molecules in the purely hard sphere analysis of Knudsen.

#### *The Wilke-Bosanquet model*

As a first approach to calculate the combined bulk and Knudsen diffusive flux using a Fickian flux formulation, the *Bosanquet formula* [11] has been suggested in literature [11, 70, 151]. In this approach, the Fick form formulation uses a diffusivity computed as the reciprocal additivity of the diffusion coefficients in the ordinary and Knudsen diffusion regimes.

*Mole based Wilke-Bosanquet model*

Similar to (2.439) the diffusion flux is:

$$\mathbf{J}_s = -cD_{s,\text{eff}}\nabla x_s \quad (2.452)$$

The  $D_{s,\text{eff}}$  is given by the harmonic average relation of Bosanquet [11, 151]:

$$\frac{1}{D_{s,\text{eff}}} = \frac{1}{D_{sm}} + \frac{1}{D_{s,K}} \quad (2.453)$$

where  $D_{sm}$  is given by (2.438) and the Knudsen diffusivity  $D_{s,K}$  can be calculated from (2.451) which is derived based on the Kinetic theory principles [46].

*Mass based Wilke-Bosanquet model*

Similar to (2.450) the diffusion flux is:

$$\mathbf{j}_s = -\rho D'_{s,\text{eff}}\nabla \omega_s, \quad (2.454)$$

The  $D'_{s,\text{eff}}$  is given by the analogue harmonic average relation of Bosanquet [11, 151]:

$$\frac{1}{D'_{s,\text{eff}}} = \frac{1}{D'_{sm}} + \frac{1}{D_{s,K}} \quad (2.455)$$

where  $D'_{sm}$  is given by (2.449) and the Knudsen diffusivity  $D_{s,K}$  can be calculated from (2.451).

The effective Knudsen diffusion coefficients are proportional to the pore diameter and independent of pressure, while the bulk diffusivities are independent of pore diameter and inversely proportional to pressure [62]. However, both bulk diffusivities and Knudsen diffusivities are dependent on the temperature. Relations for the Knudsen transport coefficient and binary diffusivities are represented in Table 2.1.

*Mole based dusty-gas model*

The dusty gas model represents an extension of the Maxwell-Stefan bulk diffusion model where a description of the Knudsen diffusion mechanisms is included. In order to include the Knudsen molecule—wall collision mechanism in the Maxwell-Stefan model originally derived considering bulk gas molecule-molecule collisions only, the wall (medium) molecules are treated as an additional pseudo component in the gas mixture. The pore wall medium is approximated as consisting of giant molecules, called *dust*, which are uniformly distributed in space and held stationary by an external clamping force. This implies that both the diffusive flux and the concentration gradient with respect to the dust particles vanish.

For the  $N + 1$ -component pseudo-mixture we may modify the formulation of the Maxwell-Stefan equation given in the last line of (2.392) and the generalized diffusional driving force expression (2.305). The dusty gas model can be expressed as:

**Table 2.1** Relations for Knudsen and binary diffusion coefficients based on kinetic theory of gases

Knudsen diffusion coefficient [46, 66, 67]:

$$D_{s,K} = 97.0 \frac{d_{\text{pore}}}{2} \left( \frac{T}{M_s} \right)^{1/2} \quad (2.451)$$

Binary diffusion coefficients [114]:

$$D_{s,r} = \frac{0.00266 \cdot 101325 T^{3/2}}{0.01^2 p \Omega_{D,sr} \sigma_{sr}^2 M_{sr}^{1/2}} \quad (2.627)$$

where the property units are;  $D_{s,r}$  [ $\text{m}^2/\text{s}$ ],  $p$  [Pa], and  $T$  [K].

The property functions are:

The molecular weight factor [kg/kmol] is defined as:

$$M_{sr} = 2 \left( \frac{1}{M_s} + \frac{1}{M_r} \right)^{-1} \quad (2.456)$$

The  $\sigma_{sr}$  [ $\text{\AA}$ ] denotes the characteristic Lennard-Jones diameter:

$$\sigma_{sr} = \frac{\sigma_s + \sigma_r}{2} \quad (2.457)$$

The Lennard-Jones characteristic energy [J] is approximated as:

$$\epsilon_{sr} = (\epsilon_s \epsilon_r)^{1/2} \quad (2.458)$$

The dimensionless collision integral,  $\Omega_{D,sr}$ , is given as:

$$\Omega_{sr} = \frac{A}{(T_{sr}^{**})^B} + \frac{C}{\exp(DT_{sr}^{**})} + \frac{E}{\exp(FT_{sr}^{**})} + \frac{G}{\exp(HT_{sr}^{**})} \quad (2.459)$$

where

$$\begin{array}{lll} T_{sr}^{**} = kT/\epsilon_{sr} & A = 1.06036 & B = 0.15610 \\ C = 0.19300 & D = 0.47635 & E = 1.03587 \\ F = 1.52996 & G = 1.76474 & H = 3.89411 \end{array} \quad (2.460)$$

$$\begin{aligned} - \sum_{r=1}^N \frac{N'_s x'_r - N'_r x'_s}{c' \tilde{D}'_{sr}} - \frac{N'_s x'_{N+1} - N'_{N+1} x'_s}{c' \tilde{D}'_{s,N+1}} &= \nabla x'_s + \frac{(x'_s - \omega'_s) \nabla p'}{p'} \\ &\quad - \frac{c'_s \mathbf{g}'_s - \omega'_s \sum_{r=1}^{N+1} c'_r \mathbf{g}'_r}{p'} \end{aligned} \quad (2.461)$$

where  $s = 1, 2, \dots, N+1$ . However, only  $N$  of these equations are independent. It is thus required to solve  $(N-1)$  equations for the bulk species and 1 for the pseudo-component denoting the pore wall medium.

The quantities marked with a prime refer to the pseudo-mixture, that is the gas mixture with the dust molecules. This distinction will be maintained by writing  $p'$ ,  $c'$ ,  $x'_s$ ,  $\tilde{D}'_{sr}$  and  $\omega'_s$  for the quantities referred to the pseudo-mixture and  $p$ ,  $c$ ,  $x_s$ ,  $\tilde{D}_{sr}$  and  $\omega_s$  for the same quantities referred to the actual ideal gas. Note also that for the species concentrations  $c_s$ , partial pressures  $p_s$  and the molar flux vectors there are no distinction between the two quantities.

To ensure that the dust molecules are motionless,  $N'_{N+1} = 0$ , a net external force is used to prevent them from moving in response to any gas pressure gradients [71]:

$$\nabla p = c_{N+1} \mathbf{g}_{N+1} \quad (2.462)$$

Moreover, it is assumed that there are no external forces acting on the actual species,  $\mathbf{g}_s = 0$  for  $s = 1, \dots, N$ . The form of the  $q$  independent equations is thus given by:

$$-\sum_{r=1}^N \frac{\mathbf{N}'_s x'_r - \mathbf{N}'_r x'_s}{c' \tilde{D}'_{sr}} - \frac{\mathbf{N}'_s x'_{N+1}}{c' \tilde{D}'_{s,N+1}} = \nabla x'_s + \frac{(x'_s - \omega'_s) \nabla p'}{p'} + \frac{\omega'_s c_{N+1} \mathbf{g}_{N+1}}{p'} \quad (2.463)$$

To obtain a form of the dusty gas model that can be used in practice the primed variables associated with the pseudo-mixture have to be transformed to the un-primed variables associated with the gas.

The two first terms on the RHS can be formulated as:

$$\begin{aligned} \nabla x'_s + \frac{x'_s}{p'} \nabla p' &= \nabla \left( \frac{p'_s}{p'} \right) + \frac{x'_s}{p'} \nabla p' = p'_s \nabla \left( \frac{1}{p'} \right) + \frac{1}{p'} \nabla p'_s + \frac{x'_s}{p'} \nabla p' \\ &= -\frac{p'_s}{p'^2} \nabla p' + \frac{1}{p'} \nabla p'_s + \frac{x'_s}{p'} \nabla p' \\ &= -\frac{x'_s}{p'} \nabla p' + \frac{1}{p'} \nabla p'_s + \frac{x'_s}{p'} \nabla p' = \frac{1}{p'} \nabla p'_s \end{aligned} \quad (2.464)$$

From the equation of state for an ideal gas we observe:

$$p' = c' RT = (c + c_{N+1}) RT = p + c_{N+1} RT \quad (2.465)$$

Hence, applying the nabla operator yields:

$$\nabla p' = \nabla p + c_{N+1} R \nabla T \quad (2.466)$$

Inserting this result into (2.462), gives:

$$c_{N+1} \mathbf{g}_{N+1} = \nabla p' - c_{N+1} R \nabla T \quad (2.467)$$

By use of the ideal gas law, (2.464) can be rewritten as:

$$\frac{1}{p'} \nabla p'_s = \frac{1}{c' RT} \nabla (c'_s RT) = \frac{c'_s \nabla (\ln T)}{c'} + \frac{\nabla c'_s}{c'} \quad (2.468)$$

Then, employing these formulas, (2.463) can be rewritten as:

$$\begin{aligned}
-\sum_{r=1}^N \frac{\mathbf{N}'_s x'_r - \mathbf{N}'_r x'_s}{c' \tilde{D}'_{sr}} - \frac{\mathbf{N}'_s x'_{N+1}}{c' \tilde{D}'_{s,N+1}} &= \nabla x'_s + \frac{x'_s \nabla p'}{p'} - \frac{\omega'_s \nabla p'}{p'} + \frac{\omega'_s c_{N+1} \mathbf{g}_{N+1}}{p'} \\
&= \frac{1}{p'} \nabla p'_s - \frac{\omega'_s \nabla p'}{p'} + \frac{\omega'_s (\nabla p' - c_{N+1} R \nabla T)}{p'} \\
&= \frac{c'_s \nabla (\ln T)}{c'} + \frac{\nabla c'_s}{c'} + \frac{\omega'_s c_{N+1} R \nabla T}{p'} \quad (2.469)
\end{aligned}$$

To complete the transformation of the dusty gas model containing primed quantities into the un-primed variables associated with the actual gas, one must employ the following definitions:

$$x'_s = \frac{c'_s}{c'} \quad (2.470)$$

$$c'_s = c_s \quad (2.471)$$

$$\tilde{D}_{sr}^e = \frac{c' \tilde{D}'_{sr}}{c} \quad (2.472)$$

$$\tilde{D}_{sK}^e = \frac{\tilde{D}'_{s,N+1}}{x'_{N+1}} \quad (2.473)$$

$$x_s = \frac{c_s}{c} \quad (2.474)$$

$$\mathbf{N}'_s = \mathbf{N}_s \quad (2.475)$$

Multiplying the first term on the LHS of (2.469) by  $c'/c'$ , we obtain:

$$-\sum_{r=1}^N \frac{\mathbf{N}'_s x'_r c' - \mathbf{N}'_r x'_s c'}{c'^2 \tilde{D}'_{sr}} = -\sum_{r=1}^N \frac{\mathbf{N}_s c_r - \mathbf{N}_r c_s}{c'^2 \tilde{D}'_{sr}} = -\sum_{r=1}^N \frac{\mathbf{N}_s x_r - \mathbf{N}_r x_s}{c' \tilde{D}_{sr}^e} \quad (2.476)$$

The mass fraction of species  $s$  can be expressed as:

$$\begin{aligned}
\omega'_s &= \frac{m_s}{m_{total}} = \frac{\frac{m_s}{V}}{\frac{m_{total}}{V}} = \frac{\rho_s}{\rho_{total}} = \frac{\rho_s}{\sum_{r=1}^N \rho_r + \rho_{N+1}} = \frac{c_s M_{w_s}}{\sum_{r=1}^N (c_r M_{w_r}) + c_{N+1} M_{w_{N+1}}} \quad (2.477)
\end{aligned}$$

When  $M_{w_{N+1}} \rightarrow \infty$ ,  $\omega'_s \rightarrow 0$ , so the last term on the RHS of (2.469) vanishes. Hence, (2.469) becomes:

$$-\sum_{r=1}^N \frac{\mathbf{N}_s x_r - \mathbf{N}_r x_s}{\tilde{D}_{sr}^e} - \frac{\mathbf{N}'_s x'_{N+1}}{\tilde{D}'_{s,N+1}} \approx c_s \nabla (\ln T) + \nabla c_s \quad (2.478)$$

By employing the relations;  $\tilde{D}_{sK}^e = \frac{\tilde{D}'_{s,N+1}}{x'_{N+1}}$  and  $\mathbf{N}'_s = \mathbf{N}_s$ , we get:

$$-\sum_{r=1}^N \frac{\mathbf{N}_s x_r - \mathbf{N}_r x_s}{\tilde{D}_{sr}^e} - \frac{\mathbf{N}_s}{\tilde{D}_{sK}^e} = c_s \nabla(\ln T) + \nabla c_s \quad (2.479)$$

Moreover, by use of the ideal gas law;  $c_s = \frac{p_s}{RT}$ , the RHS can be manipulated like:

$$\begin{aligned} -\sum_{r=1}^N \frac{\mathbf{N}_s x_r - \mathbf{N}_r x_s}{\tilde{D}_{sr}^e} - \frac{\mathbf{N}_s}{\tilde{D}_{sK}^e} &= \frac{p_s}{RT} \nabla(\ln T) + \nabla \frac{p_s}{RT} \\ &= \frac{p_s}{RT^2} \nabla T + \nabla \frac{p_s}{RT} \\ &= \frac{p_s}{RT^2} \nabla T + \frac{p_s}{R} \nabla \left( \frac{1}{T} \right) + \frac{1}{RT} \nabla p_s \\ &= \frac{p_s}{RT^2} \nabla T - \frac{p_s}{RT^2} \nabla T + \frac{1}{RT} \nabla p_s \\ &= \frac{1}{RT} \nabla p_s = \frac{c}{p} \nabla p_s \approx c \nabla x_s \end{aligned} \quad (2.480)$$

Note that the final expression on the RHS is valid for ideal gases at constant pressure only.

By splitting the combined molar flux (2.393), we obtain:

$$\sum_{r=1}^N \frac{(\mathbf{J}_s^* + c_s \mathbf{v}_m^*) x_r - (\mathbf{J}_r^* + c_r \mathbf{v}_m^*) x_s}{\tilde{D}_{sr}^e} + \frac{\mathbf{J}_s^* + c_s \mathbf{v}_m^*}{\tilde{D}_{sK}^e} \approx -c \nabla x_s \quad (2.481)$$

By simple manipulation, the commonly used mole form of the dusty gas model is achieved:

$$\sum_{r=1}^N \frac{\mathbf{J}_s^* x_r - \mathbf{J}_r^* x_s}{\tilde{D}_{sr}^e} + \frac{\mathbf{J}_s^* + c_s \mathbf{v}_m^*}{\tilde{D}_{sK}^e} \approx -c \nabla x_s \quad (2.482)$$

It is sometimes advantageous to use an explicit expression, similar to (2.406), for the diffusive flux. To achieve such an expression, we must reformulate the model by first re-arranging the terms in the following way:

$$\mathbf{J}_s^* \sum_{r=1}^N \frac{x_r}{\tilde{D}_{sr}^e} - \sum_{r=1}^N \frac{\mathbf{J}_r^* x_s}{\tilde{D}_{sr}^e} + \frac{\mathbf{J}_s^*}{\tilde{D}_{sK}^e} + \frac{c_s \mathbf{v}_m^*}{\tilde{D}_{sK}^e} \approx -c \nabla x_s \quad (2.483)$$

Since the terms occurring for  $r = s$  in the two sums cancel out, we get:

$$\mathbf{J}_s^* \left( \sum_{\substack{k=1 \\ k \neq s}}^N \frac{x_k}{\tilde{D}_{sk}^e} + \frac{1}{\tilde{D}_{sK}^e} \right) - \sum_{\substack{r=1 \\ r \neq s}}^N \frac{\mathbf{J}_r^* x_s}{\tilde{D}_{sr}^e} + \frac{c_s \mathbf{v}_m^*}{\tilde{D}_{sK}^e} \approx -c \nabla x_s \quad (2.484)$$

or, explicitly:

$$\mathbf{J}_s^* \approx D_s^e \left( \sum_{\substack{r=1 \\ r \neq s}}^N \frac{\mathbf{J}_r^* x_s}{\tilde{D}_{sr}^e} - \frac{c_s \mathbf{v}_m^*}{\tilde{D}_{sK}^e} - c \nabla x_s \right) \quad (2.485)$$

where

$$D_s^e \approx \left( \sum_{\substack{k=1 \\ k \neq s}}^N \frac{x_k}{\tilde{D}_{sk}^e} + \frac{1}{\tilde{D}_{sK}^e} \right)^{-1} \quad (2.486)$$

In some cases the convective term on the LHS of (2.482) can be neglected since  $\mathbf{J}_s^* \gg c_s \mathbf{v}_m^*$ . For such problems the dusty gas model (2.482) reduces to:

$$\sum_{\substack{r=1 \\ r \neq s}}^N \frac{\mathbf{J}_s^* x_r - \mathbf{J}_r^* x_s}{\tilde{D}_{sr}^e} + \frac{\mathbf{J}_s^*}{\tilde{D}_{sK}^e} \approx -c \nabla x_s \quad (2.487)$$

This relation can be written in the matrix form:

$$\mathbf{J}_s^* \left( \sum_{\substack{k=1 \\ k \neq s}}^N \frac{x_k}{\tilde{D}_{sk}^e} + \frac{1}{\tilde{D}_{sK}^e} \right) - \sum_{\substack{r=1 \\ r \neq s}}^N \frac{\mathbf{J}_r^* x_s}{\tilde{D}_{sr}^e} \approx -c \nabla x_s \quad (2.488)$$

or more compactly:

$$\mathbf{J}_s^* B_{ss} + \sum_{\substack{r=1 \\ r \neq s}}^N \mathbf{J}_r^* B_{sr} \approx -c \nabla x_s \quad (2.489)$$

with the coefficients:

$$B_{ss} = \left( \sum_{\substack{k=1 \\ k \neq s}}^N \frac{x_k}{\tilde{D}_{sk}^e} + \frac{1}{\tilde{D}_{sK}^e} \right) \quad (2.490)$$

and

$$B_{sr} = -\frac{x_s}{\tilde{D}_{sr}^e} \quad (2.491)$$

In vector notation, the flux relation (2.489) can thus be expressed in terms of the  $[B]$  matrix:

$$[B] \mathbf{J}^* = -c \nabla \mathbf{x} \quad (2.492)$$

After multiplying both sides by  $[B]^{-1}$ , this relation takes a more convenient form:

$$\mathbf{J}^* = -c[B]^{-1} \nabla \mathbf{x} \quad (2.493)$$

It is emphasized that in this description the gas molecule-dust interactions are accounted for by a set of effective Knudsen diffusion coefficients. Therefore, the dusty gas model contains two types of effective binary diffusion coefficients, the effective binary pair diffusivities in the porous medium and the effective Knudsen diffusivities. The effective diffusivities are related to the corresponding molecular diffusivities by:

$$\tilde{D}_{sr}^e = \tilde{D}_{sr} \frac{\varepsilon}{\tau} \quad (2.494)$$

and

$$\tilde{D}_{sK}^e = \tilde{D}_{sK} \frac{\varepsilon}{\tau} \quad (2.495)$$

where the porosity-to-tortuosity factor ( $\frac{\varepsilon}{\tau}$ ) characterizes the porous matrix and is best determined by experiment. Epstein [38] provides physical interpretations of the  $\varepsilon$  and  $\tau$  parameters. For dilute gases, both the molecular bulk and Knudsen diffusivities can be derived from kinetic theory.

#### *Mass based dusty-gas model*

On the mass basis, the dusty gas model can be written in analogy to (2.469) in the following way:

$$-\sum_{r=1}^N \frac{\frac{\mathbf{n}'_s x'_r x'_s}{\omega'_s} - \frac{\mathbf{n}'_r x'_s x'_r}{\omega'_r}}{\rho' \tilde{D}'_{sr}} - \frac{\frac{\mathbf{n}'_s x'_s x'_{N+1}}{\omega'_s}}{\rho' \tilde{D}'_{s,N+1}} = \frac{c'_s \nabla(\ln T)}{c'} + \frac{\nabla c'_s}{c'} \quad (2.496)$$

when  $M_{w_{N+1}} \rightarrow \infty$ ,  $\omega'_s \rightarrow 0$  in accordance with (2.477).

To close the mass form of the dusty gas model, using a similar transformation procedure as employed for the mole based formulation, three novel definitions are required:

$$\mathbf{n}'_s = \mathbf{n}_s \quad (2.497)$$

$$\mathbf{j}'_s = \mathbf{j}_s \quad (2.498)$$

$$\rho'_s = \rho_s \quad (2.499)$$

We multiply the first term on the LHS by  $c'^2/c'^2$  and the second term on the LHS by  $c'/c'$ :

$$-\sum_{r=1}^N \frac{\frac{\mathbf{n}_s}{\omega'_s} (x'_r c') (x'_s c') - \frac{\mathbf{n}_r}{\omega'_r} (x'_s c') (x'_r c')}{(c')^2 \rho' \tilde{D}'_{sr}} - \frac{\frac{\mathbf{n}_s}{\omega'_s} (x'_s c') x'_{N+1}}{c' \rho' \tilde{D}'_{s,N+1}} = \frac{c'_s \nabla(\ln T)}{c'} + \frac{\nabla c'_s}{c'} \quad (2.500)$$

Thereby, all the primed terms of the pseudo-mixture can then be transformed into the actual un-primed variables:

$$-\sum_{r=1}^N \frac{\frac{n_s}{\rho_s} c_r c_s - \frac{n_r}{\rho_r} c_s c_r}{c D_{sr}^e} - \frac{\frac{n_s}{\rho_s} c_s}{D_{sK}^e} = c_s \nabla(\ln T) + \nabla c_s \quad (2.501)$$

Thereafter, the terms containing the actual un-primed mixture variables can be re-written by use of (2.394) and the ideal gas law:

$$\sum_{r=1}^N \frac{\frac{x_r x_s}{\omega_s} \mathbf{j}_s - \frac{x_s x_r}{\omega_r} \mathbf{j}_r}{D_{sr}^e} + \frac{\frac{x_s}{\omega_s} \mathbf{j}_s + \mathbf{v}_m c_s M_w}{D_{sK}^e} = -\rho \nabla x_s \quad (2.502)$$

This form of the mass based dusty gas model equation, which corresponds with the mole based formulation (2.481), is restricted to constant pressure systems.

To enable effective computations it is convenient to rewrite the mole fractions into mass fractions, hence the dusty gas model takes the form:

$$\frac{M_w^2}{M_{w_s}} \sum_{\substack{r=1 \\ r \neq s}}^N \frac{\omega_r \mathbf{j}_s - \omega_s \mathbf{j}_r}{M_{w_r} D_{sr}^e} + \frac{M_w \mathbf{j}_s + \mathbf{v}_m \rho_s M_w}{M_{w_s} D_{sK}^e} = -\frac{\rho}{M_{w_s}} (\omega_s \nabla M_w + M_w \nabla \omega_s) \quad (2.503)$$

From this expression an explicit expression for  $\mathbf{j}_s$  can be obtained:

$$\mathbf{j}_s = D_s^e \left( M_w^2 \sum_{\substack{r=1 \\ r \neq s}}^N \frac{\omega_r \mathbf{j}_r}{M_{w_r} D_{sr}^e} - \frac{\mathbf{v}_m \rho_s M_w}{D_{sK}^e} - \rho (\omega_s \nabla M_w + M_w \nabla \omega_s) \right) \quad (2.504)$$

where

$$D_s^e = \left( M_w^2 \sum_{\substack{r=1 \\ r \neq s}}^N \frac{\omega_r}{M_{w_r} D_{sr}^e} + \frac{M_w}{D_{sK}^e} \right)^{-1} \quad (2.505)$$

In the particular cases in which the convective term can be neglected,  $\mathbf{j}_s \gg \rho \mathbf{v}_m \omega_s$ , the dusty gas model (2.503) reduces to:

$$M_w^2 \sum_{\substack{r=1 \\ r \neq s}}^N \frac{\omega_r \mathbf{j}_s - \omega_s \mathbf{j}_r}{M_{w_r} D_{sr}^e} + \frac{M_w \mathbf{j}_s}{D_{sK}^e} = -\rho (\omega_s \nabla M_w + M_w \nabla \omega_s) \quad (2.506)$$

The model can be written in a matrix form:

$$\mathbf{j}_s \left( M_w^2 \sum_{\substack{k=1 \\ k \neq s}}^N \frac{\omega_k}{M_{w_k} D_{sk}^e} + \frac{M_w}{D_{sK}^e} \right) - M_w^2 \sum_{\substack{r=1 \\ r \neq s}}^N \frac{\omega_s \mathbf{j}_r}{M_{w_r} D_{sr}^e} = -\rho (\omega_s \nabla M_w + M_w \nabla \omega_s) \quad (2.507)$$

A more compact notation is obtained introducing two coefficient matrices:

$$\mathbf{j}_s B_{ss} + \sum_{\substack{r=1 \\ r \neq s}}^N \mathbf{j}_r B_{sr} = -\rho(\omega_s \nabla M_w + M_w \nabla \omega_s) \quad (2.508)$$

The coefficient matrices are defined by:

$$B_{ss} = M_w^2 \sum_{\substack{k=1 \\ k \neq s}}^N \frac{\omega_k}{M_{w_k} D_{sk}^e} + \frac{M_w}{D_{sK}^e} \quad (2.509)$$

and

$$B_{sr} = -M_w^2 \frac{\omega_s}{M_{w_r} D_{sr}^e} \quad (2.510)$$

In vector notation, the mass based dusty gas model becomes:

$$\mathbf{j} = -\rho[B'']^{-1}(\omega \nabla M_w + M_w \nabla \omega) \quad (2.511)$$

From (2.480) a less restricted driving force can be derived avoiding the constant pressure assumption. The extended driving force can be expressed by:

$$\mathbf{d}_s \approx c \frac{\nabla p_s}{p} \approx \frac{\nabla(p x_s)}{RT} = \frac{1}{M_{w_s} RT} (p(\omega_s \nabla M_w + M_w \nabla \omega_s) + M_w \omega_s \nabla p) \quad (2.512)$$

In this case the dusty gas diffusive mass flux can be written as:

$$\mathbf{j} = -\rho[B'']^{-1} \frac{1}{RT} (p\omega \nabla M_w + pM_w \nabla \omega + M_w \omega \nabla p) \quad (2.513)$$

The design of a complete set of *governing equations* for the description of reactive flows requires that the combined fluxes are treated in a convenient way. In principle, several combined flux definitions are available. However, since the mass fluxes with respect to the mass average velocity are preferred when the equation of motion is included in the problem formulation, we apply the species mass balance equations to a  $q$ -component gas system with  $q - 1$  independent mass fractions  $\omega_s$  and an equal number of independent diffusion fluxes  $\mathbf{j}_s$ . However, any of the formulations derived for the multicomponent mass diffusion flux can be substituted into the species mass balance (1.39), hence a closure selection optimization is required considering the specified restrictions for each constitutive model and the computational efforts needed to solve the resulting set of model equations for the particular problem in question.

The notation and definitions used for the molar and mass based concentrations, compositions and velocities characterizing multicomponent mixtures, as well as the relationships between these variables are summarized in Table 2.2.

**Table 2.2** Notation for concentrations and velocities in multicomponent mixtures

Algebraic concentration and velocity relations:

$$c_s = \rho_s / M_{\omega_s} \qquad \rho_s = c_s M_{\omega_s} \qquad (2.514)$$

$$c = \sum_{s=1}^N c_s \qquad \rho = \sum_{s=1}^N \rho_s \qquad (2.515)$$

$$x_s = c_s / c \qquad \omega_s = \rho_s / \rho \qquad (2.516)$$

$$\sum_{s=1}^N x_s = 1 \qquad \sum_{s=1}^N \omega_s = 1 \qquad (2.517)$$

$$M_{\omega} = \sum_{s=1}^N x_s M_{\omega_s} \qquad \frac{1}{M_{\omega}} = \sum_{s=1}^N \frac{\omega_s}{M_{\omega_s}} \qquad (2.518)$$

$$x_s = \frac{\omega_s / M_{\omega_s}}{\sum_{r=1}^N \omega_r / M_{\omega_r}} \qquad \omega_s = \frac{x_s M_{\omega_s}}{\sum_{r=1}^N x_r M_{\omega_r}} \qquad (2.519)$$

$$\mathbf{v}^* = \sum_{r=1}^N \omega_s \mathbf{v}_s \qquad \mathbf{v} = \sum_{r=1}^N \omega_s \mathbf{v}_s \qquad (2.520)$$

$$\mathbf{v} - \mathbf{v}^* = \sum_{r=1}^N \omega_s (\mathbf{v}_s - \mathbf{v}^*) \qquad \mathbf{v}^* - \mathbf{v} = \sum_{r=1}^N x_s (\mathbf{v}_s - \mathbf{v}) \qquad (2.521)$$

Differential composition relations for multicomponent mixtures [9]:

$$\nabla x_s = -\frac{M_{\omega}^2}{M_{\omega_s}} \sum_{\substack{r=1 \\ r \neq s}}^N \left[ \frac{1}{M_{\omega}} + \omega_s \left( \frac{1}{M_{\omega_r}} - \frac{1}{M_{\omega_s}} \right) \right] \nabla \omega_r \qquad (2.522)$$

$$\nabla \omega_s = -\frac{M_{\omega_s}}{M_{\omega}^2} \sum_{\substack{r=1 \\ r \neq s}}^N \left[ M_{\omega} + x_s (M_{\omega_r} - M_{\omega_s}) \right] \nabla x_r \qquad (2.523)$$

Differential composition relations for binary systems [9]:

$$\nabla x_1 = \frac{\frac{1}{M_{\omega_1} M_{\omega_2}} \nabla \omega_1}{\left( \frac{\omega_1}{M_{\omega_1}} + \frac{\omega_2}{M_{\omega_2}} \right)^2} \qquad (2.524)$$

$$\nabla \omega_1 = \frac{M_{\omega_1} M_{\omega_2} \nabla x_1}{(x_1 M_{\omega_1} + x_2 M_{\omega_2})^2} \qquad (2.525)$$

### 2.9.6 Polyatomic Reactive Systems

For polyatomic reactive systems the mixture continuity, momentum and energy equations seemingly remain unchanged compared to the corresponding conservation equations for multicomponent non-reacting mono-atomic gases, as  $m_s$ ,  $m_s \mathbf{C}_s$ , and  $e_s^{\text{total}} = \frac{1}{2} m_s C_s^2 + e_s^{\text{int}}$  are summation invariants. Note that  $e_s^{\text{total}}$  denotes the total energy which equals the sum of the translational and internal energy forms. The polyatomic molecules have rotational and vibrational energy modes and the corresponding internal degrees of freedom [129]. Moreover, for polyatomic reactive systems the species mass balance deviates from the corresponding one for non-reactive systems in that it includes a reaction rate term resulting from collisions of molecules of type  $s$  with all types of molecules [55]. This means that when deriving this particular transport equation from basic principles, the collision term on the RHS of the Boltzmann equation (2.296) must be modified to account for the effects of chemical reactions. Correspondingly, transforming the mixture energy balance in terms of temperature the resulting temperature equation is slightly dif-

ferent from that of mono-atomic gases in that it contains a heat of reaction term. In addition, as expected, the Enskog perturbation solution of the mixture Boltzmann equation (2.289) is more involved than the corresponding one for simple systems containing one type of species only. However, the expressions for the fluxes in terms of the distribution function are unaffected by the reaction taking place in the gas mixture.

### 2.9.6.1 An Outline of the Seminal Friction Coefficient Concept of Maxwell

Maxwell [95, 97] was the first to derive a set of diffusion equations in a form analogous to (2.397) for dilute binary gas mixtures using kinetic theory arguments. Maxwell's [95, 97] seminal idea was that concentration gradients result from the friction between the molecules of different species, hence the proportionality coefficients,  $\hat{C}_{sk}$ , were interpreted as inverse friction or drag coefficients.

The rigorous derivation of the Maxwell-Stefan equations by use of the kinetic theory of dilute gases has already been explained in connection with (2.383) to (2.392). Nevertheless, although not very useful in practical application, it might be informative from a physical point of view to start out from the complete macroscopic species momentum balance when examining the consistent derivation of the Maxwell-Stefan equations in terms of the mass diffusion fluxes. However, it is noted that the following macroscopic derivation is not as rigorous as the alternative kinetic theory approach. The linear momentum principle for species  $s$  states that the rate of change of momentum is balanced by the forces acting on the system and the rate of production of momentum of species  $s$  [110, 159]:

$$\begin{aligned} \frac{D}{Dt} \int_{V_s(t)} \rho_s \mathbf{v}_s dv &= \int_{V_s(t)} \rho_s \mathbf{g}_s dv + \int_{A_s(t)} \mathbf{n} \cdot \mathbf{T}_s da + \int_{V_s(t)} \sum_{r=1}^N \mathbf{P}_{sr} dv \\ &+ \int_{V_s(t)} r_s \mathbf{v}_s^* dv \end{aligned} \quad (2.526)$$

where  $\rho_s \mathbf{g}_s$  represents the body force acting on species  $s$ . The term  $\mathbf{n} \cdot \mathbf{T}_s$  represents the species stress vector. The term  $\mathbf{P}_{sr}$  denotes the force per unit volume exerted by species  $r$  on species  $s$ , and the sum in the balance equation represents the force exerted on species  $s$  by all the other species. The last term  $r_s \mathbf{v}_s^*$  designates the source of species momentum. Note that the velocity of the molecules of species  $s$  generated by chemical reaction,  $\mathbf{v}_s^*$ , need not be equal to the species  $s$  velocity  $\mathbf{v}_s$ .

To convert the system balance description into an Eulerian control volume formulation the transport theorem is employed (i.e., expressed in terms of the species  $s$  velocity,  $\mathbf{v}_s$ ):

$$\frac{D}{Dt} \int_{V_s(t)} f dv = \int_{V_s} \frac{\partial f}{\partial t} dv + \int_{A_s} f \mathbf{v}_s \cdot \mathbf{n} da \quad (2.527)$$

in which  $f$  represents any scalar, vector or tensor valued function.

To convert the area integrals into volume integrals the Gauss theorem is used (App A) in the standard manner.

The transformed momentum balance yields:

$$\int_{V_s} \left( \frac{\partial(\rho_s \mathbf{v}_s)}{\partial t} + \nabla \cdot (\rho_s \mathbf{v}_s \mathbf{v}_s) - \rho_s \mathbf{g}_s - \nabla \cdot \mathbf{T}_s - \sum_{r=1}^N \mathbf{P}_{sr} - r_s \mathbf{v}_s^* \right) dv = 0 \quad (2.528)$$

From Chap. 1 it is known that this balance has to be valid for any volume, hence the integral argument must be equal to zero:

$$\frac{\partial(\rho_s \mathbf{v}_s)}{\partial t} + \nabla \cdot (\rho_s \mathbf{v}_s \mathbf{v}_s) - \rho_s \mathbf{g}_s - \nabla \cdot \mathbf{T}_s - \sum_{r=1}^N \mathbf{P}_{sr} - r_s \mathbf{v}_s^* = 0 \quad (2.529)$$

This balance equation can also be derived from kinetic theory [159]. In the Maxwellian average Boltzmann equation for the species  $s$  type of molecules, the collision operator does not vanish because the momentum  $m_s \mathbf{c}_s$  is not an invariant quantity. Rigorous determination of the collision operator in this balance equation is hardly possible, thus an appropriate model closure for the diffusive force  $\mathbf{P}_{sr}$  is required. Maxwell [95] proposed a model for the diffusive force based on the principles of kinetic theory of dilute gases. The dilute gas kinetic theory result of Maxwell [95] is generally assumed to be an acceptable form for dense gases and liquids as well, although for these mixtures the binary diffusion coefficient is a concentration dependent, experimentally determined empirical parameter.

The elementary modeling of the *diffusion force* is outlined in the sequel. For dilute multicomponent mixtures only elastic binary collisions are considered and out of these merely the unlike-molecule collisions result in a net transfer of momentum from one type of species to another. The overall momentum is conserved since all the collisions are assumed to be elastic (see Sect. 2.4.2.1), hence the net force acting on species  $s$  from  $r$  per unit volume,  $\mathbf{P}_{sr}$  equals the momentum transferred from  $r$  to  $s$  per unit time and unit volume (see e.g., [30] and [109], Sect. 4-2).

The diffusion force yields:

$$\mathbf{P}_{sr} = \mathbf{M}_{sr} Z_{sr} \quad (2.530)$$

where  $\mathbf{M}_{sr}$  represents the momentum flux transferred per collision, and  $Z_{sr}$  denotes the number of collisions between species  $s$  and  $r$  molecules per unit time and unit volume (the collision density).

Several closures have been proposed to calculate the collision density for molecules in gas mixtures [109] (pp. 52–55). To derive these expressions for the collision density one generally perform an analysis of the particle-particle interactions in an imaginary container [80, 109, 135], called the conceptual collision cylinder in kinetic theory, as outlined in Sect. 2.4.2.5. A fundamental assumption in this concept is that the rate of molecular collisions in a gas depends upon the size, number density, and average speed of the molecules. Following Maxwell [95] each type of molecules are considered hard spheres, resembling billiard balls, having diameter  $d_s$ , mass  $m_s$  and number density  $n_s$ . These hard spheres exert no forces on

each other except when they collide. Moreover, the collisions are perfectly elastic and obey the classical conservation laws of momentum and energy. In addition, the particles are uniformly distributed through the gas. Different approximations of the hitherto unknown average molecular speeds  $\langle c_s \rangle_M$  and  $\langle c_r \rangle_M$  can then be made. Suppose that a molecule of type  $s$  moves with an average speed of  $\langle |\mathbf{c}_s| \rangle_M = \langle c_s \rangle_M$  in an imaginary container that contains both  $s$  and  $r$  molecules. Preliminary, in line with the early models, we may assume that the molecules of  $r$  are stationary (this restriction will be removed shortly). Since we are using the billiard ball molecular model, a collision occurs each time the distance between the center of a molecule  $s$  and a molecule  $r$  becomes equal to  $d_{sr} = (d_s + d_r)/2$  in accordance with (2.142). This means that if we construct an imaginary sphere of radius  $d_{sr}$  around the center of molecule  $s$ , a collision occurs every time another molecule  $r$  is located within this sphere as the molecule  $s$  enclosed within the imaginary sphere travels with its average speed sweeping out a cylindrical volume  $\sigma_{AT} \langle c_s \rangle_M = \pi d_{sr}^2 \langle c_s \rangle_M$  per unit time. The total collision cross section is defined by (2.151). If  $n_r$  is the total number of  $r$  molecules per unit mixture volume, the number of centers of  $r$  molecules in the volume swept out is  $\sigma_{AT} \langle c_s \rangle_M n_r$ . This number equals the number of collisions experienced by the one molecule of  $s$  in unit time, hence the collision frequency (2.167) can be expressed by:

$$Z_{s-r} = \sigma_{AT} \langle c_s \rangle_M n_r \quad (2.531)$$

in which the same notation as used in the last part of Sect. 2.4.2 is employed. A reasonable approximation of the molecular speed may be calculated from the Maxwellian distribution function following the kinetic theory presented in Sect. 2.4.2.

Moreover, if there is a total of  $n_s$  molecules of  $s$  per unit volume in addition to the  $r$  molecules, the collision density  $Z_{sr}$  denoting the total number of  $s-r$  collisions per unit volume per unit time is:

$$Z_{sr} = Z_{s-r} n_s = \sigma_{AT} \langle c_s \rangle_M n_r n_s \quad (2.532)$$

If only the  $s$  type of molecules are present, the collision density  $Z_{ss}$  represents the collisions of  $s$  molecules with one another. The expression for this density resembles that for  $Z_{sr}$  but a pre-factor  $1/2$  has to be introduced to avoid counting each collision twice:

$$Z_{ss} = \frac{1}{2} \sigma_{AT} \langle c_s \rangle_M n_s n_s \quad (2.533)$$

This expression coincides with (2.165) when the speed is calculated from the Maxwellian velocity distribution function.

In the collision density formulas presented so far the target molecules  $r$  within the collision cylinder are assumed stagnant, hence only the averaged speed  $\langle c_s \rangle_M$  of the  $s$  molecules is considered. A better estimate of the collision density might be obtained allowing the target molecules to move within the collision cylinder, thus the average relative speeds  $\langle |\mathbf{c}_{\text{rel},sr}| \rangle_M$  and  $\langle |\mathbf{c}_{\text{rel},ss}| \rangle_M$  of the molecules should be used instead of the average speed of the individual species. Furthermore, dealing with a

mixture containing two types of molecules  $s$  and  $r$  of different masses, the  $\langle c_s \rangle_M$  and  $\langle c_r \rangle_M$  values are different. A fairly accurate model is achieved considering that the average relative speed is given by  $\langle |\mathbf{c}_{\text{rel},sr}| \rangle_M = (\langle c_s \rangle_M^2 + \langle c_r \rangle_M^2)^{1/2}$ . This average speed relation is derived using the Maxwellian distribution function as shown by Present [109] (p. 79, p. 53, p. 30). A rigorous collision density model can then be expressed as:

$$Z_{sr} = \sigma_{AT} \langle |\mathbf{c}_{\text{rel},sr}| \rangle_M x_r x_s n^2 = \sigma_{AT} \sqrt{\langle c_s \rangle_M^2 + \langle c_r \rangle_M^2} x_r x_s n^2 \quad (2.534)$$

If the gas contains only type  $s$  molecules, the average relative speed of two molecules becomes  $\langle |\mathbf{c}_{\text{rel},ss}| \rangle_M = (\langle c_s \rangle_M^2 + \langle c_s \rangle_M^2)^{1/2} = \sqrt{2} \langle c_s \rangle_M$ . Hence, the expression for  $Z_{ss}$  has to be modified replacing  $\langle c_s \rangle_M$  by  $\sqrt{2} \langle c_s \rangle_M$ , giving:

$$Z_{ss} = \frac{1}{\sqrt{2}} \sigma_{AT} \langle c_s \rangle_M n_s n_s \quad (2.535)$$

The corresponding expression for the number of collisions of one molecule of  $s$  per unit time, when only  $s$  molecules are present, becomes:

$$Z_s = \sqrt{2} \sigma_{AT} \langle c_s \rangle_M n_s \quad (2.536)$$

It is noted that the collision cross-sectional area, also referred to as the total scattering cross section (2.151), can be approximated in different ways too. In one approach the target particles are approximated as point-like particles. Thus, the cross section of the target particles are not considered in calculating the effective cross-sectional area, so  $\sigma_{AT} \approx \pi d_s^2/4$ . To achieve an improved estimate of the effective cross-sectional area the size of the target particles should be taken into account as well, thus  $\sigma_{AT} = \pi d_{sr}^2$ .

The net *momentum flux* transferred from molecules of type  $s$  to molecules of type  $r$  can be approximated by the difference between the average momentum of molecule  $s$  before and after the collision:

$$\mathbf{M}_{sr} = m_s (\mathbf{v}_s - \mathbf{v}'_s) \quad (2.537)$$

In the literature the net momentum flux transferred from molecules of type  $s$  to molecules of type  $r$  has either been expressed in terms of the average diffusion velocity for the different species in the mixture [109] or the average species velocity is used [148]. Both approaches lead to the same relation for the diffusion force and thus the Maxwell-Stefan multicomponent diffusion equations. In this book we derive an approximate formula for the diffusion force in terms of the average velocities of the species in the mixture. The diffusive fluxes are introduced at a later stage by use of the combined flux definitions. Nevertheless, the given momentum flux formula (2.537) is not useful before the unknown average velocity after the collisions  $\mathbf{v}'_s$  has been determined. For elastic molecular collisions this velocity can be calculated, in

an averaged sense, from the classical momentum conservation law and the definition of the center of mass velocity as elucidated in the following.

The velocity of the center of mass, as defined relative to a fixed point in space, can be obtained from the expression given for position vector of the center of mass (2.104):

$$\mathbf{G} = \frac{m_s \mathbf{v}_s + m_r \mathbf{v}_r}{m_s + m_r} \quad (2.538)$$

If all possible particle-particle approaches are considered, the ensemble average velocities after the collision will be equal to  $\mathbf{G} = \mathbf{G}' = \text{Constant}$ , because all directions of reflection or rebound are assumed to occur with equal likelihood in kinetic theory of dilute gases [109]. By ensemble averaging, we may write:

$$\mathbf{v}'_s = \mathbf{v}'_r = \mathbf{G}' = \mathbf{G} \quad (2.539)$$

One recalls from (1.345) that the ensemble averaged of a species  $k$  velocity  $\langle \mathbf{c}'_k \rangle_e$  is defined by:

$$\mathbf{v}'_k = \langle \mathbf{c}'_k \rangle_e = \frac{1}{N} \sum_{i=1}^N \mathbf{c}'_{k,i} \quad (2.540)$$

where  $N$  is the number of events (collisions) observed.

An ensemble averaged momentum balance considering  $N$  binary collisions between  $s$  and  $r$  molecules is obtained by averaging (2.107). The result is:

$$m_s \mathbf{v}_s + m_r \mathbf{v}_r = m_s \mathbf{v}'_s + m_r \mathbf{v}'_r \quad (2.541)$$

Inserting (2.539) into (2.541) gives:

$$m_s \mathbf{v}_s + m_r \mathbf{v}_r = m_s \mathbf{v}'_s + m_r \mathbf{v}'_r = m_s \mathbf{G}' + m_r \mathbf{G}' = (m_s + m_r) \mathbf{G}' \quad (2.542)$$

Solving for  $\mathbf{v}'_s = \mathbf{G}'$  the relation becomes:

$$\mathbf{v}'_s = \mathbf{G}' = \frac{m_s \mathbf{v}_s + m_r \mathbf{v}_r}{m_s + m_r} = \text{Constant} \quad (2.543)$$

By assuming that an ensemble average velocity equals a Maxwellian average velocity, we might introduce (2.543) into (2.537). In this way we get:

$$\mathbf{M}_{sr} = m_s \left( \mathbf{v}_s - \frac{m_s \mathbf{v}_s + m_r \mathbf{v}_r}{m_s + m_r} \right) \quad (2.544)$$

If we multiply the first term on the RHS by  $\frac{m_s + m_r}{m_s + m_r}$ , the relation can be manipulated as:

$$\begin{aligned}
\mathbf{M}_{sr} &= m_s \left( \mathbf{v}_s \left( \frac{m_s + m_r}{m_s + m_r} \right) - \frac{m_s \mathbf{v}_s + m_r \mathbf{v}_r}{m_s + m_r} \right) \\
&= m_s \left( \frac{m_s \mathbf{v}_s + m_r \mathbf{v}_s - m_s \mathbf{v}_s - m_r \mathbf{v}_r}{m_s + m_r} \right) \\
&= m_s \left( \frac{m_r \mathbf{v}_s - m_r \mathbf{v}_r}{m_s + m_r} \right) \\
&= \frac{m_s m_r (\mathbf{v}_s - \mathbf{v}_r)}{m_s + m_r}
\end{aligned} \tag{2.545}$$

By inserting (2.534) and (2.545) into (2.530), the diffusion force can be expressed as:

$$\mathbf{P}_{sr} = \mathbf{M}_{sr} Z_{sr} = x_r x_s (\mathbf{v}_s - \mathbf{v}_r) \frac{m_s m_r \pi n^2 d_{sr}^2 \sqrt{\langle c_s \rangle_M^2 + \langle c_r \rangle_M^2}}{m_s + m_r} \tag{2.546}$$

It has been proposed to insert a proportionality (drag or friction) coefficient that does not depend on the mole fractions and the velocities  $\mathbf{v}_s$  and  $\mathbf{v}_r$ . The diffusion force is thus expressed as:

$$\mathbf{P}_{sr} = x_r x_s (\mathbf{v}_s - \mathbf{v}_r) f_{sr} \tag{2.547}$$

The binary friction coefficient has been related to the binary diffusivity by the following relation [95, 148]:

$$f_{sr} = \frac{p}{\tilde{D}_{sr}} \tag{2.548}$$

The diffusion force thus becomes <sup>37</sup>:

$$\mathbf{P}_{sr} = \frac{p x_r x_s (\mathbf{v}_s - \mathbf{v}_r)}{\tilde{D}_{sr}} \tag{2.549}$$

By inserting (2.549) into (2.529), the species momentum equation yields:

$$\begin{aligned}
\frac{\partial(\rho_s \mathbf{v}_s)}{\partial t} + \nabla \cdot (\rho_s \mathbf{v}_s \mathbf{v}_s) &= \rho_s \mathbf{g}_s + \nabla \cdot \mathbf{T}_s + \sum_{r=1}^N \mathbf{P}_{sr} + r_s \mathbf{v}_s^* \\
&= \rho_s \mathbf{g}_s - \nabla p_s + \nabla \cdot \boldsymbol{\sigma}_s + p \sum_{r=1}^N \frac{x_r x_s (\mathbf{v}_r - \mathbf{v}_s)}{\tilde{D}_{sr}} + r_s \mathbf{v}_s^*
\end{aligned} \tag{2.550}$$

In deriving (2.550), the species stress tensor has been decomposed in the standard manner:

$$\mathbf{T}_s = -p_s \mathbf{e} + \boldsymbol{\sigma}_s \tag{2.551}$$

---

<sup>37</sup> This model was first obtained by Maxwell [95] for binary systems. Present [109] (Sect. 8-3) outlines a more accurate treatment by the moment transfer method which is not restricted to the billiard-ball molecular representation.

where  $\sigma_s$  is the species  $s$  viscous stress tensor.

The balance (2.550) can be simplified to obtain the Maxwell-Stefan equation, due to the following assumption:

$$\frac{\partial(\rho_s \mathbf{v}_s)}{\partial t} + \nabla \cdot (\rho_s \mathbf{v}_s \mathbf{v}_s) - \rho_s \mathbf{g}_s - \nabla \cdot \sigma_s - r_s \mathbf{v}_s^* \ll p \sum_{r=1}^N \frac{x_r x_s (\mathbf{v}_r - \mathbf{v}_s)}{\tilde{D}_{sr}} - \nabla p_s \quad (2.552)$$

It has been shown that this inequality is valid for a wide variety of conditions [159]. That is, (2.550) can be reduced to:

$$p \sum_{r=1}^N \frac{x_r x_s (\mathbf{v}_r - \mathbf{v}_s)}{\tilde{D}_{sr}} \approx \nabla p_s = p \nabla x_s + x_s \nabla p \quad (2.553)$$

If the pressure gradient in the last term on the RHS is small, the Maxwell-Stefan equation (2.392) is reproduced for the particular cases in which the driving force can be approximated by the mole fraction gradient, the gravity force is the only body force acting on the system and the thermal diffusion is neglectable.

The result is:

$$\sum_{r=1}^N \frac{x_r x_s (\mathbf{v}_r - \mathbf{v}_s)}{\tilde{D}_{sr}} - \nabla x_s \gg \frac{x_s}{p} \nabla p, \quad (2.554)$$

Therefore, the Maxwell-Stefan equations might be considered a particular approximate form of the species momentum equation.

### 2.9.6.2 Applications of Multicomponent Mass Diffusion Flux Models in Chemical Reactor Engineering

In chemical engineering multicomponent mass diffusion phenomena might be important in describing several unit operations like reaction and separation vessels containing either gas or liquid mixtures. Examples of practical applications of the different multicomponent diffusion flux model expressions are outlined in this subsection. For convenience, only dilute gas mixtures are considered for which the kinetic theory of dilute gases is valid. The modeling of multicomponent mass diffusion in fixed packed bed catalyst pellets is examined. This modeling problem has been chosen because it is well known from introductory chemical reaction engineering subjects.

#### *Relevance and previous investigations*

Heterogeneous catalysis is of utmost significance in many fields of gas conversion and processing in chemical industries. Fixed packed bed reactors are widely used for heterogeneous catalysis of many of these processes. Accurate modeling of intra-particle heat and mass transport is a prerequisite for the design of many industrial processes and the interpretation of experiments. To describe the mass diffusion processes within

the pores in catalyst pellets, three fundamentally different types of mass diffusion mechanisms [70, 71, 94] are distinguished:

- *Bulk diffusion* that are significant for large pore sizes and high system pressures in which gas molecule-molecule collisions dominate over gas molecule-wall collisions.
- *Knudsen diffusion* becomes predominant when the mean-free path of the molecular species is much larger than the pore diameter and hence molecule-wall collisions become important.
- *Surface diffusion* of adsorbed molecular species along the pore wall surface. This mechanism of transport becomes dominant for micro-pores and for strongly adsorbed species. Extensions of the Maxwell-Stefan bulk diffusion model have been proposed in order to provide a realistic description of the combined bulk, Knudsen and surface diffusion mechanisms, apparently with limited success [70, 71].

Fick's first law [40] is strictly only valid for binary mixtures. Hence, due to the shortcoming of the well-known Fick's Law of binary diffusion, numerous models for multicomponent diffusion are proposed in the literature to describe these diffusion fluxes. The Wilke [161] and Maxwell-Stefan [96, 142] diffusion flux models assume bulk diffusion, whereas the dusty gas model [62, 94] describes the combined bulk and Knudsen diffusion fluxes in the gas transition transport regime. As a simplification to the dusty gas model, the Wilke model in combination with the Bosanquet formula [11] has been proposed. However, the validity of Knudsen diffusion modeling by the dusty gas and Wilke-Bosanquet models are subjected to criticism in the literature, see for example, the recent review by Krishna [76]. Mathematical modeling of intra-particle mass and heat transport in porous pellets has thus been widely investigated by numerous researchers, e.g., [12, 34, 51, 125, 127, 128, 155, 156], because the intra-particle transport limitations often play an important role in the design of chemical reactors. Most mass diffusion problems in chemical reactor processes involve transport of multicomponent mixtures. Numerous modeling approaches have frequently been adopted considering the intra-particle heat and mass transfer limitations. An efficiency factor is used in the simpler pseudo-homogeneous reactor models to account for the intra-particle transport limitations. Hence, the solid material is not explicitly taken into account. The efficiency factor is normally computed by use of the more rigorous heterogeneous reactor models consisting of a set of equations describing the heat and mass transport processes within the pellets. The intra-particle mass diffusion fluxes may be described by the Maxwell-Stefan, Wilke, dusty gas, or the Wilke-Bosanquet models. A survey of the use of multicomponent diffusion flux closures in chemical reaction engineering for the analysis of internal pellet heat and mass transfer limitations for processes operated in packed fixed bed reactors are provided in the following.

Apécetche et al. [1] studied viscous and diffusive transport with simultaneous reaction in non-isobaric porous catalyst particles by use of the dusty gas model. A binary gaseous mixture under isothermal conditions was studied taking into account mass transfer due to the following mechanisms; viscous flow, non-equimolar

flow, bulk diffusion and Knudsen diffusion. An irreversible,  $m$ -th order reaction kinetics with respect to the gaseous reactant was assumed. It was shown that the non-isobaric effectiveness factor is significantly different from the isobaric one. A maximum pressure gradient of about 10% in the catalyst pellet was produced by Knudsen diffusion.

Burghardt and Aerts [12] proposed a method for evaluation of the pressure change in an isothermal porous pellet within which a single chemical reaction takes place, accompanied by mass transfer by Knudsen diffusion, bulk diffusion and viscous convective flow of the reacting mixture. The pressure change did also depend on the reaction and on the mixture composition on the pellet surface. It was concluded that the pressure changes in a catalyst pellet under conditions normally encountered in industry are most likely so small that they can be neglected in process simulations.

Graaf et al. [51] used the dusty gas model to investigate the relative importance of Knudsen and bulk diffusion for the intra-particle diffusion limitation problem for the methanol synthesis. In their steady-state model, they neglected the pressure gradient and assumed isothermal conditions throughout the spherical particle. Their simulation results indicated that both bulk and Knudsen diffusion mechanisms should be incorporated in the single pellet model to obtain reliable results.

Salmi and Wärnå [125] neglected the effect of Knudsen diffusion and applied the Maxwell-Stefan and Wilke models in their transport model for the catalyst pellet. Moreover, pressure changes inside the pellet were neglected and steady-state conditions were assumed to prevail. They assumed isotropic pore structure catalyst properties and included the energy balance equation in their model. The pellet equations were combined with the corresponding balances of the bulk phase collectively constituting a heterogeneous reactor model. For the water-gas shift reaction and methanol synthesis their simulation results indicated that the differences between the Maxwell-Stefan and Wilke models were minor on the level of a fixed-bed reactor, but becomes of interest for detailed calculations of single pellets.

Elnashaie and Abashar [34] developed a mathematical model to investigate the phenomena of diffusion and chemical reactions in porous catalyst pellets for steam reforming. The rigorous dusty gas model was compared to the simpler Wilke-Bosanquet model under the assumptions of steady-state, negligible viscous flow and isothermal conditions. It was found that at low steam to methane ratios the simplified diffusion model is adequate for simulating the reforming process, while at high steam to methane ratios the implementation of the dusty gas model is essential for accurate prediction of the behavior for this gas-solid system.

More recently, Solsvik and Jakobsen [140] performed a numerical study comparing several closures for mass diffusion fluxes of multicomponent gas mixtures; the Wilke, Maxwell-Stefan, dusty gas, and Wilke-Bosanquet models, on the level of the single catalyst pellet and the impacts of the mass diffusion flux closures employed for the pellet, on the reactor performance. For this investigation, the methanol synthesis operated in a fixed packed bed reactor was the chemical process adopted. In the mathematical modeling study of a novel combined catalyst/sorbent pellet, Rout et al. [121] investigated the performance of the sorption-enhanced steam methane reforming (SE-SMR) process at the level of a single pellet. Different closures

for multicomponent mass diffusion fluxes, the effect of viscous flow, and the significance of Knudsen diffusion were analyzed. Moreover, deviating effects of choosing the random-pore, multi-grain, and the parallel-pore models were studied. Solsvik and Jakobsen [137] extended the study of the combined catalyst/sorbent pellet including also the effects of pellet structure changes due to product layer generation. In this numerical analysis, both the dusty gas and Maxwell-Stefan models were adopted in the analysis of different pellet model description complexities and the sensitivity to model parameters. Rout and Jakobsen [122] further investigated possible reactor performance optimizations employing such a combined pellet reflecting both catalyst and adsorbent properties. It is noted that the mass diffusion flux closures based on the mass average velocity definition are not frequently employed in the literature. On the other hand, the mole based diffusion flux models are not consistent with the continuum mechanical reactive flow model as the fundamental energy and momentum balances are conventionally derived based on the mass average velocity definition due to the physical laws applied; the Navier-Stokes and first laws of thermodynamics. However, the novel mass based pellet equations are adopted in the recent modeling work of Kuijlaars et al. [77], Rout et al. [121] and Solsvik and Jakobsen [136, 138, 140]. For the steam methane reforming (SMR) process, methanol synthesis, and dimethyl ether production, Solsvik and Jakobsen [136, 138] derived a pellet model on both a mass and mole basis and compared the simulation results of the two model formulations. Unexpectedly, deviations between the simulation results of the mole and mass formulated pellet models were obtained. Inconsistency between the mass and mole formulations were also observed in the pellet modeling study of Rout and Jakobsen [122]. For this reason, Solsvik et al. [139] presented a throughout modeling and simulation study of mass and mole based pellet models with the aim to elucidate the effects of different modeling assumptions on the simulation results in order to propose reduced pellet model formulations that give identical simulation results for the mole and mass formulations. The SMR process and the methanol synthesis were adopted for this investigation because the two processes cover various aspects of a chemical reaction; for example, (i) one of them is very endothermic, the other exothermic, (ii) on a net basis one of them produce gas molecules, the other consumes gas molecules, and (iii) one of them is strongly diffusion limited, while the other is not. Some general conclusions regarding model discrimination can be drawn. Compared to the Wilke and Wilke-Bosanquet models the more rigorous Maxwell-Stefan equations and the dusty gas model should rather be used in industrial reaction engineering applications as these model formulations are rigorous and ensure  $\sum_{s=1}^N \mathbf{j}_s = 0$  and  $\sum_{s=1}^N \omega_s = 1$ , whereas these constraints are not always satisfied when the Wilke approximation is employed. Moreover, the simplifying assumption of a constant total pressure and thus negligible gas velocity and convective transport in porous pellets is generally a good approximation. However, such model reductions may strongly influence the consistency between the mass and mole based models.

*Models for pellet porosity and pore structure*

The relationship between the structure of a porous medium and transport phenomena occurring within the void space of the material is of great importance because the internal architecture of the porous media significantly influences the transport processes occurring within them. Hence, there are two essential aspects for the understanding of chemical processes in porous media; the structural, which is associated with the topological and morphological characteristics of the interstitial void space, and the second aspect makes a reference to the transport mechanisms and physico-chemical interactions taking place at the pore level. The effective diffusivity is a measure of the diffusivity that accounts for: (i) not all area normal to the flux direction is available for molecules to diffuse in a porous particle, (ii) diffusion paths are tortuous, (iii) pore cross-sections vary, and (iv) internal void fraction. A geometrical model of the pore system is adopted in order to convert the molecular diffusivity into the effective diffusivity. Hence, the effective diffusivity is determined based on the molecular diffusivity and the pore structure of the porous pellet. The optimum model is a realistic representation of the geometry of the voids that can be described in terms of easily measurable physical properties of the pellet. The structure of porous media is often characterized in terms of parameters such as the voidage fraction (porosity), pore size distribution, specific surface area, pore network lattice size and connectivity.

Smith [134] discusses the simple parallel-pore and random-pore models, which are extensively adopted in chemical reactor engineering describing the effective diffusivities of porous material. The parallel-pore model presents a mono-disperse pore-size distribution in a porous pellet with the following effective diffusivity [3, 126]:

$$D^e = \frac{\epsilon}{\tau} D \quad (2.555)$$

where  $\epsilon$  denotes the pellet porosity and  $\tau$  represents the tortuosity. The random pore model supposes that the pellet consists of an assembly of small particles. When the particles themselves contain pores, there exists a strongly bi-modal pore size distribution. Hence, transport in the pellet is assumed to occur by a combination of diffusion through the inter-particle and intra-particle voids. The resultant expression for the effective diffusivity may be written as:

$$D^e = D_1 \epsilon_1^2 + \frac{\epsilon_2^2 (1 + 3\epsilon_1)}{1 - \epsilon_1} D_2 \quad (2.556)$$

where  $\epsilon_1$  denotes the inter-particle voids and  $\epsilon_2$  is the void fraction of intra-particle channels. The random pore model can also be applied to mono-disperse systems:

$$D^e = D \epsilon^2 \quad (2.557)$$

The non-catalytic heterogeneous solid fluid reaction shrinking core model [41, 78, 130, 158] provides an overall or effective reaction rate constituting an approximate

description of the external film resistance, the internal diffusion resistance and the chemical reaction resistance.

For a reacting pellet at some intermediate stage of conversion, the following steps can occur in series:

- Gaseous species A diffuses through the film surrounding the pellet to its surface.
- Gaseous species A penetrates and diffuses through the blanket of product solid to reach the reaction front.
- Gaseous species A reacts with reactant B in the narrow reaction zone.
- Gaseous reaction products diffuse through the product layer from the reaction zone to the surface of the particle.
- Gaseous reaction products diffuse into the main gas stream.

The resulting effective reaction rate,  $r_{\text{eff},A}$ , can be expressed as:

$$r_{\text{eff},A} \approx \frac{4\pi C_{A0}}{\left[ \frac{1}{R^2 k_{mA}} + \frac{1}{D_{eA}} \left( \frac{1}{r_c} - \frac{1}{R} \right) + \frac{1}{r_c^2 a k_s C_{S0}} \right]} \quad (2.558)$$

where  $k_{mA}$  is the mass transfer coefficient of species A from the bulk of the fluid phase to the solid surface across the film,  $C_{S0}$  is the concentration of solid reactant in the unreacted core which is assumed to be constant for uniform particles,  $C_{A0}$  is the concentration of fluid reactant A in the bulk of fluid stream,  $R$  is the radius of the particle,  $r_c$  is the radius of the unreacted core,  $a$  is the stoichiometric coefficient representing the number of moles of fluid species A that will react with 1 mole of solid reactant S,  $k_s$  is the reaction rate constant based on the reacting surface area, and  $D_{eA}$  is the effective diffusivity of fluid A in the ash layer. The three terms in the denominator represent the three resistances in series for the reaction considered; external film diffusional-, internal diffusion- and chemical reaction resistances, respectively. The shrinking core model is used to describe situations in which solid particles are being consumed either by dissolution or reaction thus the amount of the particle material being consumed is shrinking. This model applies to areas like the formation of an ash layer around a burning coal particle, catalyst regeneration, and adsorbent particle adsorption and desorption processes.

The grain- or multigrain model consists of separate model equations for characteristic grains or micro-particles and the macro-scale pellet. The characteristic micro-grain is described by the following diffusion-reaction partial- differential equation for the product species  $s$ :

$$\frac{\partial \rho_s(r, t)}{\partial t} + \frac{1}{r^2} \frac{\partial}{\partial r} (r^2 j_{A,r}^{mg}(r, t)) + R_A(r, t) \quad (2.559)$$

where the reaction is supposed to take place in the grains only, and  $r$  is the radial coordinate for the micro-particle.

The following initial and boundary conditions are normally employed:

$$\rho_s(r, t) = \rho_s(r, t_0), \quad \forall r \quad (2.560)$$

$$\frac{\partial j_{A,r}^{mg}(r, t)}{\partial r} = 0, \quad r = 0, \quad t > 0 \quad (2.561)$$

$$j_{A,r}^{mg}(r_S, t) = -k_L^{mg}(\rho_s(R, t) - \rho_s(r_S, t)), \quad r = r_S, \quad t > 0 \quad (2.562)$$

where  $k_L^{mg}$  denotes a local mass transfer coefficient for the micro-grains, and  $r_S$  is the radius of the micro-grain.

The pellet equation is expressed as:

$$\frac{\partial \rho_s(R, t)}{\partial t} + \frac{1}{R^2} \frac{\partial}{\partial R} (R^2 j_{A,R}(R, t)) + k_L^{mg} a^{mg} (\rho_s(R, t) - \rho_s(r_S, t)) \quad (2.563)$$

where the last term denotes the effective reaction rate at any location  $R$  in the pellet,  $a^{mg}$  represent the micro-grain area concentration and  $R$  is the radial coordinate in the pellet.

The following initial and boundary conditions are normally employed:

$$\rho_s(R, t) = \rho_s(R, t_0), \quad \forall R \quad (2.564)$$

$$\frac{\partial j_{A,R}(R, t)}{\partial R} = 0, \quad R = 0, \quad t > 0 \quad (2.565)$$

$$j_{A,R_S}(R, t) = k_{L,p} a_p (\rho_s(\mathbf{r}, t) - \rho_s(R_S, t)) \quad R = R_S, \quad t > 0 \quad (2.566)$$

where  $R_S$  denotes the radius of the pellet,  $K_{L,p}$  the pellet mass transfer coefficient, and  $a_p$  is the pellet area concentration.

This fundamental form of the grain model is rather time consuming to solve, thus several simplified forms have been proposed over the years. Debling and Ray [31] and Kittilsen et al. [64] examined similar multi-grain models and model simplifications employed in polymerization processes. The grain models by [44, 54, 145, 146] consider pellets that are formed by compacting fine grains of particles with or without some binding agents. The pellet overall shape and the shape of the individual grains that make up the pellet is usually irregular. However, to allow a convenient analysis of the grain pellet problem, the pellet is normally considered spherical made up of individual spherical grains of equal size. There are normally two cases postulated on the basis of physical reasoning: (a) A region of chemical control in which the pellets react uniformly throughout the pellet volume. (b) A region of diffusion control with a sharp reaction zone. Rout et al. [123] did employ a similar grain model for describing the multicomponent mass diffusion fluxes and overall reaction rate in sorbent particles for the SE-SMR process.

A variety of modeling approaches for the geometrical pellet structure are given in the literature. Further details are given by, e.g., [33, 56, 124]. It is noticed that in practical reaction engineering, the classical models are most frequently used due to the complexity of the pellet structure.

**Table 2.3** Diffusion flux closures based on the mass average velocity definition

Wilke:

$$\mathbf{j}_s = -\rho D'_{sm} \nabla \omega_s \quad \text{where} \quad D'_{sm} = \frac{1 - \omega_s}{M_\omega \sum_{\substack{r=1 \\ r \neq s}}^N \frac{\omega_r}{M_{\omega r} D_{sr}}} \quad (2.450)$$

Wilke-Bosanquet:

$$\mathbf{j}_s = -\rho D''_{s,\text{eff}} \nabla \omega_s \quad \text{where} \quad \frac{1}{D''_{s,\text{eff}}} = \frac{1}{D'_{sm}} + \frac{1}{D_{s,K}} \quad (2.454)$$

Maxwell-Stefan:

$$\mathbf{j}_s = \frac{-\rho \omega_s \nabla \ln(M) - \rho \nabla \omega_s + M \omega_s \sum_{\substack{r=1 \\ r \neq s}}^N \frac{\mathbf{j}_r}{M_{\omega r} D_{sr}}}{M_\omega \sum_{\substack{r=1 \\ r \neq s}}^N \frac{\omega_r}{M_{\omega r} D_{sr}}} \quad (2.421)$$

Dusty gas:

$$\mathbf{j}_s = \frac{M_\omega^2 \sum_{\substack{r=1 \\ r \neq s}}^N \frac{\omega_s \mathbf{j}_r}{M_{\omega r} D_{sr}} - \frac{\mathbf{v}_s M}{D_{s,K}} - \rho(\omega_s \nabla M_\omega + M_\omega \nabla \omega_s)}{M_\omega^2 \sum_{\substack{r=1 \\ r \neq s}}^N \frac{\omega_r}{M_{\omega r} D_{sr}} + \frac{M}{D_{s,K}}} \quad (2.504)$$

### Pellet equations

For multicomponent mixtures the governing species mass balance can be written on the vector form:

$$\frac{\partial(\rho \omega_s)}{\partial t} + \nabla \cdot (\rho \mathbf{v}_m \omega_s) = -\nabla \cdot \mathbf{j}_s + \mathbf{r}_s \quad (2.567)$$

where  $\omega_s$ ,  $\mathbf{j}_s$  and  $r_s$  denote the mass fractions of species  $s$ , the diffusion flux of species  $s$ , and the  $q$  independent reactions, respectively.

For multicomponent systems the diffusive flux terms may be written in accordance with the approximate Wilke bulk flux equation (2.450), the approximate Wilke-Bosanquet combined bulk and Knudsen flux for porous media (2.454), the rigorous Maxwell-Stefan bulk flux equations (2.421), and the consistent dusty gas combined bulk and Knudsen diffusion flux for porous media (2.504). The different mass based diffusion flux models are listed in Table 2.3. The corresponding molar based diffusion flux models are listed in Table 2.4. In most simulations, the catalyst pellet is approximated by a porous spherical pellet with center point symmetry. For such spherical pellets a representative system of pellet model equations, constitutive laws and boundary conditions are listed in Tables 2.5, 2.6 and 2.7, respectively.

### Viscous flow in pellet pores

In pellet model analysis in which the convective transport of heat and species mass in porous catalyst pellets have to be taken into account simulating catalytic reactor processes, either the Maxwell-Stefan mass flux equations (2.416) or dusty gas model for the mass fluxes (2.513) might be used. The possible viscous flow in the catalyst pores is driven by a pressure gradient induced by the potential non-uniform spatial species composition and temperature evolution created by the chemical reactions.

**Table 2.4** Diffusion flux closures based on the molar average velocity definition

Wilke:

$$\mathbf{J}_s = -c D_{sm} \nabla x_s \quad \text{where} \quad D_{sm} = \frac{1-x_s}{\sum_{\substack{r=1 \\ r \neq s}}^N \frac{x_r}{D_{sr}}} \quad (2.439)$$

Wilke-Bosanquet:

$$\mathbf{J}_s = -c D_{s,\text{eff}} \nabla x_s \quad \text{where} \quad \frac{1}{D_{s,\text{eff}}} = \frac{1}{D_{sm}} + \frac{1}{D_{s,K}} \quad (2.452)$$

Maxwell-Stefan:

$$\mathbf{J}_s = \frac{-c \nabla x_s + \sum_{\substack{r=1 \\ r \neq s}}^N \frac{\mathbf{J}_r x_s}{D_{sr}}}{\sum_{\substack{r=1 \\ r \neq s}}^N \frac{x_r}{D_{sr}}} \quad (2.406)$$

Dusty gas:

$$\mathbf{J}_s = \frac{\sum_{\substack{r=1 \\ r \neq s}}^N \frac{\mathbf{J}_r x_s}{D_{sr}} - \frac{c_s \mathbf{v}^*}{D_{s,K}} - c \nabla x_s}{\sum_{\substack{r=1 \\ r \neq s}}^N \frac{x_r}{D_{sr}} + \frac{1}{D_{s,K}}} \quad (2.485)$$

**Table 2.5** Mass and molar based pellet equations in spherical coordinates*Molar based equations.*

Continuity:

$$\epsilon_p \frac{\partial c}{\partial t} + \frac{1}{r^2} \frac{\partial}{\partial r} (r^2 u_r^s c) = \sum_s S_s \quad (2.571)$$

Species mass balance:

$$\epsilon_p \frac{\partial}{\partial t} (c x_s) + \frac{1}{r^2} \frac{\partial}{\partial r} (r^2 u_r^s c x_s) = -\frac{1}{r^2} \frac{\partial}{\partial r} (r^2 J_{s,r}) + S_s \quad (2.572)$$

Heat balance:

$$\begin{aligned} & \left( (1 - \epsilon_p) C p_p'' \rho_p + \epsilon_p c \sum_{s=1}^N x_s C p_s'' \right) \frac{\partial T}{\partial t} \\ & = -c \sum_{s=1}^N x_s C p_s v_r^s \frac{\partial T}{\partial r} - \frac{1}{r^2} \frac{\partial}{\partial r} (r^2 Q_r) + \hat{S} \end{aligned} \quad (2.573)$$

*Mass based equations.*

Continuity:

$$\epsilon_p \frac{\partial \rho}{\partial t} + \frac{1}{r^2} \frac{\partial}{\partial r} (r^2 v_r^s \rho) = 0 \quad (2.574)$$

Species mass balance:

$$\epsilon_p \frac{\partial}{\partial t} (\rho \omega_s) + \frac{1}{r^2} \frac{\partial}{\partial r} (r^2 v_r^s \rho \omega_s) = -\frac{1}{r^2} \frac{\partial}{\partial r} (r^2 j_{s,r}) + S_s'' \quad (2.575)$$

Heat balance:

$$\begin{aligned} & \left( (1 - \epsilon_p) C p_p'' \rho_p + \epsilon_p \rho \sum_{s=1}^N \omega_s C p_s'' \right) \frac{\partial T}{\partial t} \\ & = -\rho \sum_{s=1}^N \omega_s C p_s v_r^s \frac{\partial T}{\partial r} - \frac{1}{r^2} \frac{\partial}{\partial r} (r^2 Q_r) + \hat{S} \end{aligned} \quad (2.576)$$

The pressure gradient in porous media is usually related to the consistent viscous gas velocity through a correlation inspired by the *Darcy's law* [29] (see e.g., [9, 71] and [132], p. 197):

$$\mathbf{v}_m = -\frac{B_0}{\mu} \nabla p \quad (2.568)$$

**Table 2.6** Constitutive laws

Ideal gas law:

$$p = cRT = \frac{\rho RT}{M_w} \quad (2.577)$$

Darcy's law (viscous gas flow) [70]:

$$\mathbf{v} = -\frac{B}{\mu} \nabla p \quad (2.578)$$

Permeability (Poiseuille flow relationship for cylindrical pores) [70]:

$$B = \frac{d_{\text{pore}}^2}{32} \quad (2.579)$$

Heat flux (Fourier's law):

$$\mathbf{Q}_r = -k \frac{\partial T}{\partial r} \quad (2.580)$$

Mole and mass source terms:

$$S_s = (1 - \epsilon_p) \rho_p r_s \quad (2.581)$$

$$S_s'' = (1 - \epsilon_p) \rho_p M_{\omega_s} r_s \quad (2.582)$$

Heat source term:

$$\hat{S} = (1 - \epsilon_p) \rho_p \sum_{k=1}^q (-\Delta H_{r_k}) r_k \quad (2.583)$$

**Table 2.7** Initial and boundary conditions*Molar based equations*

Initial conditions:

$$\begin{cases} x_s = x_s^b \\ J_{s,r} = 0 \\ T = T^b \\ Q_r = 0 \\ c = c^b \end{cases} \quad \text{for } t = 0, \forall r \quad (2.584)$$

Boundary conditions for symmetry point,  $r = 0$ :

$$J_{s,r} = 0 \quad (2.586)$$

$$Q_r = 0 \quad (2.588)$$

Boundary conditions for surface,  $r = r_p$ :

$$-k_s (c_s^b - x_s c) = J_{s,r} + u_r^s c x_s \quad (2.590)$$

$$Q_r + c C p_g T v_r = -h(T^b - T) \quad (2.592)$$

$$c = c^b \quad (2.594)$$

*Mass based equations*

Initial conditions:

$$\begin{cases} \omega_s = \omega_s^b \\ j_{s,r} = 0 \\ T = T^b \\ Q_r = 0 \\ \rho = \rho^b \end{cases} \quad \text{for } t = 0, \forall r \quad (2.585)$$

Boundary conditions for symmetry point,  $r = 0$ :

$$j_{s,r} = 0 \quad (2.587)$$

$$Q_r = 0 \quad (2.589)$$

Boundary conditions for surface,  $r = r_p$ :

$$-k_s (\rho_s^b - \omega_s \rho) = j_{s,r} + v_r^s \rho \omega_s \quad (2.591)$$

$$Q_r + \rho C p_g'' T v_r = -h(T^b - T) \quad (2.593)$$

$$\rho = \rho^b \quad (2.595)$$

Generally, the permeability  $B_0$  ( $m^2$ ) has to be determined experimentally. However, for simple structures the permeability coefficient  $B_0$  can be determined analytically. Considering a cylindrical pore, for example, the permeability can be calculated from the Poiseuille flow relationship [71]:

$$B_0 = \frac{d_0^2}{32} \quad (2.569)$$

For the multi-grain model [155]:

$$B_0 = \frac{2\epsilon_p}{9\tau(1-\epsilon)} S^2 \quad (2.570)$$

in which  $S$  is the radius of the micro-particle.

Solving this flow model for the velocity the pressure is calculated from the ideal gas law. The temperature therein is obtained from the heat balance and the mixture density is estimated from the sum of the species densities. It is noted that the viscous velocity is normally computed from the pressure gradient by use of a phenomenologically derived constitutive correlation, known as Darcy's law, which is based on laminar shear flow theory [139]. Laminar shear flow theory assumes no slip condition at the solid wall, inducing viscous shear in the fluid. Knudsen diffusion and slip flow at the solid matrix separate the gas flow behavior from Darcy-type flow. Whenever the mean free path of the gas molecules approaches the dimensions of pore diameter, the individual gas molecules are in motion at the interface and contribute an additional flux. This phenomena is called slip flow. In slip flow, the layer of gas next to the surface is in motion with respect to the solid surface. Strictly, the Darcy's law is valid only when the flow regime is laminar and dominated by viscous forces. The theoretical foundation of the dusty gas model considers that the model is applied to a transition regime between Knudsen and continuum bulk diffusion. To estimate the combined flux, the model is based on the assumption that the combined flux can be expressed as a linear sum of the Knudsen flux and the convective flux due to laminar flow.

## 2.10 Mean Free Path Concept

In this section the transport properties are determined by use of the empirical method suggested by Maxwell [95], on the basis of Clausius' mean free path concept. That is, instead of determining the transport properties from the rather theoretical Enskog solution of the Boltzmann equation, for practical applications we may often resort to the much simpler but still fairly accurate mean free path approach (e.g., [20], Sect. 5.1; [48], Sect. 9.6; [119], Chap. 20). Actually, the form of the relations resulting from the mean free path concept are about the same as those obtained from the much more complex theories, and even the values of the pre-factors are considered sufficiently accurate for many reactor modeling applications.

### 2.10.1 Transport Properties

The overall aim in this analysis is to determine a rough estimate of the transfer fluxes in dilute one-component gases using the elementary mean free path concept in kinetic theory. In this approach it is assumed that the only means for transport of information in the fluid is via molecular collisions. Due to the physical similarity

of the flux phenomena of mass, momentum and energy, a common mathematical formalism is outlined (e.g., [55], Sect. 2; [90], Sect. 3.4.2; [109], Sect. 3-4; [162] app E;). Considering a dilute gas containing  $n$  molecules per unit volume inducing a macroscopic transfer flux of property  $\psi$ . The symbol  $\psi$  denotes any property of a single molecule that can be changed by collisions, and  $\langle\psi\rangle_M$  represents the average value of  $\psi$  for the gas. The molecules are assumed to move in a geometrical configuration in which  $\frac{\partial\langle\psi\rangle_M}{\partial x} = \frac{\partial\langle\psi\rangle_M}{\partial y} = 0$ , so that the molecular motion transport the property  $\langle\psi\rangle_M$  in the  $z$ -direction only. For illustrative purposes we consider a gas confined between two infinite parallel planes denoted by  $z = z_0$  and  $z = z_2$ . Imagine a net flux of the properties in the positive  $z$ -direction through a plane at an arbitrary location  $z = z_1$  between the two planes located at  $z = z_0$  and  $z = z_2$ . Let  $F_\psi$  denote the net molecular flux of the property  $\psi$  in the  $z$ -direction.

At each collision it is assumed to be an equalizing transfer of properties between the two molecules, so in consequence  $F_{z_1}$  is determined by the relative location of the last collision experienced by a molecule before it crosses the plane at  $z = z_1$ . This particular distance is thus expected to be related to the mean free path,  $l$ . It is supposed throughout this analysis that the mean free path is small compared to the dimensions of the vessel containing the gas.

It may be expected that on the average molecules crossing the plane  $z = z_1$  from the  $z_1 - l$  side will transfer the property  $\psi_{z_1-l}$  and those crossing from the  $z_1 + l$  side will transfer the property  $\psi_{z_1+l}$ . Hence,  $F_{z_1} = \Gamma\langle\psi\rangle_M|_{z_1-l} - \Gamma\langle\psi\rangle_M|_{z_1+l}$ , where  $\Gamma_{z_1-l}$  denotes the number of molecules per unit area per second crossing the plane  $z = z_1$  from the  $z_1 - l$  side and  $\Gamma_{z_1+l}$  denotes the number of molecules per unit area per second crossing the plane  $z = z_1$  from the  $z_1 + l$  side. This means that  $\Gamma_{z_1-l} = \Gamma_{z_1+l} = \Gamma_{z_1}$ , where  $\Gamma_{z_1} = \frac{1}{6}\langle|C|\rangle_M n$ . The factor  $\frac{1}{6}$  accounts for the fact that only one-sixth of the molecules on plane  $\Gamma_{z_1-l}$  move in the  $(+z)$ -direction.<sup>38</sup> Hence:

$$F_{\psi,z_1} = \frac{1}{6}\langle|C|\rangle_M n (\langle\psi\rangle_M|_{z_1-l} - \langle\psi\rangle_M|_{z_1+l}) \quad (2.596)$$

The properties  $\langle\psi\rangle_M|_{z_1-l}$  and  $\langle\psi\rangle_M|_{z_1+l}$  in (2.596) may then be expanded in a Taylor series about  $z = z_1$ , since the mean free path is small compared to the distance over which  $\langle\psi\rangle_M$  changes appreciably. Neglecting terms of order higher than one the result is<sup>39</sup>:

<sup>38</sup> Consider isotropic molecular motion in a Cartesian coordinate system. If there are  $n$  molecules per unit volume, about one-third of them have velocities along the  $x$ -direction. Half of these, i.e.,  $\frac{1}{6}N$  per unit volume, move in the  $(+x)$ -direction and the other half of them move in the  $(-x)$ -direction. Accordingly, one-sixth of the  $N$  molecules move in the  $(+y)$ -direction, another one-sixth of the them move in the  $(-y)$ -direction, another one-sixth of them in the  $(+z)$ -direction, and finally the last one-sixth of them will move in the  $(-z)$ -direction.

<sup>39</sup> The subscript  $z_1$  is omitted since the choice of the position  $z = z_1$  was arbitrary.

$$F_{\psi, z_1} = \frac{1}{6} \langle |C| \rangle_M n (\langle \psi \rangle_M|_{z-l} - \langle \psi \rangle_M|_{z+l}) = \frac{2l \langle |C| \rangle_M}{6} n \left( \frac{\langle \psi \rangle_M|_{z-l} - \langle \psi \rangle_M|_{z+l}}{2l} \right) \quad (2.597)$$

$$\approx - \frac{l \langle |C| \rangle_M}{3} n \frac{d\langle \psi \rangle_M}{dz} \quad (2.598)$$

It has also been assumed that the gradient of the property  $\langle \psi \rangle_M$  is constant over distances of the order  $l$ .

To determine the species mass diffusion a concentration gradient is induced by assuming that the species number concentration is different at each of the planes  $z_0, z_1, z_2$ . To estimate the viscosity we create a gradient in the  $z$ -momentum by assuming that the molecules at the plane  $z_0$  are moving in the negative  $z$ -direction, at the plane  $z_1$  the molecules are stationary, and those at plane  $z_2$  are moving in the positive  $z$ -direction. To induce a thermal conduction flux the three planes are taken to be at different temperatures. Then, the specific fluxes are achieved letting the symbol  $F_\psi$  successively represent the  $y$ -component of the flux of momentum through a plane with normal in the  $z$ -direction, the flux of energy through the same plane, and the mass flux of species  $c$  through the same plane, respectively. The symbol  $\langle \psi \rangle$  represents correspondingly the  $y$ -direction momentum per molecule of mass  $m$ ,  $mv_y$ , the energy per particle ( $me$ ), and the mass per molecule of species  $c$ ,  $m_c$ .

Comparing the fluid dynamic closures with the corresponding kinetic theory results we see that:

$$F_{mv_y} = -\frac{1}{3} \langle |C| \rangle_M l n m \frac{dv_y}{dz} = P_{yz} = -\mu \frac{dv_y}{dz} \quad (2.599)$$

$$F_{me} = -\frac{1}{3} \langle |C| \rangle_M l n m \frac{de}{dT} \left|_V \frac{dT}{dz} \right. = q_z = -k \frac{dT}{dz} \quad (2.600)$$

$$F_{m\omega_c} = -\frac{1}{3} \langle |C| \rangle_M l n m \frac{d\omega_c}{dz} = j_z = -\rho D \frac{d\omega_c}{dz} \quad (2.601)$$

The molecular fluxes can be extended to systems containing gradients in the other two space dimensions as well, denoting a complete three dimensional flux formulation.

It is noted that in determining the viscosity parameter we consider a spatially uniform fluid in a state of shear such that  $\mathbf{v} = v_y(z)\mathbf{e}_y$ . In the heat conduction case we imagine that a gas is heated at constant volume so that all the energy supplied is increasing the energy of the molecules, thus  $n[d(me)/dT] = \rho C_v$ , where  $C_v = \frac{3k}{2m}$  is the specific heat per unit mass at constant volume. The mass diffusion flux is determined considering a binary mixture in which both the total pressure and temperature are uniform. The form of the species mass flux used above deviates from the standard literature on elementary kinetic theory in that the mass fraction is used instead of the species number density. A brief discussion of the two formulations is given by Rohsenow and Choi ([119], p. 495).

The standard self-diffusion flux can be derived in a similar way. The flux of particles in the positive  $z$ -direction that crosses the  $z_1$  plane is equal to the number of molecules that reach the same plane from  $z_1 - l$ , minus those that reach it from  $z_1 + l$ . The result is [90]:

$$\begin{aligned}
\Gamma_{z1} &= \Gamma|_{z1-l} - \Gamma|_{z1+l} = \frac{1}{6} \langle |\mathbf{C}| \rangle_M (\langle n \rangle_M|_{z-l} - \langle n \rangle_M|_{z+l}) \\
&= \frac{2l \langle |\mathbf{C}| \rangle_M}{6} \left( \frac{\langle n \rangle_M|_{z-l} - \langle n \rangle_M|_{z+l}}{2l} \right) \\
&\approx -\frac{l \langle |\mathbf{C}| \rangle_M}{3} \frac{d \langle n \rangle_M}{dz} = -D \frac{d \langle n \rangle_M}{dz}
\end{aligned} \tag{2.602}$$

Comparing the two last terms, we may conclude:  $D = \frac{1}{3} l \langle |\mathbf{C}| \rangle_M$ .

The molecular flux models are still not closed as the mean free path  $l$  and the molecular speed quantities  $\langle |\mathbf{C}| \rangle_M$  are not determined yet. A frequently used closure is examined in the next paragraph.

### 2.10.2 Mean Free Path

In this section approximate mathematical models determining the molecular mean free path are derived. It is anticipated that for dilute gases the mean free path is a significant parameter that governs the mechanism of transfer, defined as the mean distance traveled by a molecule between two successive collisions [119]. The basic physical interpretation of the transfer phenomenon is thus that a molecule traveling a free path of a certain distance is in effect transferring momentum, energy and mass over that distance. To derive a simple expression for the mean free path we preliminarily examine the molecular motion from the point of view of an elementary kinetic theory of dilute gases adopting the billiard ball molecular model. Consider a pure gas composed of a collection of rigid, non-attracting spherical molecules of diameter  $d_1$ , mass  $m_1$ , and number density  $n_1$  colliding at random. A molecule is singled out as it travels in straight paths from one collision to the next, anticipating that the molecular speed and direction of motion change with each collision. It is then further imagined that at a given instant all the molecules but the one in question are frozen in position, whereas this particular molecule moves with an average speed  $\langle |\mathbf{c}_1| \rangle_M$ . At the instant of a collision, the center to center distance of the two molecules is  $d_1$  (see Fig. 2.7). The total collision cross section or target area,  $\sigma_{AT}$ , of the moving molecule is then given by  $\sigma_{AT} = \pi d_1^2$ . In time  $t$  the moving molecule sweeps out a cylindrical volume of length  $\langle |\mathbf{c}_1| \rangle_M t$  and cross section  $\sigma_{AT}$  (see Fig. 2.10). Any molecule whose center is in this cylinder will be struck by the moving molecule. The number of collisions in time  $t$  is given by  $\sigma_{AT} n_1 \langle |\mathbf{c}_1| \rangle_M t$ , where  $n$  is the number of molecules present in a unit volume, assumed to be uniformly distributed in space. A crude estimate of the mean free path,  $l_1$ , is then given by the ratio of the distance traveled in time  $t$  over the number of collisions in this time [157]:

$$l_1 = \frac{\langle |\mathbf{c}_1| \rangle_M t}{\sigma_{AT} n_1 \langle |\mathbf{c}_1| \rangle_M t} = \frac{1}{\sigma_{AT} n_1} \tag{2.603}$$

The corresponding collision frequency is defined as the average number of collisions per unit time experienced by any one molecule of type 1:

$$Z_{1-1} = \sigma_{AT} n_1 \langle |\mathbf{c}_1| \rangle_M = \frac{\langle |\mathbf{c}_1| \rangle_M}{l_1} \quad (2.604)$$

The mean time between successive collisions of molecules of type 1, called the *collision time*  $\tau_1$ , is approximated by:

$$\tau_1 = \frac{1}{Z_{1-1}} = \frac{l_1}{\langle |\mathbf{c}_1| \rangle_M} \quad (2.605)$$

Several extensions of the crude model sketched above have been derived over the years, for example considering the situation that all the molecules in the cylindrical volume move with the same average speed. A third model providing results being in better agreement with the Enskog relations is obtained assuming that all the molecules possess a Maxwellian speed distribution. The Maxwellian representation of the collision frequency of one molecule of type  $m_1$  with similar molecules (2.166) is commonly rewritten using the ideal gas law:

$$Z_{1-1} = \frac{2Z_{11}}{n_1} = 4n_1 d_1^2 \sqrt{\frac{\pi kT}{m_1}} = 4 \frac{p_1}{kT} d_1^2 \sqrt{\frac{\pi kT}{m_1}} = 4p_1 d_1^2 \sqrt{\frac{\pi}{m_1 kT}} \quad (2.606)$$

The mean free path,  $l_1$ , traveled by a molecule of type  $m_1$  between successive collisions in a given time  $t$  is found by dividing the total distance traveled by all molecules of type  $m_1$  in this time by the total number of the collisions between them:

$$l_1 = \frac{n_1 \langle |\mathbf{c}_1| \rangle_M t}{\frac{n_1 t}{\tau_1}} = \langle |\mathbf{c}_1| \rangle_M \tau_1 = \frac{\langle |\mathbf{c}_1| \rangle_M}{Z_{1-1}} \quad (2.607)$$

From this formula it is seen that to calculate  $l_1$  we need to determine the mean molecular speed  $\langle |\mathbf{c}_1| \rangle_M$ . For real systems the average molecular speed is difficult to determine. Assuming that the system is sufficiently close to equilibrium the velocity distribution may be taken to be Maxwellian. For molecules in the absolute Maxwellian state the peculiar velocity equals the microscopic molecular velocity, i.e.,  $\mathbf{C}_1 = \mathbf{c}_1$ , because the macroscopic velocity is zero  $\mathbf{v}_1 = 0$ , hence it follows that the speed of the microscopic molecular velocity equals the thermal speed:  $\langle C_1 \rangle_M = \langle |\mathbf{C}_1| \rangle_M = \langle c_1 \rangle_M = \langle |\mathbf{c}_1| \rangle_M$ .

The mean value of a generalized function of the molecular velocity for a gas in the absolute Maxwellian state is defined by:

$$n \langle \psi \rangle_M = \int_{-\infty}^{\infty} \psi f d\mathbf{c} = n \left( \frac{m}{2\pi kT} \right)^{3/2} \int_{-\infty}^{\infty} \psi \exp\left(-\frac{mC^2}{2kT}\right) d\mathbf{c} \quad (2.608)$$

The present form of the integral is not really defined in a consistent manner as the integrand contains the peculiar speed  $C$ , which is defined by  $C = |\mathbf{C}|$ , whereas the integration is over the velocity space  $d\mathbf{c}$ . Transforming from Cartesian coordinates

$(C_x, C_y, C_z)$  to spherical polar coordinates  $(C, \theta, \phi)$ , we get with spherical symmetry:  $d\mathbf{C} = dC = C^2 \sin \theta d\theta d\phi dC$  (e.g., [20], p. 70; [48], p. 242; [163], p. 34).

The mean value of the thermal speed  $C$  ( $= |\mathbf{C}|$ ) can then be derived as follows<sup>40</sup>:

$$\begin{aligned}
 \langle C \rangle_M &= \left(\frac{m}{2\pi kT}\right)^{3/2} \int_{-\infty}^{\infty} C \exp\left(-\frac{mC^2}{2kT}\right) d\mathbf{C} \\
 &= \left(\frac{m}{2\pi kT}\right)^{3/2} \int_0^{\infty} C^3 \exp\left(-\frac{mC^2}{2kT}\right) \int_0^{2\pi} \int_0^{\pi} \sin \theta d\theta d\phi dC \\
 &= 4\pi \left(\frac{m}{2\pi kT}\right)^{3/2} \int_0^{\infty} C^3 \exp\left(-\frac{mC^2}{2kT}\right) dC \\
 &= 4\pi \left(\frac{m}{2\pi kT}\right)^{3/2} \times \frac{1}{2} \left(\frac{m}{2kT}\right)^{-2} = \left(\frac{8kT}{\pi m}\right)^{1/2} \quad (2.609)
 \end{aligned}$$

Thus, for a molecule of type 1 the mean value of the peculiar speed  $\langle C_1 \rangle_M$  for a gas in the Maxwellian state yields:

$$\langle C_1 \rangle_M = \langle c_1 \rangle_M = \sqrt{\frac{8kT}{\pi m_1}} = 2\sqrt{\frac{2kT}{\pi m_1}} \quad (2.610)$$

The mean free path can then be determined from (2.607) and (2.606):

$$\begin{aligned}
 l_1 &= \langle |\mathbf{c}_1| \rangle_M \tau_1 = \frac{\langle |\mathbf{c}_1| \rangle_M}{Z_{1-1}} = \left(2\sqrt{\frac{2kT}{\pi m_1}}\right) \left(\frac{1}{4n_1 d_1^2 \sqrt{\frac{\pi kT}{m_1}}}\right) \quad (2.611) \\
 &= \frac{1}{\sqrt{2} n_1 d_1^2 \pi} = \frac{kT}{\sqrt{2} p_1 d_1^2 \pi}
 \end{aligned}$$

---

<sup>40</sup> In these manipulations we have used a mathematical formula solving odd integrals on the form:

$$\int_0^{\infty} x^n \exp(-ax^2) dx$$

The solution for  $n = 3$  is (e.g., [20], Sect. 1.4; [90], pp. 526–527):

$$\int_0^{\infty} \exp(-ax^2) dx = \frac{1}{2} a^{-2}.$$

### 2.10.3 Transport Coefficients

In this section we derive theoretical expressions for the transport coefficients (i.e., viscosity, thermal conductivity, and diffusivity) for dilute gases.

Using the elementary mean free path theory (2.603), the viscosity, thermal conductivity<sup>41</sup> and self-diffusion coefficients in (2.599) and (2.601) are estimated to be (e.g., [39], Sect. 6.7 and Chap. 7; [106], Chap. 3; [109]; [157], Chap. 5):

$$\mu_1 = \frac{1}{2}\rho_1 l_1 \langle C_1 \rangle_M = \frac{1}{\pi d_1^2} \sqrt{\frac{m_1 kT}{\pi}} \quad (2.612)$$

$$k_1 = \frac{1}{2}\rho_1 l_1 \langle C_1 \rangle_M C_{v,1} = \mu_1 C_{v,1} \quad (2.613)$$

$$D_{11} = \frac{1}{2}l_1 \langle C_1 \rangle_M = \mu_1 / \rho_1 \quad (2.614)$$

In a one-component gas it is conceptually still possible to label a certain subset of particles with 1 and the complement, 2. The resulting motion of the conceptually labeled subgroup of particles is called *self-diffusion*. Diffusion in a two-component system is called *mutual diffusion*.

The following set of parameter values may be more common because they are obtained adopting a refined proportionality coefficient in the flux expressions and the more accurate mean free path relation (2.611). The parameter values are<sup>42</sup> [109] (Sect. 3-5) [106] (Chap. 3) [9] (Sects. 1-4, 9-3 and 17-3):

$$\mu_1 = \frac{1}{3}\rho_1 l_1 \langle C_1 \rangle_M = \frac{2}{3\pi d_1^2} \sqrt{\frac{m_1 kT}{\pi}} \quad (2.615)$$

$$k_1 = \frac{1}{3}\rho_1 l_1 \langle C_1 \rangle_M C_{v,1} = \mu_1 C_{v,1} = \frac{1}{\pi d_1^2} \sqrt{\frac{k^3 T}{\pi m_1}} \quad (2.616)$$

The self diffusivity which is valid for two species of identical mass and size yields:

$$D_{11} = \frac{1}{3}l_1 \langle C_1 \rangle_M = \mu_1 / \rho_1 = \frac{2}{3} \left( \frac{kT}{\pi^3 m_1} \right)^{1/2} \frac{1}{nd_1^2} = \frac{2}{3} \left( \frac{k^3}{\pi^3 m_1} \right)^{1/2} \left( \frac{T^{3/2}}{p_1 d_1^2} \right) \quad (2.617)$$

<sup>41</sup> In this section we denote the thermal conductivity by the symbol  $k$  to distinguish this parameter from the Boltzmann constant.

<sup>42</sup> Maxwell [95] was able to obtain these fairly accurate expressions for the transport coefficients which describe their primary dependence of upon temperature, pressure, mass and size of the molecules in the gas based on rather crude arguments. Historically, the mean free path theory given by Maxwell [95] predates the more accurate theory based on the Boltzmann equation by about half a century.

For species of differing mass and size, the mean free paths, velocities, and collision frequencies will be different. The derivation of the binary diffusivity is more complicated but may be expressed as (e.g., [9], Sect. 17-3 and [39, 106]):

$$D_{12} = \frac{2}{3} \left( \frac{k}{\pi} \right)^{3/2} \left( \frac{1}{2m_1} + \frac{1}{2m_2} \right)^{1/2} \left( \frac{T^{3/2}}{p(\frac{d_1+d_2}{2})^2} \right) \quad (2.618)$$

A similar result was obtained by Present [109] (p. 149) for the rigid-sphere molecular model:

$$D_{12} = \frac{1}{3} l_1 \langle C_1 \rangle_M = \frac{3}{8} \left( \frac{\pi k T}{2\mu} \right)^{1/2} \frac{1}{n\pi d_{12}^2} \quad (2.619)$$

The pressure dependence expressed by these relations is fairly accurate for pressures up to about 10–20 atmospheres. At higher pressures, multi-body collisions become important and the pressure dependence is greater. Experimental evidence also show that a temperature dependence of  $T^{3/2}$  is too weak leading to the search for more accurate relations as derived by use of the Enskog approach.

Alternative estimates of the transport coefficients can be obtained from the rigorous Chapman-Enskog expansion method of mono-atomic gases at low densities (e.g., [20, 35, 36, 39] and [90], p. 202)). The transport coefficients deduced from the Chapman-Enskog kinetic theory with the rigid elastic spheres interaction model yield (e.g., [20], Sects. 10.1–10.2; [55] Sect. 8.2; [90], p. 202):

$$\mu_1 = \frac{5}{16d_1^2} \sqrt{\frac{m_1 k T}{\pi}}, \quad (2.620)$$

$$k_1 = \frac{5}{2} \mu_1 C_{v1} = \frac{75}{64d_1^2} \sqrt{\frac{k^3 T}{m_1 \pi}} \quad (2.621)$$

$$D_{11} = \frac{3}{8n_1 d_1^2} \sqrt{\frac{k T}{m_1 \pi}} \quad (2.622)$$

The binary diffusivity can also be determined in a similar manner considering a binary mixture of dilute gases:

$$D_{12} = \frac{3}{16n_1 d_{12}^2} \sqrt{\frac{2k T}{\pi \mu}} \quad (2.623)$$

The Chapman-Enskog kinetic theory actually gives general expressions for the transport properties in terms of the intermolecular potential energy which is related to the intermolecular force as expressed by (2.54) and (2.55). The molecular interaction is most frequently described by the empirical Lennard-Jones 12-6 potential.

The transport coefficients like viscosity, thermal conductivity and self-diffusivity for a pure mono-atomic gas and the diffusivity for binary mixtures obtained from the rigorous Chapman-Enskog kinetic theory with the Lennard-Jones interaction model yield (e.g., [9], Sects. 1-4, 9-3 and 17-3; [55], Sect. 8.2):

$$\mu_1 = \frac{5}{16} \frac{\sqrt{\pi m_1 k T}}{\pi \sigma_1^2 \Omega_{\mu,1}} \quad (2.624)$$

$$k_1 = \frac{25}{32} \frac{\sqrt{\pi m_1 k T}}{\pi \sigma_1^2 \Omega_{k,1}} C_{v1} \quad (2.625)$$

$$D_{11} = 3.2027 \times 10^{-5} \sqrt{\frac{T}{M_{w1}}} \frac{1}{c \sigma_1^2 \Omega_{D,11}} \quad (2.626)$$

$$D_{12} = 0.0018583 \sqrt{T^3 \left( \frac{1}{M_{w1}} + \frac{1}{M_{w2}} \right)} \frac{1}{p \sigma_{12}^2 \Omega_{D,12}} \quad (2.627)$$

where the units of the transport coefficients are; viscosity  $\mu_1$  [Pa × s], conductivity  $k_1$  [W/mK], diffusivities  $D_{11}$  and  $D_{12}$  [m<sup>2</sup>/s], and the properties  $p$  [atm], and  $T$  [K].

The  $\sigma_1$  is a characteristic diameter of the molecules of type 1, often called the collision diameter, and may be defined differently for each molecular model. In the Lennard-Jones potential  $\sigma_1$  has the significance of being the distance from the center of mass of the two molecules to the point at which the potential changes from repulsive to attractive [39]. To calculate  $\sigma_{12}$  an analog of the rigid sphere model is generally adopted:  $\sigma_{12} = (\sigma_1 + \sigma_2)/2$ . This approach has little theoretical justification and is not accurately verified by experimental data. The collision integrals<sup>43</sup>  $\Omega_{\mu,1}$ ,  $\Omega_{k,1}$ ,  $\Omega_{D,11}$ , and  $\Omega_{D,12}$  account for the details of the paths that the molecules take during a binary collision and are usually of order unity. In one view these integrals are interpreted as describing the deviation from the rigid sphere behavior. The  $\varepsilon$  quantity in the Lennard-Jones potential is a characteristic energy denoting the maximum energy of attraction between a pair of molecules. For binary mixtures  $\varepsilon_{12}$  is usually approximated by a geometric average of the contributions from the two species  $\varepsilon_{12} \approx \sqrt{\varepsilon_1 \varepsilon_2}$ . By use of these formulas accurate calculations of the transport coefficients can thus be performed provided that the Lennard-Jones potential parameters like  $\varepsilon_1$  and  $\sigma_1$  are known. Extensive lists of these parameters are given for many substances by Hirschfelder et al. [55] and Bird et al. [9], among others.

<sup>43</sup> Chapman and Cowling [20] have shown that in kinetic theory the transport coefficients can be expressed in terms of the Sonine polynomial expansion coefficients which are complicated combinations of the bracket integrals. In the given solutions these integrals are written as linear combinations of a set of these *collision integrals*. See also Hirschfelder et al. [55], Sect. 7-4.

### 2.10.4 Dilute Gas Hypothesis

The phrase *dilute gas* indicates that the physical volume  $n[\frac{4}{3}\pi d^3]$  occupied by the gas particles (molecules) is small compared to the container volume  $V$  available to the gas. Mathematically this condition can be expressed as:

$$n \left[ \frac{4}{3} \pi d^3 \right] \ll V, \quad (2.628)$$

or

$$\frac{n \left[ \frac{4}{3} \pi d^3 \right]}{V} \ll 1, \quad (2.629)$$

where  $n$  denotes the number of particles and  $d$  is the radius of the particle.

A real gas is also considered dilute provided that the mean free path  $l$  is much larger than the particle size, i.e.,  $l \gg d$ .

Assuming that the molecules are rigid elastic spheres a typical value for the mean free path for a gas, say oxygen, can be calculated from (2.611). Consider a typical room temperature at 300 (K) and a pressure of 101325 (Pa). The collision diameter of molecular oxygen can be set to  $3.57 \times 10^{-10}$  (m) in accordance with the data given by Laidler [80], example 1.4. We can then calculate the mean free path  $l$  for oxygen from (2.611):

$$\begin{aligned} l &= \frac{RT}{\sqrt{2}\pi d^2 N_a p} \\ &= \frac{8.314(\text{JK}^{-1}\text{mol}^{-1}) \times 300(\text{K})}{\sqrt{2}\pi [3.57 \times 10^{-10}(\text{m})]^2 \times 6.022 \times 10^{23}(\text{mol}^{-1}) \times 101325(\text{Pa})} \\ &= 7.22 \times 10^{-8}(\text{m}) \end{aligned} \quad (2.630)$$

Since the molecular diameters for the different gases are of the same order, the mean free path in any gas at the given temperature and pressure is of the order  $10^{-5}$  (cm). In this case it follows that the mean free path is about hundred times the diameter of the molecule, thus the gas is dilute. However, it is noted that at higher gas pressure, say 10132500 (Pa), the mean free path is reduced and comparable with the dimensions of a molecule. In this case the assumption of molecular chaos may not be valid so the gas cannot be considered dilute [20].

### 2.10.5 Continuum Hypothesis

A dilute gas mixture is assumed to behave as a continuum when the mean free path of the molecules is much smaller than the characteristic dimensions of the problem geometry [5, 42, 43, 68, 129, 154, 164]. A relevant dimensionless group of variables, the Knudsen number,  $\text{Kn}$ , is defined as:

$$Kn = \frac{l}{L}, \quad (2.631)$$

where  $l$  is the mean free path of the molecules and  $L$  a characteristic dimension of the apparatus region in which the relevant physical phenomena take place (e.g., the thickness of boundary layers in which large gradients appear, the diameter of catalyst pores, the reactor diameter, etc). In general the *continuum hypothesis* is considered valid for  $Kn < 0.01$ .

By use of the typical numerical value for the mean free path (2.611) for a gas at temperature 300 K and pressure 101325 Pa, this condition indicates that the continuum assumption is valid provided that the characteristic dimension of the apparatus is  $L > 0.001$  cm. Nevertheless, it is noted that at low gas pressures, say 10 Pa, the mean free path is increased and might be comparable with the characteristic dimensions of the apparatus. In particular, for low pressures and small characteristic dimensions we might enter a flow regime where the continuum assumption cannot be justified.

The gas flow regimes are generally characterized as:

$$Kn < 0.01 - 0.001 \quad \text{Continuum flow} \quad (2.632)$$

$$0.01 < Kn \leq 0.1 \quad \text{Slip flow} \quad (2.633)$$

$$0.1 < Kn \leq 10 \quad \text{Transition flow} \quad (2.634)$$

$$Kn > 10 \quad \text{Free molecular flow} \quad (2.635)$$

In the *slip flow regime* velocity slip, and species mass- and temperature jump phenomena occur in the vicinities of the boundaries. In this regime, the ordinary gas dynamics conservation equations might still be employed with sufficient modifications of the boundary conditions. The *free molecular flow regime* occurs at the verge of large Knudsen number where the gas is very rarefied. However, the molecular collisions with the vessel walls prevail thus some law of molecular reflection on the vessel wall is required. In this flow regime the mean free path  $l$  is much larger than  $L$ , and the equilibrium Maxwell velocity distribution might be considered. In the *transitional regime* between the slip flow regime and the free molecule region, the collisions of the molecules with the vessel walls and the mutual collisions of the molecules in the oncoming flow have about equal importance. The analysis becomes challenging, and the molecular gas dynamics methods must be adopted.

## 2.11 Ideal Gas Law

The description of the behavior of an ideal gas in terms of the macroscopic state variables<sup>44</sup>  $p$ ,  $V$ ,  $n$ , and  $T$  can be related to simple averages of microscopic quantities such as the mass and speed of the molecules in the gas [20, 39, 109, 149, 157].

<sup>44</sup> A state variable is a precisely measurable physical property which characterizes the state of a system, independently of how the system was brought to that state.

From the point of view of kinetic theory, an ideal gas consists of a large number of molecules making elastic collisions with each other and with the walls of the container containing the gas, and there are no intermolecular attractive forces. In such an ideal gas, all the internal energy is in the form of kinetic energy and any change in internal energy is accompanied by a change in temperature. The ideal gas law can thus be viewed as arising from the kinetic pressure of the ideal gas molecules colliding with the walls of a container in accordance with Newton's laws.

For convenience, the underlying model assumptions employed deriving the ideal gas law are briefly summarized prior to the model derivation:

- The ideal gas molecules are considered hard spheres without internal structure (mono-atomic molecules).
- Out of the three possible types of degrees of freedom for molecular motion, i.e., translation, rotation and vibrational, only three translational degrees of freedom are present for the ideal gas molecules with no internal structure (mono-atomic molecules).
- The intermolecular collisions are elastic.
- The molecular collisions with the wall are elastic.
- The molecules in an ideal gas move randomly, even though the molecules experience intermolecular interactions and collisions with the walls:

$$\langle C^2 \rangle = \langle C_x^2 \rangle + \langle C_y^2 \rangle + \langle C_z^2 \rangle = 3\langle C_x^2 \rangle \quad (2.636)$$

The random molecular movement requires that:

$$\langle C_x^2 \rangle = \langle C_y^2 \rangle = \langle C_z^2 \rangle. \quad (2.637)$$

- In an ideal gas, the molecules are separated, on the average, by distances that are large compared with their diameters. The gas molecules are thus considered point particles. Moreover, the collisions are considered instantaneous.
- The attractive forces between molecules are considered negligible. The equivalent condition of low density is to be understood such that the molecules of the gas are so far apart that they do not interact except during collisions.
- The average kinetic energy is considered proportional to temperature through the kinetic energy equipartition theorem.
- No external forces are acting on the system. In the absence of external forces, there is no preferred position for a molecule in the container, and no preferred direction for its velocity vector. Actually gravity is such an external force acting on the gas in the container, thus the density of molecules at the bottom of the container will be slightly greater than at the top. However, the variation over a normal sized container is generally negligible. Hence, the molecular movement is considered random in accordance with (2.637).

Under these idealized conditions, both the system momentum and kinetic energy are conserved in the molecular collisions, thus the intermolecular collisions have no effect on the total momentum in any direction. For this reason, the molecular

**Fig. 2.12** Gas molecules in a rectangular container. In a time interval  $\Delta t$ , the molecules closer to the right wall than a distance  $C_x \Delta t$  will hit the right wall if they are moving to the right

collisions can be omitted in the subsequent analysis calculating the pressure that an ideal gas exerts on the container walls. The ideal gas pressure is due to the collisions between the gas molecules and the container walls which are solely induced by the translational motion of the molecules. Pressure is defined as a force per unit area and, by Newton's second law, this force equals the rate of change of momentum of the gas molecules colliding with the wall. That is, Newton's second law can be expressed as:

$$\mathbf{F} = m\mathbf{a} = \frac{d\mathbf{p}}{dt} = \frac{d(m\mathbf{C})}{dt} \quad (2.638)$$

For simplicity, consider a rectangular container of volume  $V$  containing  $N$  gas molecules, each of mass  $m$  moving with a speed  $C$ . To calculate the force exerted by these molecules on the right hand wall, which is perpendicular to the  $x$  axis and has area  $A$ , a simple geometrical analysis is required. The molecules hitting this wall in a time interval  $\Delta t$  are those that are within a distance  $C_x \Delta t$  of the wall (see Fig. 2.12) and are moving to the right. The number of molecules hitting the right hand wall during the time interval  $\Delta t$  is  $\frac{1}{3}$  times the number per unit volume  $N/V$  times the volume  $C_x \Delta t A$  times  $\frac{1}{2}$  because, on average, only half the molecules moving along the  $x$ -axis are moving to the right. In other words, on average,  $N/3$  of the molecules moving along a given axis, whereas  $N/6$  of the molecules move towards each of the walls. That is, the number of molecules that hit the right hand wall in the time interval  $\Delta t$  is  $\frac{1}{6} \frac{N}{V} C_x \Delta t A$ . The  $x$  component of momentum of a molecule is  $+mC_x$  before it hits the wall, and  $-mC_x$  after an elastic collision with the wall. The change in momentum thus has the magnitude  $2mC_x$ . The magnitude of the total change in momentum  $|\Delta \mathbf{p}|_x$  of all molecules moving along the  $x$ -axis during a time interval  $\Delta t$  is  $2mC_x$  times the number of molecules that hit the wall during this interval:

$$|\Delta \mathbf{p}|_x = (2mC_x) \times \left( \frac{1}{6} \frac{N}{V} C_x \Delta t A \right) = \frac{1}{3} \frac{N}{V} m C_x^2 A \Delta t \quad (2.639)$$

From Newton's third law, the magnitude of the force exerted by the wall on the molecules and by the molecules on the wall is equal and may be approximated by  $|\Delta \mathbf{p}|_x / \Delta t$ . The pressure is the magnitude of this force divided by the area  $A$ :

$$p_x = \frac{F_x}{A_x} = \frac{1}{A_x} \frac{|\Delta \mathbf{p}|_x}{\Delta t} = \frac{1}{3} \frac{N}{V} m C_x^2 \quad (2.640)$$

or

$$p_x V = \frac{1}{3} N m C_x^2 \quad (2.641)$$

To allow for the fact that all the molecules in a container do not have the same speed,  $C_x^2$  is replaced with the average speed  $\langle C_x^2 \rangle$ . The latter relation can then be written in terms of the kinetic energy  $\frac{1}{2} m C_x^2$  associated with the motion along the  $x$  axis:

$$p_x V = \frac{2}{3} N \langle \frac{1}{2} m C_x^2 \rangle \quad (2.642)$$

In kinetic theory, in accordance with the kinetic energy equipartition theorem, the kinetic temperature  $T$  of a gas at a uniform state at rest or in uniform translation is defined directly in terms of the average peculiar speeds of the molecules, by the three dimensional relation  $\frac{1}{2} m \langle C^2 \rangle_M = \frac{3}{2} k T$  obtained from (2.200) and (2.199). In accordance with (2.200) and (2.192) the static pressure  $p$  of a gas in equilibrium is given by  $p = 3 p_x = n m \langle C_x^2 \rangle_M = \frac{1}{3} n m \langle C^2 \rangle_M = k n T$ . Considering the mass  $M$  of gas contained in a volume  $V$ , the number of mono-atomic molecules  $N$  in the mass  $M$  is  $M/m$ , and the number density  $n$  is therefore  $N/V$ . The thermodynamic pressure is then given by  $pV = NkT$ . Alternatively one can write  $N = n N_a$ , where  $n$  is the number of moles of gas present and  $N_a$  is Avogadro's number. Then, the *ideal gas law*, yields:

$$pV = nRT \quad (2.643)$$

where  $R = k N_a$  is the universal gas constant. This formula may also be valid for a gas not in equilibrium provided that the molecules possess only translational energy.

### 2.11.1 Non-Ideal Gases

The ideal gas law is not accurately followed at high pressure because the molecular size becomes important as the molecules are packed closer together. Likewise, at low temperatures the molecular interactions may become more important and can cause deviations from the ideal gas behavior. For such system conditions, more complex equations of state formulations are required.

Considering real non-ideal gases, the basic kinetic theory for ideal gases must be modified to account for the anomalous real gas behavior caused by the fact that real gas molecules attract each other and have finite volumes. The van der Waals equation

of state, among other equations of state formulations proposed in the literature, includes parameters that relate to molecular size and interactions:

$$p = \frac{nRT}{V - nb} - \frac{an^2}{V^2} \quad (2.644)$$

## 2.12 Extending the Kinetic Theory to Denser Gases

The preceding sections in this chapter deal with the kinetic theory of dilute gases summarizing the statistical modeling concepts, deriving the governing conservation equations and fairly accurate relations determining the transport coefficients from first principles. The starting point for the kinetic theory of dilute mono-atomic gases is the Boltzmann equation determining the evolution of the distribution function in time and space. The formulation of the collision term is restricted to gases that are sufficiently dilute so that only binary collisions need to be taken into account. It is also required that the molecular dimensions are small in comparison with the mean distance between the molecules, hence the transfer of molecular properties is solely regarded as a consequence of the free motion of molecules between collisions. Obviously, these restrictions are not met in dense gases, so the dilute gas results are not acceptable for higher-density systems (e.g., [39], p. 356). After recognizing these model restrictions, Enskog [37] made a first attempt to extend the kinetic theory of dilute mono-atomic gases to slightly higher densities.

Enskog's [37] kinetic theory extension consists in the introduction of corrections that account for the fact that for dense gases the molecular diameter is no longer small compared with the average intermolecular distance. The fundamental postulate is that as a dilute gas is compressed two novel effects become important because the molecules have finite volumes. First, it is expected that during a molecular collision momentum and energy are transferred over a distance equal to the separation of the molecules. In the particular case of rigid spherical molecules this collisional transfer of momentum and energy takes place instantaneously and results in a transfer over the distance between their centers. Second, the collision frequency may be altered. One possible mechanism is that the collision frequency is increased because the particle diameter is not negligible small compared with the average distance between the molecules. However, the collision frequency may also decrease because the molecules are close enough to shield one another from oncoming molecules. Nevertheless, the probability of multiple simultaneous collisions is considered negligible. In the following subsections the derivation of Enskog's equation is examined [37].

### 2.12.1 Boltzmann Equation Collision Frequency Reformulation

To derive the Enskog's equation for a dense gas, Enskog [37] did departure from the kinetic theory of dilute mono-atomic gases that is described by the Boltzmann

equation determining the evolution of the single distribution function in time and space. Moreover, the original formulation of the collision term is restricted to gases that are sufficiently dilute so that only binary collisions need to be taken into account. Even for the dilute gas Boltzmann equation, the choice of using the Maxwellian billiard ball- or rigid sphere model representing the molecules allows a reformulation of the collision frequency and the collision term. That is, it has been shown that the collision frequency (2.160) which is formulated in terms of the solid angle  $d\Omega_{g'}$  and used in the Boltzmann equation (2.184) for dilute gas, can be expressed in an alternative form in terms of the alternative solid angle  $d\mathbf{k}$ . Hence, before the Enskog modifications to the Boltzmann equation are treated, this prerequisite collision frequency reformulation is outlined in this subsection.

In the analysis of a binary collision between molecules with velocities  $\mathbf{c}_1$  and  $\mathbf{c}_2$  the direction of the line of centers at collision can be specified by the unit vector  $\mathbf{k}$  along the apse-line (i.e., in the particular case of rigid spherical molecules, the apse-line corresponds to the line joining the centers of the two molecules at the instant of contact), Fig. 2.7. This unit vector is precisely characterized by the polar angles  $(\psi, \phi)$ . Therefore, instead of describing the deflection<sup>45</sup> with the angles  $(\theta, \phi)$ , it is more convenient to use the angles  $(\psi, \phi)$  since in these variables the final velocity  $\mathbf{g}'_{21}$  is more simply related to the initial velocity  $\mathbf{g}_{21}$  (i.e., by symmetry the projections of  $\mathbf{g}_{21}$  and  $\mathbf{g}'_{21}$  on  $\mathbf{k}$  are equal and of opposite sign:  $\mathbf{k} \cdot \mathbf{g}_{21} = -\mathbf{k} \cdot \mathbf{g}'_{21}$ , as discussed in Sect. 2.4.2.2). In particular, in Sect. 2.4.2 we found that when the collision term in (2.184) is expressed in terms of the impact parameter (i.e.,  $b db d\phi$ ),  $\mathbf{c}'$  and  $\mathbf{c}'_1$  should be given as functions of  $\mathbf{c}$ ,  $\mathbf{c}_1$ ,  $b$  and  $\phi$ . Alternatively, when the collision term is rewritten in terms of  $\sigma_A(\theta, g) d\Omega'$  the velocities  $\mathbf{c}'$  and  $\mathbf{c}'_1$  must be given as functions of  $\mathbf{c}$ ,  $\mathbf{c}_1$  for given  $\Omega'$ , through the law of collision. We can then, for example, use (2.132)–(2.134) expressed in the particular reference frame chosen (i.e., the center of force frame). However, a third and more common approach (i.e., made possible by the use of the hard sphere molecular model thus available both for dilute and dense gases) is to use the unit vector  $\mathbf{k}$  to describe the scattering. That is, we express the scattering cross section in terms of the variable  $\mathbf{k}$  rather than  $\theta$ . Therefore, when the scattering cross section is expressed in terms of the unit vector  $\mathbf{k}$ , (2.132)–(2.134) can be used directly to compute  $\mathbf{c}'$  and  $\mathbf{c}'_1$  as these relations are independent of the laboratory frame. The latter formulation plays a fundamental role in the applications of kinetic theory to denser gases, hence it is worthwhile to display its derivation in further details.

The scattering cross section is expressed in terms of the variable  $\mathbf{k}$ , simply by defining a function  $s_A(\psi, g)$  by [109, 117]:

$$s_A(\psi, g) \sin \psi d\psi d\phi = \sigma_A(\theta, g) \sin \theta d\theta d\phi \quad (2.645)$$

---

<sup>45</sup> The deflection angle  $\theta$  is defined as the angle between the final and initial velocities:  $\theta = \pi - 2\psi$ . It appears that the phrase scattering is used for the case of Maxwellian billiard ball particles, whereas the phrase deflection is used in the more general case considering a center of force.

in such a way that the number of particles deflected into the corresponding differential surface element of a sphere of unit radius per unit time (2.139) becomes:

$$I\sigma_A(\theta, g) \sin \theta d\theta d\phi = Is_A(\psi, g) \sin \psi d\psi d\phi \quad (2.646)$$

By trigonometric manipulations using (2.146), we obtain:

$$s_A(\psi, g) = \sigma_A(\theta, g) \frac{\sin \theta d\theta d\phi}{\sin \psi d\psi d\phi} = 4\sigma_A(|\pi - 2\psi|; g) \cos \psi \quad (2.647)$$

where we have required that  $s_A$  is a positive factor by using a positive angle:  $\theta = |\pi - 2\psi|$ .

It appears that the variable  $\mathbf{k}$  will be convenient shortly calculating the collision term because it allows us to write down the number of scattered particles in a form independent of the particular system of coordinates used in the previous calculations (i.e., the laboratory frame). Trigonometrical considerations imply that:

$$\cos \psi = \mathbf{k} \cdot \mathbf{e}_{g'} = \mathbf{k} \cdot \frac{\mathbf{g}'_{21}}{|\mathbf{g}'_{21}|} \quad (2.648)$$

or,

$$\psi = \arccos(\cos \psi) = \arccos\left(\frac{\mathbf{k} \cdot \mathbf{g}'_{21}}{g}\right) \quad (2.649)$$

and we introduce a novel quantity

$$d\mathbf{k} = \sin \psi d\psi d\phi \quad (2.650)$$

denoting a differential area of a sphere of unit radius. Hence,  $\psi$  and  $\phi$  represent the polar angles around  $\mathbf{k}$ .

It follows that the number of particles scattered into the differential area element per unit time, given by (2.646), can be rewritten using (2.648)–(2.650). The result is:

$$\begin{aligned} I\sigma_A(\theta, g) \sin \theta d\theta d\phi &= Is_A(\psi, g) \sin \psi d\psi d\phi = Is_A(\psi, g) d\mathbf{k} \\ &= Is_A\left(\arccos\left(\frac{\mathbf{k} \cdot \mathbf{g}'_{21}}{g}\right), g\right) d\mathbf{k} \\ &= Is_A(\arccos(\mathbf{k} \cdot \mathbf{e}_{g'}), |\mathbf{g}'_{21}|) d\mathbf{k} = Is_A(\mathbf{k}, \mathbf{g}'_{21}) d\mathbf{k} \end{aligned} \quad (2.651)$$

which is independent of the laboratory reference frame, as it is expressed in a system of coordinates moving with the center of mass.

For hard spheres (2.651) takes a particularly simple form, using (2.149), (2.647) and (2.648), we get:

$$s_A(\mathbf{k}, \mathbf{g}'_{21}) = s_A(\arccos(\frac{\mathbf{k} \cdot \mathbf{g}'_{21}}{g}), g) = 4\sigma_A(\psi, g)\mathbf{k} \cdot \mathbf{e}_{g'} = 4(\frac{d_{12}^2}{4})\mathbf{k} \cdot \mathbf{e}_{g'} = d_{12}^2\mathbf{k} \cdot \mathbf{e}_{g'} \quad (2.652)$$

Making an inversion of the trajectory with respect to the origin  $O$  and reversing the velocities, the unit vector along the apse-line changes sign, whereas the deflection angle  $\theta$  does not change in these transformations [117]. Hence, in accordance with the Liouville law for elastic collisions, the cross sections of the two processes are the same and consistently  $s(\mathbf{k}', \mathbf{g}_{21}) = s(\mathbf{k}, \mathbf{g}_{21}) = s(-\mathbf{k}, \mathbf{g}_{21})$ .

Reformulating (2.651), using (2.648) and (2.652), we get:

$$|\mathbf{g}_{21}|I\sigma_A(\theta, g)d\Omega' = |\mathbf{g}_{21}|Is_A(\mathbf{k}, \mathbf{g}'_{21})d\mathbf{k} = Id_{12}^2\mathbf{k} \cdot \mathbf{g}_{21}d\mathbf{k} \quad (2.653)$$

or, simply

$$g\sigma_A(\theta, g)d\Omega' = d_{12}^2\mathbf{k} \cdot \mathbf{g}_{21}d\mathbf{k} = d_{12}^2gd\mathbf{k} \cos \psi \quad (2.654)$$

It follows that the elementary area  $bd\phi db$  is the projection of  $d_{12}^2d\mathbf{k}$  on a plane normal to  $\mathbf{g}_{21}$ , where  $\mathbf{g}_{21} = \mathbf{c}_2 - \mathbf{c}_1$ , and if  $\psi$  is the angle between  $\mathbf{g}_{21}$  and  $\mathbf{k}$  we get:

$$gbd\phi db = d_{12}^2gd\mathbf{k} \cos \psi = d_{12}^2\mathbf{k} \cdot \mathbf{g}_{21}d\mathbf{k} \quad (2.655)$$

The collision frequency can now be obtained from (2.160) as:

$$f(\mathbf{r}, \mathbf{c}, t)f_1(\mathbf{r}_1, \mathbf{c}_1, t)d_{12}^2\mathbf{g}_{21} \cdot \mathbf{k}d\mathbf{k}d\mathbf{c}_1d\mathbf{c}d\mathbf{r} \quad (2.656)$$

This formulation of the collision frequency is valid for the rigid sphere molecular model and forms the basis for the Enskog's equation development.

### 2.12.2 Enskog's Equation

For dilute mono-atomic gases we have shown that the evolution of the distribution function is given by the Boltzmann equation as expressed by (2.184). Hence, considering dense gases it might be natural to start out from this result. Enskog [37] derived a modified Boltzmann equation for the evolution of the distribution function supposedly valid for denser gases. No changes was made to the LHS of the equation, whereas an extended form of the collision term was introduced due to the finite size of the molecules. More precisely, Enskog [37] considered a mono-atomic gas composed of rigid spherical molecules of diameter  $d$ . The restriction to rigid spheres was made because multi-body collisions need not be considered, as for this special molecular model there are essentially no three-body and higher order collisions. For dense gas, the binary molecular collisions were assumed elastic just as for dilute gas. The major aim was to take into account the mechanisms of instantaneous momentum and energy transfer over the distance separating the centers of the two colliding molecules,  $d_{12} = d$ . Another important goal was to extend the collision frequency formula correcting for the finite size of the molecules. Considering the impact of

collisions for dilute mono-atomic gases we have shown in the foregoing paragraphs that we need to know the numbers of pairs of molecules both lying in the element  $d\mathbf{r}$  which are going to collide in the time interval  $dt$  and elementary knowledge from scattering theory. Hence, during a time interval  $dt$  the expected number of collisions in the volume element  $d\mathbf{r}$  about  $\mathbf{r}$  between molecules in the velocity ranges  $d\mathbf{c}$  about  $\mathbf{c}$  and  $d\mathbf{c}_1$  about  $\mathbf{c}_1$ , with the infinitesimal solid angle in the range  $d\Omega'$  about  $\Omega'$ , is given by the collision term on the RHS of (2.184).

For convenience, the Maxwell-Boltzmann equation (2.67) with the collision operator definition (2.69) is rewritten here defining the point of departure in Enskog's model development:

$$\frac{\partial f}{\partial t} + \mathbf{c} \cdot \frac{\partial f}{\partial \mathbf{r}} + \mathbf{F} \cdot \frac{\partial f}{\partial \mathbf{c}} = \int_{-\infty}^{\infty} \int_{4\pi} (f' f'_1 - f f_1) g \sigma_A(\Omega) d\Omega' d\mathbf{c}_1 \quad (2.67)$$

By use of (2.654) or (2.656), the collision operator in the Maxwell-Boltzmann equation (2.67) can be reformulated. The reformulated Maxwell-Boltzmann equation is given as:

$$\frac{\partial f}{\partial t} + \mathbf{c} \cdot \frac{\partial f}{\partial \mathbf{r}} + \mathbf{F} \cdot \frac{\partial f}{\partial \mathbf{c}} = \int_{-\infty}^{\infty} \int_{4\pi} (f' f'_1 - f f_1) d_{12}^2 (\mathbf{g}_{12} \cdot \mathbf{k}) d\mathbf{k} d\mathbf{c}_1 \quad (2.657)$$

### 2.12.2.1 Enskog's Boltzmann Equation Modifications

Just as in the Boltzmann theory [10], in Enskog's theory [37] the state of the gas is characterized by a single-particle distribution function  $f(\mathbf{r}, \mathbf{c}, t)$  defined such that  $f(\mathbf{r}, \mathbf{c}, t) d\mathbf{r} d\mathbf{c}$  gives the number of molecules in the volume element between  $\mathbf{r}$  and  $\mathbf{r} + d\mathbf{r}$  and with velocities between  $\mathbf{c}$  and  $\mathbf{c} + d\mathbf{c}$  at time  $t$ . Moreover, Enskog proposed that the basic assumptions of molecular chaos and elastic molecular collisions hold also for dense gas. So far it has been shown that the collision frequency (2.160) which is formulated in terms of the solid angle  $d\Omega_{g'}$  and used in the Boltzmann equation (2.184) for dilute gas, can be expressed in an alternative form (2.656) in terms of the alternative solid angle  $d\mathbf{k}$ . In addition to this minor collision frequency manipulation, Enskog [37] considered that in a dense gas the volume of the molecules is comparable with the total volume occupied by the gas. The effect of this relative volume change is to reduce the volume in which the centre of any one molecule can lie, and thus to increase the probability of a collision. The collision term on the RHS of Boltzmann equation (2.184) was thus modified by Enskog [37] in order to take these effects into account. First, the frequency of collisions (2.656) is changed by a pre-factor  $\chi$ , to increase the probability of a collision for a dense gas:

$$\chi f(\mathbf{r}, \mathbf{c}, t) f_1(\mathbf{r}_1, \mathbf{c}_1, t) d_{12}^2 \mathbf{g} \cdot \mathbf{k} d\mathbf{k} d\mathbf{c}_1 d\mathbf{c} d\mathbf{r} \quad (2.658)$$

where  $\chi$  is a free volume correction function that is unity for dilute gases, and increases with increasing gas density towards infinity as the gas density approaches

the state of closest packing where no motion is possible.  $\chi$  is considered a function of position but, by the assumption of molecular chaos, not on velocity.

The correction function  $\chi$  is related to the virial expansion of the equation of state and fitted to experimental data [55]. Enskog ([37], p. 9) and Chapman and Cowling ([20], p. 299) gave an approximate relation for the value for  $\chi$  for a fairly rare uniform gas:

$$\chi \approx 1 + \frac{5}{8}b\rho \quad (2.659)$$

where  $b\rho = 2\pi n\sigma_A^3/3$ ,  $b = 2\pi\sigma_A^3/m$  and  $\rho = mn$ .

Second, due to the finite size of the colliding molecules the centers of the two molecules are not at the same point. If, at the instant of collision, the center of the first molecule is at  $\mathbf{r}$ , the center of the second one is at  $\mathbf{r} \pm d_{12}\mathbf{k}$ . For this reason the two distribution functions should be evaluated at different points, so that for the direct collision  $f(\mathbf{r}_1, \mathbf{c}_1, t)$  is replaced by  $f(\mathbf{r} - d_{12}\mathbf{k}, \mathbf{c}_1, t)$ . The correction function is determined at the point of contact between the two particles, hence the collision frequency for the direct collision is approximated as:

$$\chi(\mathbf{r} - \frac{1}{2}d_{12}\mathbf{k}) f(\mathbf{r}, \mathbf{c}, t) f(\mathbf{r} - d_{12}\mathbf{k}, \mathbf{c}_1, t) d_{12}^2 \mathbf{g} \cdot \mathbf{k} d\mathbf{k} d\mathbf{c}_1 d\mathbf{c} d\mathbf{r} \quad (2.660)$$

As for dilute gases, corresponding to any direct collision specified by the variables  $\mathbf{c}, \mathbf{c}_1, \mathbf{k}$  there is an analogous inverse collision in which  $\mathbf{c}, \mathbf{c}_1$  are the velocities of the molecules after the collision, while  $-\mathbf{k}$  is the direction of the apse-line. In such a collision the center of the second molecule is at  $\mathbf{r} + d_{12}\mathbf{k}$ , while the point of contact is at  $\mathbf{r} + \frac{1}{2}d_{12}\mathbf{k}$ . The correction function is still determined at the point of contact between the two particles, hence the collision frequency for the inverse collision is approximated as:

$$\chi(\mathbf{r} + \frac{1}{2}d_{12}\mathbf{k}) f(\mathbf{r}, \mathbf{c}, t) f(\mathbf{r} + d_{12}\mathbf{k}, \mathbf{c}_1, t) d_{12}^2 \mathbf{g} \cdot \mathbf{k} d\mathbf{k} d\mathbf{c}_1 d\mathbf{c} d\mathbf{r} \quad (2.661)$$

It follows that the Enskog's equation describing the evolution of the distribution function for a dense gas of rigid spherical molecules is analogous to the Boltzmann equation (2.184) but containing the modified collision term on the following form:

$$\begin{aligned} \frac{\mathcal{D}f}{\mathcal{D}t} = & \int \int [\chi(\mathbf{r} + \frac{1}{2}d_{12}\mathbf{k}) f'(\mathbf{r}, \mathbf{c}', t) f'_1(\mathbf{r} + d_{12}\mathbf{k}, \mathbf{c}_1, t) \\ & - \chi(\mathbf{r} - \frac{1}{2}d_{12}\mathbf{k}) f(\mathbf{r}, \mathbf{c}, t) f_1(\mathbf{r} - d_{12}\mathbf{k}, \mathbf{c}_1, t)] d_{12}^2 (\mathbf{g} \cdot \mathbf{k}) d\mathbf{k} d\mathbf{c}_1 \end{aligned} \quad (2.662)$$

This extended Boltzmann equation is called the *Enskog equation*.

Enskog [37] further considered that a prerequisite in order to solve this equation is that all quantities must be evaluated at a common point. Assuming that the conditions in the dense gas are sufficiently smooth, each of the functions  $\chi(\mathbf{r} \pm \frac{1}{2}d_{12}\mathbf{k})$ ,  $f_1(\mathbf{r} - d_{12}\mathbf{k}, \mathbf{c}_1, t)$  and  $f'_1(\mathbf{r} + d_{12}\mathbf{k}, \mathbf{c}'_1, t)$  on the RHS of (2.662) was expanded in a Taylor

series near  $\mathbf{r}$ , neglecting the third- and higher-order terms. Then, Enskog's equation can be written as [69]:

$$\frac{\partial f}{\partial t} + c_i \frac{\partial f}{\partial x_i} + F_i \frac{\partial f}{\partial c_i} = J_0(ff) + J_1(ff) + J_2(ff) \quad (2.663)$$

where

$$J_0(ff) = \chi \int_{-\infty}^{\infty} \int_{4\pi} (f'_1 f' - f_1 f) d_{12}^2 (\mathbf{g}_{12} \cdot \mathbf{k}) d\mathbf{k} d\mathbf{c}_1 \quad (2.664)$$

$$J_1(ff) = d_{12} \int_{-\infty}^{\infty} \int_{4\pi} \left\{ \chi \left[ f' \frac{\partial f'_1}{\partial x_i} + f \frac{\partial f_1}{\partial x_i} \right] + \frac{1}{2} \frac{\partial \chi}{\partial x_i} (f'_1 f' - f_1 f) \right\} k_i d_{12}^2 (\mathbf{g}_{12} \cdot \mathbf{k}) d\mathbf{k} d\mathbf{c}_1 \quad (2.665)$$

$$J_2(ff) = \frac{d_{12}^2}{2} \int_{-\infty}^{\infty} \int_{4\pi} \left\{ \chi \left[ f' \frac{\partial^2 f'_1}{\partial x_i \partial x_j} - f \frac{\partial^2 f_1}{\partial x_i \partial x_j} \right] + \frac{\partial \chi}{\partial x_i} \left[ f' \frac{\partial f'_1}{\partial x_i} + f \frac{\partial f_1}{\partial x_i} \right] + \frac{1}{4} \frac{\partial^2 \chi}{\partial x_i \partial x_j} (f'_1 f' - f_1 f) \right\} k_i k_j d_{12}^2 (\mathbf{g}_{12} \cdot \mathbf{k}) d\mathbf{k} d\mathbf{c}_1 \quad (2.666)$$

where all quantities are evaluated at  $\mathbf{r}$ .

In Enskog's equation (2.662),  $(\mathbf{c}, \mathbf{c}_1)$  and  $(\mathbf{c}', \mathbf{c}'_1)$  are the velocities of two molecules before and after collision, respectively, and they are connected by the relations (being analogue to the dilute mono-atomic gas relations (2.133) and (2.134)):

$$\mathbf{c}' = \mathbf{c} + (\mathbf{k} \cdot \mathbf{g}_{21}) \mathbf{k} \quad (2.667)$$

$$\mathbf{c}'_1 = \mathbf{c}_1 + (\mathbf{k} \cdot \mathbf{g}_{21}) \mathbf{k} \quad (2.668)$$

in which  $\mathbf{g}_{21} = \mathbf{c}_2 - \mathbf{c}_1$  is the relative linear velocity and  $\mathbf{k}$  is the unit vector in the direction of the line which joins the two molecules centers at collision pointing from the molecule labeled by 1 to the other. Moreover,  $d_{12}$  is the diameter of the molecule and  $d\mathbf{k} = \sin \psi d\psi d\phi$ ;  $0 \leq \psi \leq \pi/2$  is the angle between  $\mathbf{k}$  and  $\mathbf{g}_{21}$  while  $0 \leq \phi \leq 2\pi$  is the angle between the plane containing  $\mathbf{k}$  and  $\mathbf{g}_{21}$  and a reference plane through  $\mathbf{g}_{21}$ . The plus or minus sign corrections refer to collisions that take  $(\mathbf{c}, \mathbf{c}_1)$  or  $(\mathbf{c}', \mathbf{c}'_1)$  as initial velocities, respectively.

### 2.12.3 Flux Vectors

In Sect. 2.5 the flux of molecular property  $\psi$  across a small surface element  $dA$  in a dilute gas at low pressure was considered. For dilute gases the molecules could be considered to be point masses. In dense gases, however, the finite size of the molecules

must be taken into account and, thus the instantaneous *collisional transfer* of the molecular property  $\psi$  across  $dA$ . That is, the instantaneous transfer due to collisions between molecules whose centers lie on opposite side of  $dA$  while the line joining their centers cuts  $dA$  must be taken into account.

The sign convention is define by  $\mathbf{n}$  being the unit normal to  $dA$ , located at  $\mathbf{r}$ , pointing from the negative to the positive side. Consider a collision between a molecule having velocity  $\mathbf{c}$  and a molecule having velocity  $\mathbf{c}_1$ . If the first molecule lies on the positive side of  $dA$  and the second on the negative side, the inner product  $\mathbf{k} \cdot \mathbf{n}$  is positive. At collision, the line joining the centers of the molecules must cut  $dA$ , so the center of the first molecule must lie within a cylinder having  $dA$  as base and whose generators are parallel to  $\mathbf{k}$  and of length  $d$ . Thus, the volume of this cylinder is  $d(\mathbf{k} \cdot \mathbf{n})dA$ . The mean positions of the centers of the two molecules at the instant of the collision are  $\mathbf{r} + \frac{1}{2}d\mathbf{k}$  and  $\mathbf{r} - \frac{1}{2}d\mathbf{k}$ , and the mean position of the point of contact is  $\mathbf{r}$ . Hence, the average number of such collisions per unit time at  $t$ , in which  $\mathbf{c}$ ,  $\mathbf{c}_1$  and  $\mathbf{k}$  lie in the range  $d\mathbf{c}$ ,  $d\mathbf{c}_1$  and  $d\mathbf{k}$ , respectively, is, by analogy with (2.660):

$$\chi(\mathbf{r})f(\mathbf{r} + \frac{1}{2}d_{12}\mathbf{k}, \mathbf{c}, t)f_1(\mathbf{r} - \frac{1}{2}d_{12}\mathbf{k}, \mathbf{c}_1, t)d_{12}^3\mathbf{g} \cdot \mathbf{k}d\mathbf{k}d\mathbf{c}_1d\mathbf{c}(\mathbf{k} \cdot \mathbf{n})dA \quad (2.669)$$

For convenience, henceforth a new notation is introduced:

$$d\Gamma = d_{12}^3\mathbf{g} \cdot \mathbf{k}d\mathbf{k}d\mathbf{c}_1d\mathbf{c} \quad (2.670)$$

Each such collision causes the transfer of a quantity  $(\psi - \psi')$  of the molecular property  $\psi$  across  $dA$ , so the total transfer by collisions of this type, per unit time and per unit area, is:

$$\chi(\mathbf{r}) \int \int \int (\psi' - \psi)f(\mathbf{r} + \frac{1}{2}d_{12}\mathbf{k}, \mathbf{c}, t)f_1(\mathbf{r} - \frac{1}{2}d_{12}\mathbf{k}, \mathbf{c}_1, t)(\mathbf{k} \cdot \mathbf{n})d\Gamma \quad (2.671)$$

in which the integration is over all values of the variables such that  $(\mathbf{g}_{21} \cdot \mathbf{k})$  and  $(\mathbf{k} \cdot \mathbf{n})$  are positive. That is, the condition  $(\mathbf{g}_{21} \cdot \mathbf{k}) > 0$  ensures that the molecules collide, whereas the condition  $(\mathbf{k} \cdot \mathbf{n})$  is a consequence of the definition of  $\mathbf{k}$  and  $\mathbf{n}$ .

The resulting *flux vector* associated with the collisional transfer of property  $\psi$  is expressed as:

$$\Phi_\psi = \chi(\mathbf{r}) \iiint_{\substack{\mathbf{g}_{21} \cdot \mathbf{k} > 0 \\ \mathbf{k} \cdot \mathbf{n} > 0}} (\psi' - \psi)f(\mathbf{r} + \frac{1}{2}d_{12}\mathbf{k}, \mathbf{c}, t)f_1(\mathbf{r} - \frac{1}{2}d_{12}\mathbf{k}, \mathbf{c}_1, t)\mathbf{k}d\Gamma \quad (2.672)$$

The summational invariant quantities like mass, momentum and energy, certain simplifying manipulations are possible because  $\psi + \psi_1 = \psi' + \psi'_1$ . We may then let the variables of integration  $\mathbf{c}$  and  $\mathbf{c}_1$  be interchanged. This operation is equivalent to interchanging the roles of the two colliding molecules, so that  $\mathbf{k}$  is replaced by  $-\mathbf{k}$ ,  $\mathbf{g}_{21}$  is replaced by  $-\mathbf{g}_{21}$ , and  $\psi' - \psi$  by  $\psi'_1 - \psi_1$  which is equal to  $-(\psi' - \psi)$ . Consequently, the integrand of (2.672) is unchanged but the region of integration is

now restricted by the condition  $\mathbf{g}_{21} \cdot \mathbf{k} > 0$  and  $\mathbf{k} \cdot \mathbf{n} < 0$ . The flux vector associated with the collisional transfer of a summational invariant  $\psi$  is, therefore, equal to:

$$\begin{aligned} \Phi_{\psi, \text{collision}} & \quad (2.673) \\ &= \frac{1}{2} \chi(\mathbf{r}) \iiint_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} (\psi' - \psi) f(\mathbf{r} + \frac{1}{2} d_{12} \mathbf{k}, \mathbf{c}, t) f_1(\mathbf{r} - \frac{1}{2} d_{12} \mathbf{k}, \mathbf{c}_1, t) \mathbf{k} d\Gamma \end{aligned}$$

If the conditions in the gas are sufficiently smooth,  $f(\mathbf{r} \pm \frac{1}{2} d_{21} \mathbf{k})$  may be expanded in a Taylor series around  $\mathbf{r}$ , so that  $\Phi$  may be approximated as:

$$\begin{aligned} \Phi_{\psi, \text{collision}} &= \frac{1}{2} \chi(\mathbf{r}) \iiint_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} (\psi' - \psi) f(\mathbf{r}, \mathbf{c}, t) f_1(\mathbf{r}, \mathbf{c}_1, t) \mathbf{k} d\Gamma \quad (2.674) \\ &+ \frac{1}{4} d_{12} \chi(\mathbf{r}) \iiint_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} (\psi' - \psi) \left( \mathbf{k} \cdot f(\mathbf{r}, \mathbf{c}, t) f_1(\mathbf{r}, \mathbf{c}_1, t) \nabla_r \ln \frac{f(\mathbf{r}, \mathbf{c}, t)}{f_1(\mathbf{r}, \mathbf{c}_1, t)} \right) \mathbf{k} d\Gamma \end{aligned}$$

The kinetic flux contribution due to the flow of molecules across the surface is given by (2.186):

$$\Phi_{\psi, \text{kinetic}} = \int_{-\infty}^{\infty} \psi f \mathbf{C} d\mathbf{c} \quad (2.675)$$

The total flux of the property  $\psi$  is then the sum of the two contributions:

$$\Phi_{\psi} = \Phi_{\psi, \text{kinetic}} + \Phi_{\psi, \text{collision}} \quad (2.676)$$

The Chapman-Enskog solution method, as discussed in Sect. 2.8 for a dilute mono-atomic gas, can be applied to the Enskog's equation as well. Solving the Enskog's equation by the perturbation method to determine  $f$ , we find that the *zero-order approximation* (i.e.,  $f \approx f^{(0)}$ ) of the *pressure tensor* and the *heat flux* vector are obtained from (2.675) with  $\psi = m\mathbf{c}$  and  $\psi = \frac{1}{2} m C^2$ , respectively:

$$\mathbf{p}_{\text{kinetic}}^{(0)} = \Phi_{m\mathbf{c}, \text{kinetic}}^{(0)} = nkT\mathbf{e} \quad (2.677)$$

$$\mathbf{q}_{\text{kinetic}}^{(0)} = \Phi_{\frac{1}{2} m C^2, \text{kinetic}}^{(0)} = 0 \quad (2.678)$$

However, in this case the product  $nkT$  is not equal to the static pressure in the gas, because the collisional contribution to the pressure does not vanish. With  $f \approx f^{(0)}$ , the collisional flux relation (2.674) gives for the *pressure tensor* (i.e., with  $\psi = m\mathbf{c}$ ):

$$\Phi_{m\mathbf{c}, \text{collision}}^{(0)} = \frac{1}{2} \chi(\mathbf{r}) \iiint_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} m(\mathbf{c}' - \mathbf{c}) f^{(0)}(\mathbf{r}, \mathbf{c}, t) f_1^{(0)}(\mathbf{r}, \mathbf{c}_1, t) \mathbf{k} d\Gamma \quad (2.679)$$

This integral can be integrated analytically, thus the result is [39]:

$$\mathbf{p}_{\text{collision}}^{(0)} = \Phi_{mc, \text{collision}}^{(0)} = \frac{2}{3} \pi n d_{12}^3 \chi n k T \mathbf{e} \quad (2.680)$$

Combining (2.676), (2.677) and (2.680) we conclude that in a zero-order theory, the pressure tensor assumes the form:

$$\begin{aligned} \mathbf{p}^{(0)} &= \mathbf{p}_{\text{kinetic}}^{(0)} + \mathbf{p}_{\text{collision}}^{(0)} = n k T \mathbf{e} + \frac{2}{3} \pi n d_{12}^3 \chi n k T \mathbf{e} \\ &= (1 + \frac{2}{3} \pi n d_{12}^3 \chi) n k T \mathbf{e} \end{aligned} \quad (2.681)$$

From this analysis, it follows that in a zero-order theory the kinetic theory approximates the static pressure as:

$$p^{(0)} = \frac{1}{3} \mathbf{p}^{(0)} : \mathbf{e} = (1 + \frac{2}{3} \pi n d_{12}^3 \chi) n k T \quad (2.682)$$

The static pressure in equilibrium is related to the temperature and density of the gas through this equation of state. A comparison with the ideal gas law defined in (2.643) might be informative.

In a similar manner, with  $f \approx f^{(0)}$  the collisional part of the molecular *heat flux* (i.e.,  $\psi = \frac{1}{2} m C^2$ ) is found from (2.674):

$$\Phi_{mC^2, \text{collision}}^{(0)} = \frac{1}{2} \chi(\mathbf{r}) \iiint_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} \frac{1}{2} m (C'^2 - C^2) f^{(0)}(\mathbf{r}, \mathbf{c}, t) f_1^{(0)}(\mathbf{r}, \mathbf{c}_1, t) \mathbf{k} d\Gamma \quad (2.683)$$

In a zero-order theory the analytical solution to this integral is zero [39]:

$$\mathbf{q}_{\text{collision}}^{(0)} = \Phi_{\frac{1}{2}mC^2, \text{collision}}^{(0)} = 0 \quad (2.684)$$

Combining (2.676), (2.678) and (2.684) we conclude that in a zero-order theory, the heat flux vector assumes the form:

$$\mathbf{q}^{(0)} = \mathbf{q}_{\text{kinetic}}^{(0)} + \mathbf{q}_{\text{collision}}^{(0)} = 0 \quad (2.685)$$

In the *first order approximation* considering that the gas is not in the uniform steady-state, a first approximation to  $f$  is given by  $f = f^{(0)}(1 + \Phi^{(1)})$ . The solution procedure is thus analogous to the dilute gas approach outlined in Sect. 2.8.2. However, for dense gas the perturbation function,  $\Phi^{(1)}$ , differs from the corresponding perturbation function (2.267) for a dilute gas only in that the term involving  $\nabla \ln T$  is multiplied by  $(1 + \frac{2}{3} \pi n d_{12}^3 \chi)/\chi$  and the term involving  $\nabla \mathbf{v}$  by  $(1 + \frac{4}{15} \pi n d_{12}^3 \chi)/\chi$ . The dense gas perturbation function is given by:

$$\Phi^{(1)} = -\frac{1}{n\chi} \left\{ (1 + \frac{2}{3} \pi n d_{12}^3 \chi) \mathbf{A} \cdot \nabla \ln T + (1 + \frac{4}{15} \pi n d_{12}^3 \chi) \mathbf{B} : \nabla \mathbf{v} \right\} \quad (2.686)$$

The first order *pressure tensor* approximations are given as [39]:

$$\begin{aligned} \mathbf{p}^{(1)} &= \mathbf{p}_{\text{kinetic}}^{(1)} + \mathbf{p}_{\text{collision}}^{(1)} \\ &= p\mathbf{e} - \kappa(\nabla \cdot \mathbf{v})\mathbf{e} - 2 \left[ \frac{1}{\chi} \left( 1 + \frac{4}{15} \pi n d_{12}^3 \chi \right)^2 \mu^{(0)} + \frac{3}{5} \kappa \right] \mathbf{S} \end{aligned} \quad (2.687)$$

where

$$\begin{aligned} \mathbf{p}_{\text{kinetic}}^{(1)} &= \Phi_{mc, \text{kinetic}}^{(1)} + \Phi_{mc, \text{kinetic}}^{(0)} \\ &= xnkT\mathbf{e} - \frac{2}{\chi} \left( 1 + \frac{4}{15} \pi n d_{12}^3 \chi \right) \mu^{(0)} \mathbf{S} \end{aligned} \quad (2.688)$$

$$\begin{aligned} \mathbf{p}_{\text{collision}}^{(1)} &= \Phi_{mc, \text{collision}}^{(1)} + \Phi_{mc, \text{collision}}^{(0)} \\ &= \frac{2}{3} \pi n d_{12}^3 \chi n k T \mathbf{e} - \frac{8}{15} \pi n d_{12}^3 \left( 1 + \frac{4}{15} \pi n d_{12}^3 \chi \right) \mu^{(0)} \mathbf{S} - \kappa \left[ \frac{6}{5} \mathbf{S} + (\nabla \cdot \mathbf{v}) \mathbf{e} \right] \end{aligned} \quad (2.689)$$

in which

$$\kappa = \frac{4}{9} n^2 d_{12}^4 \chi (\pi m k T)^{1/2} \quad (2.690)$$

By application of the same solution procedure, the first order *heat flux* approximations are given as [39]:

$$\mathbf{q}^{(1)} = \mathbf{q}_{\text{kinetic}}^{(1)} + \mathbf{q}_{\text{collision}}^{(1)} = - \left[ \frac{1}{\chi} \left( 1 + \frac{2}{5} \pi n d_{12}^3 \chi \right)^2 k^{(0)} + C_v \kappa \right] \nabla T \quad (2.691)$$

where

$$\begin{aligned} \mathbf{q}_{\text{kinetic}}^{(1)} &= \Phi_{\frac{1}{2}mC^2, \text{kinetic}}^{(1)} + \Phi_{\frac{1}{2}mC^2, \text{kinetic}}^{(0)} \\ &= - \frac{1}{\chi} \left( 1 + \frac{2}{5} \pi n d_{12}^3 \chi \right) k^{(0)} \nabla T \end{aligned} \quad (2.692)$$

$$\begin{aligned} \mathbf{q}_{\text{collision}}^{(1)} &= \Phi_{\frac{1}{2}mC^2, \text{collision}}^{(1)} + \Phi_{\frac{1}{2}mC^2, \text{collision}}^{(0)} \\ &= - \left[ \frac{2}{5} \pi n d_{12}^3 \left( 1 + \frac{2}{5} \pi n d_{12}^3 \chi \right) k^{(0)} + C_v \kappa \right] \nabla T \end{aligned} \quad (2.693)$$

It is seen that for mono-atomic dense gases both the pressure tensor,  $\mathbf{p}^{(1)}$ , and the heat flux vector  $\mathbf{q}^{(1)}$ , contain two flux contributions (i.e., a kinetic- and a collisional flux contribution) [20, 39, 55].

The *transport coefficients* for a moderately dense gas can be extracted from these results. A comparison of Newton's viscosity law (1.77) from continuum mechanics with (2.687) and of Fourier's law (2.580) with (2.691), approximate values of the transport coefficients (i.e., for the dynamic viscosity and the conductivity) can be determined. The dynamic viscosity,  $\mu^{(1)}$ , is given by:

$$\mu^{(1)} = \frac{1}{\chi} \left( 1 + \frac{4}{15} \pi n d_{12}^3 \chi \right)^2 \mu^{(0)} + \frac{3}{5} \kappa \quad (2.694)$$

The thermal conductivity,  $k^{(1)}$ , is given by the expression:

$$k^{(1)} = \frac{1}{\chi} \left( 1 + \frac{2}{5} \pi n d_{12}^3 \chi \right)^2 k^{(0)} + C_v \kappa \quad (2.695)$$

In the zero-order approximation, the dynamic viscosity and the conductivity are given by:

$$\mu^{(0)} = 1.0160 \times \frac{5}{16 d_{12}^2} \left( \frac{m k T}{\pi} \right)^{1/2} \quad (2.696)$$

$$k^{(0)} = 2.5 C_v \mu^{(0)} \quad (2.697)$$

The zero-order approximation transport coefficient values corresponds to the dilute gas values (2.620) and (2.621), respectively.

### 2.12.4 Enskog's Macroscopic Equations of Change

Analogous to the equation of change of mean molecular properties for dilute gas that was examined in Sect. 2.6, similar macroscopic conservation equations may be derived for dense gas from the Enskog equation. Multiplying the Enskog's equation (2.663) with the summation invariant property,  $\psi$ , and integrating over  $\mathbf{c}$ , the result is the *Enskog's equation of change* on the form:

$$\frac{\partial}{\partial t} \int \psi f d\mathbf{c} + \nabla_r \cdot \int (\psi \mathbf{c} f) d\mathbf{c} + \mathbf{F} \cdot \int f \nabla_c \psi d\mathbf{c} = I_0 + I_1 + I_2 \quad (2.698)$$

where  $I_i = \int \psi J_i(f f) d\mathbf{c}$ ,  $i = 0, 1, 2$ .

Analogous to the analysis of dilute gas in Sect. 2.6, it is easily proved that the integral  $I_0$  vanishes as it is an identical integral with a pre-factor that is independent of the integration. Moreover, by invoking some manipulations considering the equivalence of collisions and their inverses, and by interchanging the roles of the two colliding molecules, the integral  $I_1$  can be written as [39]:

$$I_1 = \frac{1}{2} \nabla_r \cdot \chi \iiint (\psi - \psi') f f_1 \mathbf{k} d\mathbf{\Gamma} \quad (2.699)$$

The last part of  $J_2(f f)$  gives a zero contribution to the integral  $I_2$  due to the same reason that  $I_0$  vanishes. The remainder two parts can after several manipulations be approximated as [39]:

$$I_2 = \frac{1}{4} d_{12} \nabla_r \cdot \chi \iiint (\psi - \psi') \left( \mathbf{k} \cdot f f_1 \nabla_r \ln \frac{f}{f_1} \right) \mathbf{k} d\Gamma \quad (2.700)$$

A comparison of the resulting fluxes  $I_i$ ,  $i = 0, 1, 2$  with (2.674) reveals that:

$$I_0 + I_1 + I_2 = -\nabla_r \cdot \Phi_\psi \quad (2.701)$$

The *Enskog's macroscopic equation of change* (2.698) may thus be written as:

$$\frac{\partial}{\partial t} \int \psi f d\mathbf{c} + \nabla_r \cdot \int (\psi \mathbf{c} f) d\mathbf{c} + \mathbf{F} \cdot \int f \nabla_c \psi d\mathbf{c} = -\nabla_r \cdot \Phi_\psi \quad (2.702)$$

This equation is a generalization of the macroscopic moment equation for dilute gas to dense gas of identical, rigid spherical molecules.

If we choose  $\psi$  as the summational invariants  $m$ ,  $m\mathbf{C}$  and  $mC^2$ , we obtain the Cauchy set of conservation equations named the continuity (2.217), the equation of motion (2.223), and the equation of energy (2.230). The only difference in the final result is that the pressure tensor,  $\mathbf{p}$ , and the heat flux vector,  $\mathbf{q}$ , are made up of two parts (i.e., a kinetic and a collisional contribution):

$$\mathbf{p} = \mathbf{p}_{\text{kinetic}} + \mathbf{p}_{\text{collision}} \quad (2.703)$$

$$\mathbf{q} = \mathbf{q}_{\text{kinetic}} + \mathbf{q}_{\text{collision}} \quad (2.704)$$

The kinetic parts corresponds to the dilute gas pressure tensor and heat flux, as defined by (2.270) with (2.271) and (2.272), respectively.

Substitution of the first order dense gas flux approximations (2.687) and (2.691) into the conservation equations results in the set of non-equilibrium gas dynamics equations (i.e., sometimes named the Navier-Stokes equations) for a mono-atomic dense gas. If the zero order dense gas flux approximations were employed instead, the outcome is the set of equilibrium Euler equations.

## 2.13 Governing Equations for Polydispersed Multiphase Systems

To describe polydispersed multiphase systems the Boltzmann equation can be extended by including the dependency of the internal property coordinates such as the particle size and shape in the definition of the distribution function. In this way a statistical balance formulation can be obtained by means of a distribution function on the form:  $p(\xi, \mathbf{r}, \mathbf{v}_\xi, \mathbf{c}, t) d\xi d\mathbf{r} d\mathbf{v}_\xi d\mathbf{c}$ , defined as the probable number of particles with internal properties in the range  $d\xi$  about  $\xi$ , with a velocity range in property space  $d\mathbf{v}_\xi$  about  $\mathbf{v}_\xi$ , located in the spatial range  $d\mathbf{r}$  about the position  $\mathbf{r}$ , with a velocity range  $d\mathbf{c}$  about  $\mathbf{c}$ , at time  $t$ . The particular Boltzmann type of equation is given by:

$$\frac{\partial p}{\partial t} + \nabla_{\mathbf{r}} \cdot (\mathbf{c} p) + \nabla_{\mathbf{c}} \cdot (\mathbf{F} p) + \nabla_{\xi} \cdot (\mathbf{v}_\xi p) + \nabla_{\mathbf{v}_\xi} \cdot (\mathbf{a}_\xi p) = \mathcal{I} \quad (2.705)$$

The first term on the LHS denotes the time variation of the distribution function  $p$ . The second term on the LHS represents the change in the number density distribution because of fluid particle convection into and out of the range  $d\mathbf{r}$ . The third term on the LHS represents the change in the number density distribution because of acceleration of the fluid particle into and out of the range  $d\mathbf{c}$  in the standard manner. However, in this case the net force  $\mathbf{F}$  acting to accelerate or decelerate the fluid particle includes the body and drag forces (per unit mass). The fourth term on the LHS represents the change in the number density distribution because of transport processes in the property space for example due to fluid particle growth into and out of the range  $d\xi$ . The fifth term on the LHS represents the change in the number density distribution because of accelerations in the property space for example due to acceleration of the fluid particle interface into and out of the range  $d\mathbf{v}_\xi$ . The term on the RHS represents the rate of change in the number density distribution due to particle coalescence, breakage and collisions.

A critical review of the population balance model derivation shows that there exist several transport equations of this type having different theoretical origin and interpretations [141]. The different model versions have specific inherent advantages and disadvantages. Following the same procedure as outlined in Sects. 2.6 and 2.6.1 deriving the governing single phase conservation equations from the original Boltzmann equation, the extended Boltzmann equation can be multiplied by a generalized property function whereupon the resulting equation is integrated over the whole velocity space to give a generic transport equation for the conserved multiphase quantities [118]. In particular, considering that the property function is unity a transport equation for the number distribution function  $f(\xi, \mathbf{r}, t)$  is obtained [82]. This transport equation is generally referred to as the *population balance equation*.

Hulburt and Katz [58] applied this approach to derive a transport equation for the number distribution function describing particulate systems considering growth, nucleation and agglomeration processes. Reyes Jr [118] and Lafi and Reyes [79] derived an extended set of mass, momentum and energy equations to describe poly-dispersed bubbly flows using a fluid particle continuity equation analogous to the Boltzmann's transport equation. In a similar manner Laurent et al. [88] derived the governing conservation equations for poly-dispersed dense sprays of evaporating liquid droplets. Lathouwers and Bellan [83–87] and Chao et al. [16, 17] proposed a similar model for poly-dispersed gas-solid multicomponent reactive processes in fluidized beds. The main challenge in formulating these equations is related to the definition of the collision operator. So far this approach has been restricted to the formulation of the population balance equation. That is, in most cases a general transport equation which is complemented with postulated source term formulations for the particle behavior is used. Randolph [112] and Randolph and Larson [113] used this approach deriving a microscopic population balance equation for the purpose of describing the behavior of particulate systems. Ramkrishna [111] provides further details on a different statistical approach considering also fluid particle systems. The population balance modeling framework is further discussed in Chap. 9.

## 2.14 Multifluid Models with Granular Flow Closures

Enskog's dense gas theory for rigid spheres has also been used as basis developing multifluid granular flow models. The modifications suggested extending the dense gas kinetic theory to particulate flows are discussed in Chap. 4.

## **Part II**

# **Multiphase Fundamentals**

## Chapter 3

# Multiphase Flow

In this chapter the pertinent multiphase modeling concepts established in fluid mechanics are examined. The modeling framework constituting the basis for the next generation of chemical reactor models is presented. The average multi-fluid model represents a trade-off between accuracy and computational efforts. This concept is a direct multi-dimensional extension of the conventional reactor models with the addition of the momentum equations. The multi-fluid model is actually the only approach that can be used analyzing chemical reactive systems on industrial scales considering both inherent physics and feasible computational efforts. The remaining sections of the chapter are devoted to the derivation of the two-fluid and multi-fluid models, and to the description of the averaging procedures commonly used in multiphase flow analysis.

### 3.1 Introduction

It is primarily a knowledge of chemical kinetics and reactor design that distinguishes the chemical engineers from other engineers. This multi-disciplinary profession emerged as a branch of engineering that is concerned with the design, construction and operation of chemical process plants in which the chemical reactor is a central unit. Both catalytic and non-catalytic chemical processes are operated in these chemical reactor units, as described in basic reaction engineering courses [82]. However, the major motivation for performing multi-phase flow analysis in chemical reaction engineering is highly linked to the discovery of catalysts. A catalyst is, as is well known by chemical engineers, a substance that affects the rate of a reaction but emerges from the process unchanged. The major application of catalysis are in petroleum refining and in chemical production, and this is thus a very important field of research in an oil and gas producing country like Norway. The development and use of catalysts has been a major part of the constant search for new ways of increasing product yield and selectivity from chemical reactions. Catalysis is usually referred to

as the occurrence, study, and use of catalysts and catalytic processes. In this context *yield* refers to the amount of a specific product formed in a given process per mole of entering reactant, while *selectivity* is related to the number of moles of desired product formed per mole of undesired product formed. Both homogeneous and heterogeneous catalytic systems are used. Homogeneous catalysis concerns processes in which a catalyst is in solution with at least one of the reactants. A heterogeneous catalytic process involves more than one phase, usually the catalyst is a solid and the reactants and products are in liquid or gaseous form. The discovery of solid catalyst and their application to chemical processes led to a breakthrough of the chemical industry [65]. Catalytic processing, involving multiphase systems, is utilized in the production of most industrial chemicals. The chemical or biochemical catalysts employed have a determining influence on the plant size, complexity, product distribution, by-products, economy and emission to the environment. The success of catalytic processing of multiphase systems has resulted from a synergetic approach to the problem by industrial chemistry and chemical engineering researchers. Traditionally, the focus of the industrial chemistry scientists has been on the catalyst, its preparation, active form, activity, active centers, kinetics and poisons that might damage it. Chemical engineers were mainly concerned with how to provide chemicals in sufficient amounts, enable mixing of the reactants on the molecular scales bringing the species effectively in contact with the chosen catalyst, and how to separate the products (and the catalyst particles) from the effluent process mixture (suspension). The engineers also concerned themselves with design and scale-up issues, as to how to produce the selectivity and rates reached in the laboratory on the industrial process scale.

Chemical reaction engineering (CRE) emerged gradually as a powerful methodology that quantifies the interplay between transport phenomena and kinetics on a variety of scales. A fundamental task for chemical reaction engineers is the formulation of a reactor model for which the basis are the species mass transport equations and the heat balance. The fluid velocity is normally considered a model parameter, or approximated by idealized flow formulas. These models have been used successfully determining various quantitative measures of reactor performance such as production rate, conversion and selectivity. The ability to establish such quantitative links between measures of reactor performance and input and operating variables is essential in optimizing the operating conditions in manufacturing, for proper reactor selection in design and scale-up, and in correct interpretation of data in research and pilot plant work. However, the conventional reactor model formulations are normally strictly not precise on the microscopic scales (yet usually sufficient in engineering practice) as the fundamental or 'rigorous' version of the governing transport equations were considered too complex to be conveniently solved for practical applications. There are generally two ways to obtain simplified models, i.e., either by direct simplification of the fundamental equations neglecting insignificant terms that have no practical interest or by averaging integrating the governing equations over suitable scales in time—and space. The averaging procedure is more common in practice, as the direct simplifications are only applicable for a few idealized flows. The choice of averaging scales in space (e.g., whole reactor, reactor section or differential volume)

to which the averaging procedure is applied determines the level of sophistication of the reactor model on macroscopic scales. As it is very common in chemical reactors to have flow predominantly in one direction, i.e., normally in the axial direction as in tubular reactors, a cross sectional averaged model may be used when only the spacial gradients in the principal flow direction have to be considered. The resulting equations are conventionally referred to as the non-ideal *axial dispersion model* (ADM). In the presence of packing or multiple fluid phases, a distinction is made between the true local fluid velocity, sometimes called the interstitial velocity ( $m/s$ ), and the velocity considered over the whole cross section, as if there were only one phase and no packing, called the superficial velocity ( $m^3$  fluid/ $m^2$  cross section  $s$ ). If the convective transport is completely dominant over any diffusive transport, the idealized *Plug Flow Reactor* (PFR) model is achieved. Otherwise, when the dispersion terms are very large, we can average out all space gradients in the species mass densities and the enthalpy quantity leading to the ideal *Continuous Stirred Tank Reactor* (CSTR) model.

The conventional models are often sufficient determining proper descriptions of the kinetics and the molecular transport processes, which then enables us to properly quantify the species overall or effective generation rates. Hence, the idealized reactor models are still preferred for the conventional chemical reactor analysis. They are also frequently utilized in chemical process simulations, optimization and control. However, it is obvious that all terms in a reactor model should be described at the same level of accuracy. It is certainly not optimal to have a detailed description of one term in the model if the others can only be very crudely described. Therefore, the improvement in accuracy obtained by the more detailed description of the kinetics at the molecular scale in turn required a more detailed description of the flow fields. The search for more fundamental reactor models solving all the pertinent balance equations simultaneously (e.g., the continuity equation, species mass balances, heat balance and momentum equations) in a predictive manner is gradually emerging defining a strategic goal in chemical reaction engineering. Sufficient modeling progress achieving such predictive capabilities is not imminent. It appears that the fundamental multi-phase reactor models still have limited inherent capabilities to fully replace the empirically based analysis in use today. Nevertheless, in the last two or three decades an increasing trend in applying fundamental modeling approaches to elucidate details of the reactor flow performance has been seen in the literature and recognized as useful by the industry. It is emphasized that almost only cold flow analysis of the reactor flow fields have been performed hitherto concluding that even the flow patterns in industrial reactors are almost prohibitively complex, hence the fundamental modeling is a challenging task. So, in chemical reactor engineering the multi-fluid flow models are merely related to modern academic research investigating details of cold flow patterns, physicochemical hydrodynamics and to a very limited extent improving the basic understanding of the complex interactions between flow phenomena, thermodynamics, molecular and turbulent transport processes, and chemical reaction kinetics.

**Fig. 3.1** Multiphase flow regimes. *A* Slug flow. *B* Bubbly flow. *C* Droplet Flow. *D* Annular flow. *E* Packed and porous fixed bed. *F* Particulate flow. *G* Stratified free surface flow

## 3.2 Chemical Reactor Flow Structure Characteristics

Detailed descriptions of the chemical reactor flow patterns are given in Chaps. 8, 10, 7 and 11. Meanwhile, a preliminary overview of the pertinent reactor flow characteristics is given to determine which modeling concepts are available describing the behavior of the relevant flows.

Typical multiphase flow regimes identified in general gas-liquid and gas-solid flows in vertical and horizontal tubes are illustrated in Fig. 3.1.

Examples of typical reactor flows are listed belows:

- Single phase fluid flows (single phase reactors, i.e., laminar and turbulent flows).
- Flow through porous beds of solids (fixed bed reactors, i.e., continua of gas; three phase fixed beds, i.e., continua of gas through a porous fixed solid and trickling liquids on the solid surface).
- Granular flows (fluidized bed reactors, i.e., discrete particles in a continuous gas phase).
- Bubbly flows (two phase bubble columns, stirred tank reactors, waste water treatment, i.e., bubbles in liquid).
- Slurries (i.e., discrete particles in liquid).
- Complex multiphase flows (e.g., slurry bubble columns and stirred tank reactors i.e., bubbly flows in slurries; three phase fluidized beds, i.e., liquid droplets and particles in continuous gas) where many phases interact simultaneously.

In addition to the complex flow structure encountered in these reactor systems, typically one has to deal with component and energy transport within the individual phases and momentum, heat and mass transfer both between the various phases and

to the external reactor walls. The interactions with chemical reaction kinetics are difficult both with respect to physical modeling and numerical solution approximations due to the very wide range of time and length scales involved.

### 3.3 Modeling Concepts for Multiphase Flow

The development of computational methods for multiphase flows was pioneered by Harlow and Welch [102], Hirt [112], Amsden and Harlow [6], Harlow and Amsden [103], Nichols and Hirt [167], Hirt and Nichols [114], and Hirt and Nichols [113] at the Los Alamos science laboratory in New Mexico. These methods were based on finite difference discretizations of the continuity and Navier-Stokes equations using velocity and pressure as the primitive variables. The early work on incompressible flows showed the need to use staggered grids and upwind differencing at high Reynolds numbers to obtain stable and physical solutions. The idea of solving the pressure from the continuity equation was accepted. In Europe the interest in computational fluid mechanics was initiated by the publication of a book by another pioneering group at Imperial College in London UK introducing the basic principles of the finite volume method and the wall function concept making primitive turbulence simulations feasible [92]. The work of Spalding on multiphase modeling and solution methods [221–225] at Imperial College is perhaps better known as he produced the very first commercial CFD program code (PHOENICS) for solving multiphase flow problems. An excellent review on models and numerical methods for multiphase flow has been presented by Stewart and Wendroff [226]. Similar reviews with emphasis on dilute gas-particle flows models have been published by Crowe [40], Crowe et al. [41] and Crowe et al. [42]. For multiphase systems a rough distinction can be made between systems with *separated flows* and those with *dispersed flows*, as sketched in Fig. 3.1 (i.e., regime G versus regimes B, C and F). This classification is not only important from a physical point of view, but also from a computational perspective since for each class different computational approaches are required. In view of the multi-phase reactor flow structure characteristics summarized in Sect. 3.2, it is obvious that dispersed flow systems are dominating. For these flows roughly three different computational strategies can be distinguished based on the scales resolved by the model formulation:

1. The *Eulerian-Lagrangian models* for very dilute flows where small discrete particles are considered in the control volume formulating the governing microscopic model equations. For slightly denser flows different types of Eulerian and Lagrangian averaging procedures are applied deducing the more practical macroscopic model equations.
2. The *Eulerian-Eulerian multifluid models* for dense flows where a relatively large number of particles are considered determining a continuous phase in the control volume formulating the governing microscopic model equations. Different

types of Eulerian averaging procedures are applied deducing the corresponding macroscopic model equations.

3. The *High resolution methods* for multiphase flows containing any number of particles where the model equations are formulated considering very small control- and averaging volumes. That is, the relative size of fluid particles with respect to the averaging volumes is large enough so the particles (not the interfaces!) can in principle be resolved [13, 236, 237, 260]. The modeling frameworks used are Eulerian, Lagrangian, or a combination of these concepts.

In the sequel the averaged *Eulerian-Lagrangian*, averaged *Eulerian-Eulerian*, and *High Resolution* methods are outlined.

### 3.3.1 Averaged Models

In this section the governing equations determining the averaged Eulerian-Lagrangian and the Eulerian-Eulerian modeling concepts are discussed.

#### 3.3.1.1 Averaged Eulerian-Lagrangian Multi-Phase Models

For dispersed multiphase flows a Lagrangian description of the dispersed phase are advantageous in many practical situations. In this concept the individual particles are treated as rigid spheres (i.e., neglecting particle deformation and internal flows) being so small that they can be considered as point centers of mass in space. The translational motion<sup>1</sup> of the particle is governed by the Lagrangian form of Newton's second law [42, 109, 128, 158]:

$$\frac{d}{dt}(m_p \mathbf{v}_p) = \mathbf{f}_{hp} + \mathbf{f}_p + \mathbf{f}_E + \mathbf{f}_G + \mathbf{f}_D + \mathbf{f}_V + \mathbf{f}_L + \mathbf{f}_B \quad (3.1)$$

where  $m_p = \rho_p V_p$  is the mass of the particle. Treating the dispersed phase as rigid spheres  $\rho_p$ ,  $V_p$  and  $m_p$  are constants in time. The forces listed on the RHS of (3.1) denote surface and body forces acting on the particle as considered in Sect. 5.1.  $\mathbf{f}_{hp}$  denotes the force due to the hydrostatic pressure,  $\mathbf{f}_p$  designates the force due to any external pressure gradients,  $\mathbf{f}_G$  denotes the body force due to gravity,  $\mathbf{f}_E$  denotes any body force created by external fields apart from gravity,  $\mathbf{f}_D$  is the steady drag force,  $\mathbf{f}_V$  is the virtual mass force,  $\mathbf{f}_L$  is the transversal lift force, and  $\mathbf{f}_B$  is the Basset history force.

The particle trajectory is calculated from the definition of the translational velocity of the center of mass of the particle:

---

<sup>1</sup> For non-spherical rigid particles the particle rotation may become important. This requires that an angular momentum equation for each particle has to be solved [42].

$$\frac{d\mathbf{r}_p(t)}{dt} = \mathbf{v}_p(t, \mathbf{r}_p(t)) \quad (3.2)$$

A group of Euler-Lagrangian concepts are classified with respect to the complexity involved describing the interfacial coupling between the phases [70]. In a *one way coupled* system the particle volume loading is assumed to be small enough so that any effects that the presence of the dispersed phase may have on the continuous phase can be neglected. Thus, the local velocity of the continuous phase has a direct impact on the particle while the reverse is not true. For slightly denser systems the effects of the particles on the carrier fluid cannot be ignored and *two way coupling* is required. For dense systems *four way coupling* is necessary to take into account the additional particle-particle collision effects and any fluid turbulence modification caused by the particles. When one way coupling is used, the Eulerian velocity field is computed independent of the particle tracking by a standard single-phase simulation. Thereafter, the trajectories of the individual particles are computed independently from one another. In contrast, a two way coupled Euler-Lagrangian simulation must solve the fully time dependent dispersed and continuous phase equations in an iterative manner. In a four way coupled system there are mutual (binary) interactions between the individual particles as well as a two way coupling between the dispersed and continuous phases, making the dynamic equations of all the phases strongly coupled so the iterative process becomes even more difficult to handle both regarding computational time and stability. The complexity of the interfacial coupling depends mainly on the value of the dispersed phase volume fraction and the number of particles. That is, for a given value of the dispersed phase volume fraction the number of particles depends on the current particle size distribution. In practice, as a general rule of thumb, for very dilute flows (say  $\alpha_p < 10^{-6}$ ) containing very small particles a simple one-way coupling between the dispersed and continuous phases is assumed sufficient, while two way coupling is considered a reasonable approach for moderately dense dispersions (say  $\alpha_p \leq 10^{-3}$ ). For denser systems four-way coupling is recommended [42, 217]. However, the computational speed and storage capabilities of the present computers are limited so in many practical simulations the number of particles are prohibitively large and the computational loads have to be reduced considering statistical methods. It is thus distinguished between direct Euler-Lagrangian models which are tracking all the particles simultaneously, and statistical model formulations computing an ensemble of representative particle trajectories only. For flows involving a relative small number of tiny particles (typically less than  $10^3$  particles) it is normally feasible to solve a set of Lagrangian equations for every element. However, if the number of tiny particles is large (typically more than  $10^4$  particles), a statistical approach is more practical. In such a description the total population is represented by a finite number of computational parcels, each of which represents a group of particles having the same properties. In this case caution is required as the Euler-Lagrange method is not fully consistent whenever the cloud of particles tracked constitutes a volume larger than the fluid parcel considered averaging the governing equations. Moreover, the number of computational parcels (samples) must be large enough so that the properties of the whole popula-

tion are well represented. For simulations involving two- and four way coupling the continuous phase is described by slightly modified single phase momentum equations formulated in the Eulerian framework [53, 54, 133, 139, 158, 163]. That is, the Eulerian momentum equations contain an additional interaction term denoting the sum of the individual interactions by each particle. These interaction terms are deduced based on Newton's third law (i.e., the individual drag forces experienced by the particles act with equal magnitude but in the opposite direction on the continuous phase, *actio=reactio*). It is noted the drag terms require the interpolation of the continuum phase velocity from the Eulerian grid to the local particle position. The main advantage of the Eulerian-Lagrangian approach (i.e., compared to the alternative Euler-Euler model described in the next section) is its flexibility with respect to the incorporation of the microscopic transport phenomena. Particle dynamics can in principle be described in detail, a particle size distribution can easily be incorporated, direct particle-particle interactions can be accounted for as well as the hydrodynamic interaction between neighboring particles. The major disadvantage of the Eulerian-Lagrangian approach is its relatively high computational load (i.e., again compared to the Eulerian-Eulerian approach). The flows in multiphase chemical reactors, for example, are usually very dense so it is not feasible to keep track of the high number of dispersed particles, thus only the statistical approach can be used [128]. Note also that all the averaged multiphase model formulations require appropriate closure laws for the interfacial transport of momentum. The correct form of these closure laws is still being debated. Rigorous derivations of the constitutive relations and model coefficients exist at best solely for idealized flow situations, whereas semi-empirical parameterizations and parameter fitting are used in practical applications in which the flow characteristics deviate largely from the idealized cases.

### 3.3.1.2 Averaged Eulerian-Eulerian Multi-fluid Models

The averaged Eulerian-Eulerian multi-fluid model denotes the averaged mass and momentum conservation equations as formulated in an Eulerian frame of reference for both the dispersed and continuous phases describing the time-dependent motion. For multiphase isothermal systems involving laminar flow, the averaged conservation equations for mass and momentum are given by:

$$\frac{\partial}{\partial t}(\alpha_k \rho_k) + \nabla \cdot (\alpha_k \rho_k \mathbf{v}_k) = \Gamma_k \quad (3.3)$$

and

$$\begin{aligned} \frac{\partial}{\partial t}(\alpha_k \rho_k \mathbf{v}_k) + \nabla \cdot (\alpha_k \rho_k \mathbf{v}_k \mathbf{v}_k) = & -\alpha_k \nabla p - \nabla \cdot (\alpha_k \boldsymbol{\sigma}_k) \\ & + \mathbf{M}_{k,l} + \Gamma_k \mathbf{v}_l + S_k + \alpha_k \rho_k \mathbf{g}_k \end{aligned} \quad (3.4)$$

where  $\rho_k$ ,  $\mathbf{v}_k$ ,  $\alpha_k$  and  $\boldsymbol{\sigma}_k$  represent, respectively, the density, velocity, volume fraction and viscous stress tensor of the  $k$ th phase,  $p$  the pressure,  $\Gamma_k$  a source term describing mass exchange between phase  $k$  and the other phases,  $\mathbf{M}_{k,l}$  the interface momentum exchange term between phase  $k$  and phase  $l$ , and  $S_k$  a momentum source term of phase  $k$  due to external forces other than gravity.

An advantage of the multi-fluid model is that in principle it can be used to compute any multiphase flow regime, provided that an adequate closure relation for the interfacial coupling terms are provided. Besides, when this model is applied to describe dense dispersed flows, the Euler–Euler approach is normally less computationally demanding than the alternative Euler-Lagrangian model simulations described in the previous section. Nevertheless, at the same time, a severe disadvantage of a multi-fluid model is the need for empirical closure laws for the interfacial transport processes. The formulation of the Eulerian interfacial closure laws for both dilute and dense suspensions are based on simple average of the Lagrangian single particle relationships for idealized flows, thus the accuracy reflected by the Eulerian interfacial coupling terms is generally even poorer than for the corresponding Lagrangian models. Although promising results have been obtained in recent years, there are still no general agreement on the correct mathematical form of the net interfacial forces acting on the dispersed phase particles, nor on the net hydrodynamic and fluid-particle turbulence interactions. Prudence must also be shown to limit numerical diffusion in the Eulerian model fields, for instance, by applying at least second order schemes both in time and space instead of the first order schemes commonly applied in the commercial program codes [33, 83, 131, 149, 215, 216]. Notwithstanding, as the flow in most operating chemical reactors is dense, the Euler–Euler type of models has been found to represent a trade-off between accuracy and computational efforts for practical applications [128].

### 3.3.2 High Resolution Methods

The purpose of this section is to give an overview of the pertinent high resolution methods often referred in the literature on multiphase reactor modeling. These are: The Marker and Cell (MAC) method [102], the Simplified MAC method [6], the volume of fluid (VOF) method [114], the level set (LS) front capturing method [22, 199, 228], the front tracking method<sup>2</sup> [235, 241] and finally a brief description of the phase-field method [8].

Using the volume averaged Eulerian-Eulerian and Eulerian-Lagrangian multiphase models the spatial resolution considered deriving the constitutive relations is generally coarse compared to the size of the particles. However, small-scale structures in the fluid and most likely also within the dispersed fluid particles may under specific

---

<sup>2</sup> It is noticed that after some re-evaluation Tryggvason and co-workers [236, 242] classified their front tracking method [241] as an embedded interface method, since it is best described as a hybrid between a front tracking and a front capturing method.

conditions govern important phenomena encountered in multiphase reactors. In this context the physicochemical phenomena affecting the fluid particle coalescence and breakage rates are highlighted. In this area much fundamental work remains to be done. In view of the discussion in Sect. 3.3.1, numerical methods that are designed to resolve the interfacial configurations in time and space are attractive elucidating the impacts of the microscopic phenomena on the macroscopic quantities. Such high resolution models are often divided into various classes due to their mathematical characteristics. One class of these methods can be recognized by the use of a single set of transport equations for the whole flow field [196, 238], *the whole field formulation*. Another useful formulation of the balance equations decomposes the problem into any number of bulk phase domains where the usual single phase transport equations holds, and the interfaces across which the physical quantities are required to have specific jumps. This alternative formulation is thus sometimes called *the jump-condition form*. In the latter approach each phase is treated separately. From another mathematical point of view the various methods for interface simulation can be divided into two classes, depending on whether a fixed or a moving grid is used in the bulk of the phases as well as to locate the interface and determining its orientation. In *fixed-grid* methods, there is a predefined grid that does not move with the interface. In this case the interface is making a 2D plane cut across the fixed 3D grid. In *moving-grid* methods, the interface is a boundary between two elements or sub-domains of the bulk grid. The interface then identifies, at some order of approximation, with element boundaries [196]. Lately, the complexity of the methods has increased tremendously, so a more compound characterization is frequently used to distinguish the different techniques. Hence, three important methods are named in accordance with the concepts used to identify the position and orientation of the interface, the grids adopted, as well as the frameworks employed formulating the governing equations. In the early *particle methods* the flow fields of the bulk phases are solved on a fixed grid, and the position of the interface is identified using passive marker particles which are following the bulk flow. In the modern *front capturing* methods, the interface or front separating the bulk phases appears directly on a fixed grid as a region with steep gradients in the primary variables [242]. The *front tracking* methods are usually constructed by explicitly tracking the interface by use of a moving grid, a front, determining a material boundary between the fluid phases which are thus treated separately on a fixed grid [238, 242]. Following these classifications, the MAC, SMAC, VOF and LS techniques are all front capturing methods. The MAC and SMAC techniques are also referred to as particle methods. In the VOF and LS methods a similar marker function is used to identify the phases and reconstruct the interface, hence they are sometimes called *volume tracking* methods [117, 241]. The embedded interface (EI) method can be characterized as a hybrid between a front capturing and a front tracking technique [236, 238]. In this type of methods a stationary or fixed regular grid is used for the fluid flow, but the interface is tracked by a separate grid of lower dimension. This grid is usually called the front. However, unlike front tracking methods where each phase is treated separately, the embedded interface method follow most front capturing methods and treats all phases by a single set of governing equations for the whole flow field.

### 3.3.2.1 The Marker and Cell Method

The original Marker and Cell Method (MAC) of Harlow and Welch [102] was the first marker method developed aiming at numerical simulations of time-dependent *incompressible* flows with a free surface [117]. The MAC model constitutes the continuity and Navier-Stokes equations for the continuous fluid, and the Lagrangian equations of motion for the marker particles. As part of this method Harlow and Welch proposed a novel staggered grid arrangement of the dependent variables (i.e., separate grid cells were used for  $v_x$ ,  $v_y$  and  $p$  in 2D), which is essential for treating the pressure-velocity coupling in the Navier-Stokes equations and is still frequently used in fluid flow codes. On this grid the continuity and Navier-Stokes equations were discretized using a second order finite difference scheme in space, applying simple averaging for points where the variables are not defined in the grid. As in all incompressible flow codes, the continuity equation was treated implicitly. The velocity tendencies were approximated using a first order explicit scheme. Hence, all the terms in the Navier-Stokes equations are approximated using the velocity values at time level  $t_n$ . In the first phase of the MAC algorithm the pressure at time level  $t_{n+1}$  is calculated, solving a Poisson equation in which the source term is a function of the velocity values at time level  $t_n$  only. Thereafter, the full Navier-Stokes equations are used to find the time level  $t_{n+1}$  velocities. It is emphasized that the Poisson equation is derived by combining the implicit incompressibility condition with the momentum equations, thus the resulting momentum equations satisfy the continuity automatically. The pressure field obtained from this procedure is the true pressure instead of a pseudo pressure as used in later methods such as SIMPLE [172] and the typical fractional step projection algorithms [37]. In the second phase of the MAC method marker particles are scattered initially to identify the spatial region occupied by a single fluid with a free surface (facing vacuum) and to track the movement of the free surface during the simulation. The particles are transported in a Lagrangian manner along with the materials. Surfaces are then defined as lying at the boundary between regions with and without marker particles, hence the location and shape of the free surface can be found. However, the free surface stresses and the effects of the surface tension were ignored. The simplified MAC method, the SMAC technique of Amsden and Harlow [6], denotes a three-stage fractional time step advancement procedure that resembles the technique suggested by Chorin [37]. In the SMAC procedure tentative estimates of the  $t_{n+1}$  time level velocity field is determined first using an explicit algorithm approximating the momentum equations, ensuring that the vorticity is correct but the continuity may not be satisfied. Then, a corrected pressure is calculated from the continuity in-balance in such a way as to preserve the vorticity but bringing the divergence to zero. Finally, an updated velocity is calculated from the new pressure estimate. The advantages of SMAC, compared to the original MAC method, are related to simpler program implementations, higher convergence rates, and more convenient boundary treatment. In the second phase of the algorithm the free surface treatment is still the same as for the original MAC method. It appears that a method that defines fluid regions rather than interfaces offers the advantage of logical simplicity for situations involving interacting multiple free

boundaries. While the marker particle method provides this simplicity, it suffers from a significant computer memory and storage demand. It also requires considerable computational efforts to move all the particle points to the new locations. Besides, no successful extensions of the MAC method which enable proper reconstruction of sharp interfaces seemed feasible. It was thus natural to seek an alternative interface capturing method which requires less computer resources but still provides sufficient accuracy. No real breakthrough in this respect was achieved till the use of marker particles was abandoned and a marker function advected by the flow was used instead [114].

### 3.3.2.2 The Volume of Fluid Method

In this section the basis elements of the volume of fluid (VOF) method are described. In general the VOF model is composed of a set of continuity and momentum equations, as well as a transport equation for the evolution of a phase indicator function which is used to determine the location and orientation of the interface. We distinguish between the jump condition—and the whole field formulations of the method, in which both forms are based on a macroscopic view defining the interface as a 2D surface. The jump condition form is especially convenient for free-surface flow simulations, whereas the whole field formulation is commonly used for interfacial flow calculations in which the internal flow of all the phases are of interest.

A common feature for all the different formulations of the VOF model is that the location and orientation of the interface are defined through a volume fraction function. The evolution of this volume fraction function in time and space is determined by a scalar advection equation defined by:

$$\frac{D\alpha_1}{Dt} = \frac{\partial\alpha_1}{\partial t} + (\mathbf{v}_m \cdot \nabla)\alpha_1 = 0 \quad (3.5)$$

The propagation procedure contains the calculation of the volume fraction,  $\alpha_1$ , that represents the fractional volume of the cell occupied by fluid 1. A unit value of  $\alpha_1$  corresponds to a cell full of fluid 1, while a zero value indicates that the cell contains no fluid 1. Cells with  $\alpha_1$  values between zero and one must then contain an interface. The VOF models thus require a proper numerical advection scheme to approximate the transport of the scalar function in an accurate manner avoiding numerical diffusion. Most VOF algorithms solve the problem of updating the volume fraction field,  $\alpha_1$ , given the fixed grid and the velocity field,  $\mathbf{v}_m$ , using a second order explicit discretization scheme in time and a higher (second) order discretization scheme on the flux form in space. In many program codes the fractional step or operator split method, which updates the volume fraction by advecting the interface along one spatial direction at the time, has been used [98, 131, 192, 193, 196, 240]. Thus, in 3D three consecutive reconstruction and convection steps are required per time step. In unsplit methods there is only one reconstruction step and the volume fluxes across the cell faces are computed simultaneously.

In the *jump-condition formulation* the physical problem is generally decomposed into  $k$  bulk phase domains where the continuity and momentum equations for isothermal incompressible flows holds, and at the interface between these domains boundary conditions are specified using the interface jump conditions. That is, across the interface some quantities are required to be continuous, while others are required to have specific jumps. The discontinuous (singular) momentum jump condition can be derived by use of the surface divergence theorem<sup>3</sup> (see e.g., [68] p. 51; [28]). A rigorous derivation of the jump balances for the multi-fluid model is given in Sect. 3.4.

The governing equations for the jump condition form of the VOF method are thus defined by [177]:

$$\nabla \cdot \mathbf{v}_k = 0 \quad (3.6)$$

$$\frac{\partial \mathbf{v}_k}{\partial t} + \mathbf{v}_k \cdot \nabla \mathbf{v}_k = -\frac{1}{\rho_k} \nabla p_k + \nu_k \nabla^2 \mathbf{v}_k \quad (3.7)$$

The interface boundary conditions, i.e., the momentum jump conditions, are expressed as (i.e., no surface tension gradients are considered):

$$\sum_{k=1}^2 \mathbf{T}_k \cdot \mathbf{n}_k = 2\sigma_I H_I \mathbf{n}_I \quad (3.8)$$

This condition may be split into a normal stress condition:

$$\sum_{k=1}^2 \mathbf{n}_I \cdot \mathbf{T}_k \cdot \mathbf{n}_k = \mathbf{n}_I \cdot 2\sigma_I H_I \mathbf{n}_I \quad (3.9)$$

or

$$\sum_{k=1}^2 [(\mathbf{n}_I \cdot \mathbf{n}_k) p_k + \mathbf{n}_I \cdot \boldsymbol{\sigma}_k \cdot \mathbf{n}_k] = 2\sigma_I H_I \quad (3.10)$$

and a tangential stress condition:

$$\sum_{k=1}^2 [\mathbf{t}_k^{(k)} \cdot \boldsymbol{\sigma}_k \cdot \mathbf{n}_k]_I = 0 \quad (3.11)$$

where the vectors  $\mathbf{t}^{(k)}$  may be any set of  $d - 1$  independent tangent vectors to the interface  $A_I$ , and  $d$  is the dimension of space [141, 196, 260].

---

<sup>3</sup> The work of Brenner [28] also contains a micro-mechanical derivation of the differential equation of interface statics that clearly distinguish between micro-scale and macro-scale viewpoints. From thermodynamic analysis it is concluded that the surface tension manifests itself in the normal direction as a force that drives surfaces towards a minimum energy state characterized by a configuration of minimum surface area.

Performing macro-scale experiments it has been observed that the normal surface tension force induces higher normal stresses in the fluid on the concave side of the interface than on the other fluid on the convex side of the interface. In a micro-scale view we may say that this interfacial tension force is exerted by the interfacial material lying on the convex side of the surface upon the material lying on the concave side. The normal component of the surface force is thus frequently (not always!) defined positive into the mean curvature of the surface, in line with the physical observations. The direction of the normal component of the interface force given by (3.9) is determined by two factors, the interface normal unit vector  $\mathbf{n}_I$  which we have defined positive into the curvature,<sup>4</sup> and the mean curvature variable which we have chosen to define as an absolute value. That is, the variable used here determining the mean curvature of the surface ( $H_I = (\kappa_1 + \kappa_2)/2$ ) is consistent with the definition given by Slattery [213] (p. 1116) and by most classical textbooks on differential geometry.  $\kappa_1$  and  $\kappa_2$  denote the absolute values of the principal curvatures of the surface. The principal curvatures are the maximum and minimum values of the normal curvature. Another mode of expressing the principal curvatures  $\kappa_1$  and  $\kappa_2$  is in terms of the principal radii of curvature  $R_1$  and  $R_2$ :  $\kappa_1 = 1/R_1$  and  $\kappa_2 = 1/R_2$ . Finally, the mean curvature of a surface may also be expressed in terms of the variation of the unit surface normal  $\mathbf{n}_I$  with position in the surface. Thus, the mean surface curvature may be given by:  $H_I = -\frac{1}{2}\nabla \cdot \mathbf{n}_I$ .

*Free-surface flow* is a limiting case of flow with interfaces, in which the treatment of one of the phases is simplified. For instance, for some cases of gas-liquid flow, we may consider the pressure  $p_{\text{gas}}$  in the gas to depend only on time and not on space and the viscous stresses in the gas to be negligible. For such flows the jump condition formulation must be used, since the bulk momentum equation breaks down. The jump conditions become boundary conditions on the border of the liquid domain [196, 260]:

$$p_l + \mathbf{n}_l^{lg} \cdot \boldsymbol{\sigma}_l \cdot \mathbf{n}_l^{lg} = p_{\text{gas}} + 2\sigma_I H_I \quad (3.12)$$

and

$$\mathbf{t}_l^{lg,(k)} \cdot \boldsymbol{\sigma}_l \cdot \mathbf{n}_l^{lg} = 0 \quad (3.13)$$

The original VOF model designed for free surface flow simulations constitutes the mass and momentum conservation equations for incompressible fluids in the jump condition form [114, 167].

The pioneering SOLA-VOF method [114] evolved from the MAC/SMAC techniques [6, 102], thus the velocity and pressure fields are obtained in accordance with the SMAC method with only minor modifications. That is, in the SOLA codes the condition of a zero velocity divergence is still treated as an equation for the

---

<sup>4</sup> If we define  $\mathbf{n}_I$  positive out of the curvature instead, the curvature itself must be defined in a consistent manner with sign defining its orientation. Note that several variations of sign conventions may be chosen. The choice of conventions is to a large extent a matter of convenience.

pressure but now, merely to save memory, the pressure-velocity coupling is solved iteratively adjusting the pressure and velocity simultaneously. The original SOLA-VOF method considers the motion of a fluid zone in vacuum. Therefore, no shear forces were present at the fluid surface. The effect of velocity gradients on the surface pressure was neglected, hence at the free surface a fixed boundary value was specified for the pressure,  $p_s(t)$ . Later on, the surface tension effects have been included with only minor additional efforts. The boundary pressure values were then determined from the surface tension force,  $p = p_s - 2H_I\sigma_I$ , where  $H_I$  is the mean curvature of the interface.

The SOLA-VOF method time integration consists of three basic steps:

- A tentative estimate of the velocity field in the new time-step is achieved by an explicit step, using the previous time level values for all advective, pressure and diffusive terms.
- Iterate on the pressure-velocity changes until the continuity is satisfied.
- The new fluid distribution is determined updating the volume fraction function.

The SOLA-VOF method has been used simulating bubble motion in liquid [14]. An important part of this simulation is the tracking of the free surface and determining boundary conditions on it. The simplified jump condition form of the VOF method was applicable because for large differences in liquid and gas densities and large Reynolds numbers the motion of the gas inside the bubble becomes unimportant and the pressure distribution in it can be assumed uniform constituting a free surface flow.

The alternative VOF models designed to describe stratified and dispersed flows with internal motions in all the phases are based on the *whole domain formulation*. The basis for this approach is a set of equations valid for the whole calculation domain, in which the governing mass and momentum balances are expressed as [35, 98, 141, 177, 196, 228, 236, 241]:

$$\nabla \cdot \mathbf{v}_m = 0 \quad (3.14)$$

$$\frac{\partial}{\partial t}(\rho \mathbf{v}_m) + \nabla \cdot (\rho \mathbf{v}_m \mathbf{v}_m) = -\nabla p_m - \nabla \cdot \boldsymbol{\sigma}_m + \rho \mathbf{g} + 2\sigma_I H_I^2 \mathbf{n}_I \delta_I(\mathbf{r} - \mathbf{r}') \quad (3.15)$$

where  $\sigma_I$  is the surface tension,  $H_I$  the local mean curvature, and  $\mathbf{n}_I$  the normal to the interface pointing into phase 1.  $\delta_I(\mathbf{r} - \mathbf{r}')$  is a Dirac delta function that is zero everywhere except at the interface, where  $\mathbf{r} = \mathbf{r}'$ . The effect of the discontinuous (singular) surface tension force is to act as an additional forcing term in the direction normal to the fluid interface.

The density and viscosity occurring in these equations are defined as:

$$\rho_m = \alpha_1 \rho_1 + (1 - \alpha_1) \rho_2 \quad (3.16)$$

and

$$\mu_m = \alpha_1 \mu_1 + (1 - \alpha_1) \mu_2 \quad (3.17)$$

The model can be classified as a homogeneous mixture model which is formulated directly on the averaging scales (i.e., the control volume coincides with the averaging volume). It is further assumed that the relative velocity in the interface grid cells is zero ( $\mathbf{v}_r = 0$ ), and that all the scales of turbulence are resolved (i.e., in this respect this homogeneous model formulation resembles a direct numerical simulation). The derivation of the given whole field formulation, introducing the Dirac delta function ( $\delta_I$ ) into the surface tension force relation to maintain the discontinuous (singular) nature of this term, is to a certain extent based on physical intuition rather than first principles (i.e., in mathematical terms this approach is strictly not characterized as a continuum formulation on the differential form). Chandrasekhar [34] (pp. 430–433) derived a similar model formulation and argued that to some extent the whole field momentum equation can be obtained by a formal mathematical procedure. However, the fact that the equation involves  $\delta_I$ -functions means that to interpret the equation correctly at a point of discontinuity, we must integrate the equation, across the interface, over an infinitesimal volume element including the discontinuity. In addition, we need to specify which quantities are continuous and which bounded at an interface between two fluids. Similar whole field formulations have been used and further discussed by Lafaurie et al. [141], Sussman et al. [228], Chang et al. [35], Popinet and Zaleski [177], Gueyffier et al. [98] and Tryggvason [196, 236]. Several numerical techniques have been proposed to approximate the singular interface terms occurring in the VOF model formulations. A convenient way to categorize these techniques is due to the physical images of the interface used as basis designing the numerical method. It is so that interfacial physics are conventionally described adopting either a superficial 2D macroscopic—or a somewhat more physical 3D microscopic representation of the interface. Since an interface is generally observed and characterized on a macroscopic scale that is large relative to the thickness of the interfacial zone, an interface is often conveniently idealized as a 2D, discontinuous (singular) surface possessing a macroscopically defined location, configuration and orientation between a pair of contiguous, 3D, immiscible bulk fluid phases. The alternative representation of the interface is more fundamental denoting a microscopic, 3D interface structure, accounting for the diffuse transition region existing between the two fully developed bulk fluid phases on either side. These two models are mutually consistent describing the interface behavior on the macroscopic scales, but the microscopic view possibly affords a more rational means for deriving interfacial constitutive laws when the microscopic physics are known allowing for the deduction of macroscale models by proper averaging. Such approaches may also be valuable explaining the underlying mechanisms determining the 2D interfacial properties which are normally parameterized directly on the macroscopic scales. The first generation methods that were proposed involved interface reconstruction and approximation of the singular interfacial term from the 2D interface properties. These models thus rely on a proper

numerical procedure to locate the interface within the mesh based on the volume fraction field. The local curvature may then be calculated in each surface grid cell.

The first VOF methods were naturally developed for 2D problems. Such an interface is considered to be a continuous, piecewise smooth line and the problem of its reconstruction is that of finding an approximation to the section of the interface in each cell, by knowing only the volume fraction,  $\alpha_1$ , in that cell and in the neighboring ones. The simplest types of VOF-methods are the Simple Line Interface Calculation (SLIC) as used in the SOLA-VOF algorithm [114]. Typically, the reconstructed interface is made up of a sequence of segments aligned with the grid. The more accurate techniques attempt to fit the interface through piecewise linear segments. These techniques are known as the Piecewise Linear Interface Construction (PLIC) methods [10, 192]. The key part of the reconstruction step is the determination of the location of the segment. This is equivalent to the determination of the unit normal vector,  $\mathbf{n}_I$ , to the segment. This kind of VOF methods can be generalized to three dimensions with little conceptual difficulty [196, 260]. The second fairly modern group of methods introduces (of numerical reasons) a 3D continuous surface force (CSF) or a 3D continuum surface stress (CSS) acting locally within the whole transition region constituting a meso-scale interface. Notice that since we are primarily interested in the interfacial forces, the latter group of techniques were used approximating the surface effects without actually reconstructing the interface.

The pioneering work, determining the basis for all the techniques in this group, was performed by Brackbill et al. [27] developing the *the continuum surface force method (CSF)* for modeling the surface tension effects on fluid motion. In the CSF model the interface discontinuity (singular) term has been smoothed to avoid numerical instabilities, and the surface tension force becomes replaced by a continuous formulation. In other words, the discontinuous (singular) surface tension force determined from a macro-scale point of view, is reformulated considering a more diffuse transition region (inspired by microscopic physics and the micro-scale point of view) that is not necessarily aligned with the grid. Brackbill et al. [27] replaced the discontinuous characteristic function by a smooth variation of fluid volume fraction  $\tilde{\alpha}_1$  between 0 and 1 over a distance of order  $h$ , where  $h$  is a length comparable to the resolution afforded by a computational mesh with spacing  $\Delta V = h^3$ . This replaces the jump condition boundary-value problem at the interface by an approximate continuous model and mimics the problem specification in a numerical calculation, where one specifies the values of  $\alpha_1$  at grid points and interpolates between. The interface where the fluid changes from fluid 1 to fluid 2 discontinuously is replaced by a continuous transition, and the surface tension force acts everywhere within the transition region. The CSF method thus eliminates the need for interface construction, simplifies the calculation of the surface tension effects, enables accurate modeling of two- and three-dimensional fluid flows driven by surface forces, and imposes no modeling restrictions on the number, complexity, or dynamic evolution of fluid interfaces having surface tension. A restriction related to this numerical approximation is of course that we are introducing a smoothed representation (i.e., in itself relying on the assumption that the interface is limited to an explicitly defined finite thickness)

of the physical phenomena which are occurring at very small scales. In addition, the Eulerian discretization schemes applied approximating (3.5) are diffusive and smear out the  $\alpha_k$  profile and thus the interface. Therefore, the main difficulty in using these methods is to maintain a sharp interface between the different phases. It might be worth mentioning that, as this numerical discretization technique replaces the conventional 2D interface specification with a 3D description, the interface reformulation makes it convenient to introduce an alternative notation for the interface characteristics as well expressing the curvature with sign defining its orientation. The reformulated surface force is then defined positive acting on one of the fluid fields, in accordance with the choice of unit normal sign convention. A common practice is to define the unit normal vector positive pointing out of phase 1. A constraint therefore is to make sure that consistent sign conventions are adopted for the normal unit vector and the orientation of the surface curvature (as the unit normal vector pointing out of phase 1 may at some instants be oriented into the curvature and at other instants out of the curvature, since the surface orientation may change with time).

On the meso-scopic scale the smoothly varying volume fraction  $\tilde{\alpha}_1$  is constructed as follows:

$$\tilde{\alpha}_1(\mathbf{r}) = \frac{1}{\Delta V} \int_{\Delta V} \alpha_1(\mathbf{r}') \delta_I(\mathbf{r} - \mathbf{r}') dv' \quad (3.18)$$

where  $\delta_I(\mathbf{r} - \mathbf{r}')$  is a smooth integration kernel (i.e., an interpolation function like the B-spline [27]). We let  $\delta_I(\mathbf{r} - \mathbf{r}') \rightarrow \delta_I$  as the grid spacing  $h \rightarrow 0$ .

Further,  $\tilde{\alpha}_1$ , is differentiable because  $\delta_I$  is, hence:

$$\nabla \tilde{\alpha}_1(\mathbf{r}) = \frac{1}{\Delta V} \int_{\Delta V} \alpha_1(\mathbf{r}') \nabla \delta_I(\mathbf{r} - \mathbf{r}') dv' \quad (3.19)$$

Using Gauss' theorem and noting that  $\alpha_1$  is constant within each fluid, Brackbill et al. [27] converted the volume integral into an integral over the interface  $\delta A_I$ :

$$\nabla \tilde{\alpha}_1(\mathbf{r}) = \frac{[\alpha_1]}{\Delta V} \int_{\delta A_I} \mathbf{n}_1 \delta_I(\mathbf{r} - \mathbf{r}'; \epsilon) da' = \frac{1}{\Delta V} \int_{\delta A_I} \mathbf{n}_1 \delta_I(\mathbf{r} - \mathbf{r}'; \epsilon) da' \quad (3.20)$$

where  $[\alpha_1]$  is the jump in the volume fraction variable, i.e.,  $[\alpha_1] = 1$ .

This relation can be used calculating a weighted mean of the surface normal. This approximation of the normal converges to the true normal of the interface as the smoothing kernel becomes more concentrated on the interface. Several alternative high-order kernels have been discussed by Aleinov and Puckett [5].

The volume averaged force formulation then yields:

$$\begin{aligned}
\mathbf{F}_{I,1} &= \frac{1}{\Delta V} \int_{\Delta V} 2\mathbf{n}_I \sigma_I \delta_I H_I dv' \approx \frac{2}{\Delta V} \int_{\Delta V} \sigma_I \nabla \tilde{\alpha}_1 H_I dv' \approx \frac{2}{\Delta V} \sigma_I \nabla \tilde{\alpha}_1 H_I \int_{\Delta V} dv' \\
&\approx 2\sigma_I \nabla \tilde{\alpha}_1 H_I
\end{aligned} \tag{3.21}$$

Brackbill et al. [27] also found it very difficult to use the classical expressions calculating the mean curvature of any 3D surface in a numerical model, since they require an algorithm determining the principal curvatures being the maximum and minimum values of the normal curvature (see e.g., [68], pp. 44–47). To improve on this limitation of the VOF model, Brackbill et al. [27] suggested an alternative and computationally much simpler expression for the mean curvature,  $H_I$ , which could be used determining the net surface force per unit area,  $\mathbf{F}_{I,1}$ , on any element of the surface  $A_I$ . The mean curvature is expressed in terms of the unit normal pointing into phase 1:

$$H_I = -\frac{1}{2} \nabla_I \cdot \mathbf{n}_I \tag{3.22}$$

The unit normal vector is determined from the spatial distribution of the volume fraction of the phase 1 field:

$$\mathbf{n}_I = -\frac{\nabla \tilde{\alpha}_1}{|\nabla \tilde{\alpha}_1|} \tag{3.23}$$

The normal component of the volume force, that is non-zero only within the phase transition regions, can then be expressed in terms of the volume fraction gradient [27]:

$$\mathbf{F}_{I,1} \approx 2[-\nabla \tilde{\alpha}_1] \sigma_I \left(-\frac{1}{2}\right) \nabla \cdot \left[-\frac{\nabla \tilde{\alpha}_1}{|\nabla \tilde{\alpha}_1|}\right] \approx -\nabla \tilde{\alpha}_1 \sigma_I \nabla \cdot \left[\frac{\nabla \tilde{\alpha}_1}{|\nabla \tilde{\alpha}_1|}\right] \tag{3.24}$$

where Chang et al. [35] stated that the color function is defined so that the normal vector points in the outward direction.<sup>5</sup>

The momentum equations in the whole field formulation can also be rewritten in a momentum conserving form [98, 141, 196], defining a 3D capillary pressure tensor:

$$\mathbf{T}'_I = -\sigma_I (\mathbf{e} - \mathbf{n}_I \mathbf{n}_I) \delta_I \tag{3.25}$$

where  $\mathbf{e}$  is the unit tensor  $\delta_{ij}$ .

To enable a physical interpretation of this tensor, the particular normal vector used in this relation is required to give meaning outside the surface  $A_I$ . Using this quantity the capillary force can be represented as the divergence of  $\mathbf{T}'_I$ ,

$$\nabla \cdot \mathbf{T}'_I = \sigma_I \nabla \cdot \{(\mathbf{e} - \mathbf{n}_I \mathbf{n}_I) \delta_I\} = \sigma_I H_I \mathbf{n}_I \delta_I \tag{3.26}$$

<sup>5</sup> In the case of two immiscible fluids, a characteristic phase indicator function,  $X_I$ , may be defined that is equal to 1 in one of the phases and 0 in the other phase. Then  $X_I$  and  $\mathbf{n}_I$  are related by  $\mathbf{n}_I \delta_I = \nabla X_I$  analogue to the relations used in standard volume averaging procedures [58, 177]. An averaged representation of this relation may be given as  $\frac{1}{\Delta V} \int_{\delta A_I} \mathbf{n}_I \delta_I da' = -\nabla \tilde{\alpha}_1$

The momentum Eq. (3.15) can then be cast in a conservative form:

$$\frac{\partial}{\partial t}(\rho \mathbf{v}) = -\nabla p - \nabla \cdot (\rho \mathbf{v} \mathbf{v} + \boldsymbol{\sigma} + \mathbf{T}'_I) + \rho \mathbf{g} \quad (3.27)$$

For this reason the surface tension force can be interpreted as a correction to the momentum stress tensor, i.e., it represents a continuum surface stress (CSS) tensor. This model formulation constitutes a volume conserving (i.e., exact only when  $\rho_1 = \rho_2$ ) variant of the VOF algorithm. The model is considered relatively simple to implement in a program code, computationally efficient and easy to parallelize. Both the 2D and 3D CSS simulations performed well without using the smoothed function (3.18) calculating the normal vector and the curvature, indicating that the CSS method may be more stable than the original CSF technique. The volume conservative algorithm can thus use the volume fraction itself which varies sharply over one or two grid cells across the interface. If (3.18) is used instead, the CSS methods amounts to a variant of the basic CSF method.

The CSF and CSS based versions of the VOF method have been used to calculate improved estimates of the single particle drag and lift coefficients and for simulating breakage and coalescence of dispersed flows containing a few fluid particles [20, 53, 54, 150, 232]. A third variant of the VOF method calculates the interface tension force by the CSS method and perform an independent PLIC reconstruction of the interface to improve the design of the advection schemes. In this way the tailored advection discretization schemes prevent numerical smoothing of the interface [160].

In reactor technology the VOF methods have become very popular for such simulations because they are reasonable accurate, relative simple to implement and much faster than the more accurate level set and front tracking methods (discussed shortly). However, it is noted that none of the VOF approaches are useful in predicting the rebound outcome of colliding fluid particles because the surface tension force or stress approximation fails to predict the complex physics involved in these cases. That is, when two interfaces from two different particles are placed in the same grid cell, the particles might automatically merge or coalesce as a numerical mode due to the low order local approximation of the interface normal in combination with an insufficient interface resolution. Hence, this approach cannot be used in coalescence—rebound outcome studies determining a physical coalescence criterion. However, by use of an in-house code<sup>6</sup> based on the CSS-PLIC approach Gotaas et al. [94] simulated binary droplet collisions under conditions that gave permanent coalescence, and coalescence followed by reflexive or stretching separation. It was concluded that the VOF predictions were in excellent agreement with experimental data in most cases. A typical collision map for the air/water system is given in Fig. 3.2. Nevertheless, for head-on collisions the simulated outcomes for operating conditions on the border between the coalescence and reflexive separation regimes did not always coincide with experimental observations, as a coalescence outcome prevailed somewhat into

---

<sup>6</sup> These droplet-droplet collisions are simulated by use of an in-house VOF code called FS3D developed at University of Stuttgart and Institut für Thermodynamik der Luft-und Raumfahrt, ITLR.

**Fig. 3.2** Typical droplet-droplet collision outcome map with four regimes [94]; Bouncing (Bo), Coalescence (Co), Stretching Separation (Ss), and Reflexive Separation (Rs).  $\chi$  denotes the impact factor, and  $We$  is the Weber number

the experimental reflexive separation regime. It was revealed that in these odd cases the in-house code is not able to conserve the thin liquid film which is present when the droplets are at their maximum deformation. Instead the film ruptures and this in turn results in an unphysical loss of kinetic energy so that the final separation observed in the experimental analysis doesn't occur. It is mentioned that this film rupture problem did not occur simulating the coalescence outcome conditions. Gotaas et al. [94] did use a model resolution of  $1\mu\text{m}$  which represents the present computer capacities at the University in Trondheim. The VOF code might thus become inaccurate due to insufficient numerical resolution or, more severely, because the macroscopic VOF model breaks down when such a film or interface becomes very thin as the basic model concept is based on the continuum hypothesis. In such flow situations the liquid film might reach scales much less than the scales on which short range molecular forces act to attract or repel interface molecules. These mechanisms are normally considered significant on scales of the order of 10–40 nm and are thus generally not taken into account by the VOF model. However, the given threshold is very uncertain as the molecular forces are largely affected by the fluid properties and the presence of surfactants [99, 170, 196]. In this area much fundamental work remains to be done.

The VOF technique thus works best analyzing flow situations where the macroscopic interface motion may be nearly independent on the microscopic interface physics. For example, many analyzes on stratified or free-surface flows may be performed successfully by such a model. It is also noted that the VOF model concept is not primarily intended for multicomponent reactive flow analyzes, so no interfacial heat- and mass transfer fluxes or any variations in the surface tension are usually considered.

### 3.3.2.3 The Level Set Method

In the previous section we did learn that the VOF algorithms locate the interface by tracking a marker function,  $\alpha_k$ , which corresponds to the local volume fraction of the phase  $k$ . At an interface,  $\alpha_k$  goes between 0 and 1, hence identifies its location. As  $\alpha_k$  is discontinuous at an interface, a practical computation method smears out the  $\alpha_k$  profile and thus the location of the interface. This numerical problem, leading to a thickening of the interface, led researchers to propose an extension of the VOF technique. These extended VOF algorithms, introducing a modified interface tracking function, are called level set (LS) methods. The level set algorithms are defined with a fixed interface thickness. These LS models can therefore be implemented and solved using the same numerical difference techniques for the advection terms as those used for the VOF technique, without allowing the interface to smear out in space.

The design of the LS methods may be sketched as follows. To determine the exact location of the interface, we utilize some inherent properties of a mathematical function characterized as a distance function. In this context a distance function,  $d$ , denotes the signed normal distance to the interface. This type of functions satisfies:

$$|\nabla d| = 1 \quad \text{for } \mathbf{r} \in \Omega \quad \text{with } d = 0 \quad \text{for } \mathbf{r} \in \Gamma \quad (3.28)$$

and  $\nabla d$  determines a unit normal vector at the interface,  $\Gamma$ .

If such a function did exist, the surface tension force could be represented by [199] [228] (p. 151):

$$\mathbf{F}_I = 2\mathbf{n}\sigma_I\delta(d)H_I \quad (3.29)$$

In this formulation the surface tension term is considered to be a force concentrated on the interface,  $\Gamma$ .

In practice, a mathematical function that behave like a distance function over the whole calculation domain as the interface evolves in space is very difficult to define. Therefore, as a compromise, we may utilize the so-called zero level set of a smooth function,  $\varphi$ , that behaves like a distance function locally in the vicinity of the interface. The novel idea of the level set methodology is thus to introduce a higher dimensional smooth function  $\varphi(\mathbf{r}, t = 0)$  defined as:

$$\varphi(\mathbf{r}, t = 0) = \pm d \quad (3.30)$$

where  $\mathbf{r}$  is a point in space and  $d$  is still the shortest distance from  $\mathbf{r}$  to the initial interface. The sign of  $\varphi(\mathbf{r}, t = 0)$  indicates whether  $\mathbf{r}$  is inside or outside the regions closed by the initial interface (i.e., for two-phase flow the positive sign denotes one of the phases, whereas the negative sign denotes the transition interface zone).

As pointed out by Sussman et al. [228] and Chang et al. [35], the surface tension force can be cast into the level set formulation:

$$\mathbf{F}_I = 2\mathbf{n}\sigma_I\delta(d)H_I = 2\nabla\varphi\sigma_I\delta(\varphi)H_I(\varphi) \quad (3.31)$$

This relation is true only for the ideal case where  $\varphi$  remains a distance function, as:  $\mathbf{n} = (\frac{\nabla\varphi}{|\nabla\varphi|})_{\varphi=0}$ ,  $H_I = \nabla \cdot (\frac{\nabla\varphi}{|\nabla\varphi|})_{\varphi=0}$ , and  $|\nabla\varphi|_{\varphi=0} = 1$ .

The derivation of this relation can apparently be found in Chang et al. [35], in which it was also shown (using rather complex mathematics) that this formulation admits solutions that are consistent with the boundary condition applied in the jump-condition formulation. In a similar manner as for the VOF technique, the evolution of the interface is determined solving a transport equation for the level set function. That is, instead of solving Eq. (3.5), the following equation is solved [192]:

$$\frac{D\varphi}{Dt} = \frac{\partial\varphi}{\partial t} + (\mathbf{v} \cdot \nabla)\varphi = 0 \quad (3.32)$$

The level set Eq. (3.32) describes the evolution of the distance function as the interface moves along its normal vector field with normal speed  $F = \mathbf{n} \cdot \mathbf{v}$ . By use of the relation determining the normal vector pointing into the positive phase,  $\mathbf{n} = \frac{\nabla\varphi}{|\nabla\varphi|}$ , we may rewrite the equation as:

$$\frac{D\varphi}{Dt} = \frac{\partial\varphi}{\partial t} + (\mathbf{v} \cdot \nabla)\varphi = \frac{\partial\varphi}{\partial t} + \mathbf{v} \cdot \frac{\nabla\varphi}{|\nabla\varphi|} |\nabla\varphi| = \frac{\partial\varphi}{\partial t} + \mathbf{v} \cdot \mathbf{n} |\nabla\varphi| = \frac{\partial\varphi}{\partial t} + F |\nabla\varphi| = 0 \quad (3.33)$$

Both forms of the transport equation have been used describing the evolution of the interface. The choice of formulation seems to be a matter of convenience.

Since the density and viscosity are constant in each fluid, they take two different values depending on the sign of  $\varphi$ , we may write:

$$\rho(\varphi) = \rho_2 + (\rho_1 - \rho_2)H(\varphi) \quad (3.34)$$

and

$$\mu(\varphi) = \mu_2 + (\mu_1 - \mu_2)H(\varphi) \quad (3.35)$$

where  $H(\varphi)$  is the Heaviside function given by ([229], p. 273):

$$H(\varphi) = \begin{cases} 0 & \text{if } \varphi < 0 \\ \frac{1}{2} & \text{if } \varphi = 0 \\ 1 & \text{if } \varphi > 0. \end{cases} \quad (3.36)$$

In practice, however, a smoothed level set function is defined so that  $|\nabla\varphi| = 1$  when  $|\varphi| \leq \epsilon$  due to the finite resolution applied in numerical simulations smearing the front out on several grid cells.

To alleviate further numerical problems due to sharp changes in some of the physical variables across the front and also because of the numerical difficulties presented by the Dirac delta function in the surface tension term, the interface is defined having a fixed thickness that is proportional to the spatial mesh. This allows us to smooth the functions across the interface and replace the Dirac delta function with a smoothed delta function  $\delta_\epsilon$ . In other words, we maintain a fixed thickness of

the interface within the LS approach. The approximated delta function is defined as (e.g., [228]):

$$\delta_\epsilon(\varphi) = \begin{cases} \frac{1}{2}(1 + \cos(\pi\varphi/\epsilon))/\epsilon & \text{if } |\varphi| < \epsilon, \\ 0 & \text{Otherwise.} \end{cases} \quad (3.37)$$

where  $\epsilon$  denotes the prescribed *thickness* of the interface (e.g., [228] used  $\epsilon = \frac{3}{2}\Delta x$ ).

The Heaviside function is also replaced with a smoothed Heaviside function  $H_\epsilon(\varphi)$  defined as ([229], p. 274):

$$H_\epsilon(\varphi) = \begin{cases} 0 & \text{if } \varphi < -\epsilon \\ \frac{1}{2}[1 + \frac{\varphi}{\epsilon} + \frac{1}{\pi}\sin(\frac{\pi\varphi}{\epsilon})] & \text{if } \varphi \leq \epsilon \\ 1 & \text{if } \varphi > \epsilon. \end{cases} \quad (3.38)$$

The smoothed delta function is then given by  $\delta_\epsilon = \frac{dH_\epsilon}{d\varphi}$ , whereas the thickness of the interface can be approximated by  $2\epsilon/|\nabla\varphi|$ . The smoothed density and viscosity are now given as:

$$\rho_\epsilon(\varphi) = \rho_2 + (\rho_1 - \rho_2)H_\epsilon(\varphi) \quad (3.39)$$

and

$$\mu_\epsilon(\varphi) = \mu_2 + (\mu_1 - \mu_2)H_\epsilon(\varphi), \quad (3.40)$$

respectively.

The surface tension force is represented by [35, 228, 229]:

$$\mathbf{F}_I = 2\mathbf{n}\sigma_I\delta(d)H_I \approx 2\nabla\varphi\sigma_I\delta_\epsilon(\varphi)H_I(\varphi) \quad (3.41)$$

We can derive this force relation from the CSF model of Brackbill et al. [27] if we let the smoothed color function,  $\nabla\tilde{\alpha}_I$ , be given as a smoothed Heaviside function  $H_\epsilon$ . This implies that<sup>7</sup>:  $\nabla\tilde{\alpha}_I = \delta_\epsilon(\varphi)\nabla\varphi$ .

The mean curvature,  $H_I$ , of the zero level set is then found from:

$$H_I(\varphi) = -\frac{1}{2}\nabla \cdot \mathbf{n}(\varphi) = -\frac{1}{2}\nabla \cdot \left( \frac{\nabla\varphi}{|\nabla\varphi|} \right) \quad (3.42)$$

where the last term is given by appropriate finite difference approximations (e.g., [199, 228], p. 58).

It is clear that we can choose  $\varphi(\mathbf{r}, t = 0)$  to be a distance function. However, under the evolution of  $\varphi(\mathbf{r}, t)$ , solving (3.32) or (3.33), it will not necessarily remain a distance function (i.e.,  $|\nabla\varphi| \neq 1$ ). A procedure is needed to reinitialize the level set function at each time step to retain its distance function properties without changing

<sup>7</sup> The reformulation is based on the relationship:  $\nabla H_\epsilon(\varphi) = \frac{\partial H_\epsilon}{\partial x} + \frac{\partial H_\epsilon}{\partial y} + \frac{\partial H_\epsilon}{\partial z} = \frac{\partial H_\epsilon}{\partial \varphi} \left( \frac{\partial \varphi}{\partial x} + \frac{\partial \varphi}{\partial y} + \frac{\partial \varphi}{\partial z} \right) = \frac{\partial H_\epsilon}{\partial \varphi} \nabla \varphi$ .

its level set. Sussman and Smereka ([229], p. 275) suggested that this can be achieved by solving the following PDE:

$$\frac{\partial d}{\partial t'} = \text{sign}(\varphi)(1 - |\nabla d|) \quad (3.43)$$

with initial conditions  $d(\mathbf{r}, 0) = \varphi(\mathbf{r})$ , where

$$\text{sign}(\varphi) = \begin{cases} -1 & \text{if } \varphi < 0 \\ 0 & \text{if } \varphi = 0 \\ 1 & \text{if } \varphi > 0 \end{cases} \quad (3.44)$$

and  $t'$  is an artificial time.

The steady state solution of this PDE are distance functions. Furthermore, when  $\text{sign}(0) = 0$ ,  $d(\mathbf{r}, t')$  has the same zero level set as  $\varphi$ . Therefore, Sussman and Smereka [229] solved this PDE to steady state and then replaced  $\varphi(\mathbf{r})$  by  $d(\mathbf{r}, t'_{\text{steady}})$ . They also found that  $\varphi$  only needs to be a distance function close to the front. Therefore, it is not necessary to solve the PDE to steady state over the whole domain. We may then locate the interface as the local areas within the calculation domain where  $|d| \leq \epsilon$ , and we iterate on  $d$  until  $|\nabla d| = 1$  near the interface. The front will then have a uniform thickness, as this solution corresponds to  $|\nabla \varphi| = 1$  when  $|\varphi| \leq \epsilon$ .

Compared to the VOF method, the level set methods offer interface identification through the use of a distance function which is continuous everywhere in the field. The solution of the field equation for this function then identify the interface location, the zero level sets. Furthermore, this level set function reflects advantageous numerical properties being a smooth function. In other words, the main difference between the VOF and the level set methods is related to the properties of the improved marker function formulation. Advantages of the level-set method are that, unlike the VOF method, the interface is represented as a continuous surface. Furthermore, there is no need for the complex interface reconstruction algorithms. The improved function formulation also reduces the main disadvantage of the VOF method, that is, it does not smear out the location of the interface. However, according to Rider et al. [192], level set methods although conceptually appealing suffer from a number of detriments. First among these is the lack of volume (mass) conservation. Computational cost is also an issue. For these reasons the LS method has not (yet) become as popular as the VOF method, analyzing dispersed flows in chemical reactors. However, the LS method has been used to describe the detailed flow around individual fluid particles and thus may contribute to improve our understanding of these phenomena.

Pan and Suga [171], for example, performed 3D dynamic simulations of binary droplets collisions for cases of different Weber numbers and impact parameters. The systems used are water drops in air and tetradecane drops in nitrogen at atmospheric conditions. The bulk fluids are considered incompressible. The simulations cover the four major regimes of binary collision: bouncing, coalescence, reflexive separation,

and stretching separation. The method predicted the outcomes of both head on and off-center collisions in all the regimes for both systems in excellent agreement with the available experimental data. However, contrary to the work of Gotaas et al. [94] in which a VOF method was used to investigate the capacity of accurately predicting the flow regime transition lines as sketched in Fig. 3.2, Pan and Suga focused on operating conditions in the bulk of the different flow regimes. Nevertheless, from the results presented in their papers it can be seen that both the VOF and LS methods have problems to conserve the thin liquid films created when the drops collide and a reflexive separation outcome is expected at the transition areas between the coalescence and reflexive separation regimes. On the other hand, it is emphasized that the LS model captures the bouncing collision outcome even though the model in principle can predict automatic coalescence in cases when the gas film becomes extremely thin before rupture due to the computational model limitations which are similar to those of the VOF method. No physical coalescence criterion is prescribed in any of these models. At first sight, it may thus seem like the inherent interface force discretization and the *continuous* level set function reinitialization procedure give slightly more accurate predictions of the collision outcome than the VOF method. However, at lower Weber numbers than that of the bouncing collision, the LS model fails to predict the expected coalescence regime seen in the experimental data. The simulated results might thus suggest that the mechanism of bouncing collision is governed by macroscopic dynamics, whereas the collision regime of coalescence after minor deformation may be related to microscopic phenomena. Typical errors in mass conservation were reported to be less than 5 % by volume.

The LS models are apparently more accurate than the computationally cheaper VOF methods, but the LS models still suffer from not having the possibility to prescribe a physical coalescence criterion instead of relying on the numerical mode outcome of the discretization approximations.

In reactor engineering the level-set method is generally too computationally demanding for direct applications to industrial scale units. The level set method can be applied for about the same cases as the VOF method and works best analyzing flows where the macroscopic interface motion is independent of the microscopic phenomena. These concepts are not primarily intended for multi-component reactive flows, so no interfacial heat- and mass transfer fluxes or any variations in the surface tension are normally considered.

### 3.3.2.4 The Embedded Interface Method

In this section the *embedded interface (EI) method* (frequently referred to as a front tracking method) developed for direct numerical simulations of viscous multi-fluid flows is outlined and discussed. The unsteady model is based on the whole field formulation in which a sharp interface separates immiscible fluids, thus the different phases are treated as one fluid with variable material properties. Therefore, Eqs. (3.14) and (3.15) account for both the differences in the material properties of the different phases as well as surface tension effects at the phase boundary. The bulk fluids are

incompressible. The numerical surface tension force approximation used is consistent with the VOF and LS techniques [35, 236], hence the major novelty of the embedded interface method is in the way the density and viscosity fields are updated when the fluids and the interface evolve in time and space.

Tryggvason and co-workers [75, 76, 135, 136, 183, 238, 239, 241, 242] solve the Navier-Stokes equations using a projection method very similar to the MAC method [102]. The interface is tracked explicitly by connected marker points. In the solution procedure a fixed structured grid is used for the transport equations, and a moving grid of lower dimension marks the boundary between the bulk phases. This moving grid is called the *front*. The properties of each fluid particle remain constant, thus a set of advection equations can be set up expressing these constraints:

$$\frac{D\rho}{Dt} = 0 \quad (3.45)$$

$$\frac{D\mu}{Dt} = 0 \quad (3.46)$$

These relations are referred to as the EOSs for the material properties [101, 170, 238, 242].

However, an essential feature of the EI method is that the fluid properties are not advected solving the above EOSs directly. Instead, the interface between the different fluids is moved. This is achieved by explicit tracking points on the interface between the two fluids in a Lagrangian manner [241]:

$$\frac{d\mathbf{r}_I}{dt} = \mathbf{v}_I \quad (3.47)$$

After the discrete points on the interface are moved with the flow, the continuous interface is reconstructed by connecting these points by appropriate linear or triangular elements (i.e., a finite element technique). It is noticed that explicit front tracking is generally more complex than the advection of a marker function as in the VOF and LS methods, nevertheless this technique is also considered more accurate [238].

Seeing that the momentum equations are solved on a fixed grid but the surface tension is found on the front, it is necessary to convert the interface quantity that exists at the front to a grid value. It follows that at each time step information must be passed between the moving Lagrangian interface and the stationary Eulerian grid by interpolation since the Lagrangian interface points do not necessarily coincide with the Eulerian grid points. This is done by a method known as the immersed boundary technique [135, 242]. With this technique, the interface is approximated by a smooth distribution function that is used to distribute the interface terms over grid points nearest to the interface. In a similar manner, this function is used to interpolate the variables from the stationary grid to the interface. In particular, an indicator function,  $I(\mathbf{r})$ , that is 1 inside the fluid particle and 0 in the continuous fluid, is constructed from the known position of the interface. In fact, the jump in the indicator function

across the interface is distributed to the fixed grid points nearest to the interface using the distribution function. The immersed boundary technique then generates a grid-gradient field  $\nabla I(\mathbf{r}) = \int_{\text{Font}} \delta_I(\mathbf{r} - \mathbf{r}_{\text{Font}}) \mathbf{n}_{\text{Font}} dA_{\text{Font}}$  which is zero except in a thin zone near the interface. This transition zone has a finite thickness which is fixed during the simulation. The indicator function (i.e., a Heaviside function) is then obtained by solving a Poisson equation [75]:

$$\nabla^2 I = \nabla \cdot \nabla I = \nabla \cdot \int_{\text{Font}} \delta_I(\mathbf{r} - \mathbf{r}_{\text{Font}}) \mathbf{n}_{\text{Font}} dA_{\text{Font}} \quad (3.48)$$

To relate the gradient to the  $\delta_I$  function marking the interface, it is found convenient to express the indicator function in terms of an integral over the product of 1D  $\delta_I$  functions [238].

Since the property variables are discontinuous across the interface, one may expect either excessive numerical diffusion or problems with oscillations around the jump if no special treatment is used at the front. To avoid these problems local smoothing of the variables across the discontinuous interface is introduced. This is accomplished by use of the smoothed indicator function calculating the fluid properties at each point on the fixed grid by:

$$\mu(\mathbf{r}) = \mu_c + (\mu_d - \mu_c) \mathbf{I}(\mathbf{r}) \quad (3.49)$$

$$\rho(\mathbf{r}) = \rho_c + (\rho_d - \rho_c) \mathbf{I}(\mathbf{r}) \quad (3.50)$$

Notice that these relations imply that the material properties in each phase have a smooth incompressible extension into the other phase.

The net effects of the immersed boundary technique are that in the interface transition zone the fluid properties change smoothly from the value on one side of the interface to the value on the other side. The artificial interface thickness is fixed as a function of the mesh size applied to provide stability and smoothness, and it does not change during the calculations. Therefore no numerical diffusion is present. The finite thickness also serves to position the interface more accurately on the grid. The surface tension force (normal contribution only) is then calculated estimating the mean curvature based on geometric information obtained from the restructured interface.

Describing collisions between fluid particles using the EI model, the fluid film drainage and particle deformation processes will be described in detail. However, after the fluid within the film between the particles has drained until there are only the thickness of the two interfaces left (i.e., one interface grid for each particle), the particles move together being influenced by the interfaces, until the particles eventually rebound. Coalescence of the two particles is only allowed if an empirical closure, i.e., a *coalescence model*, is used together with a numerical procedure for merging the two moving grids. To accommodate topology changes in the model, the interface is artificially reconnected when two points come closer than a specified small distance. The threshold is chosen rather arbitrarily since there exist no reliable

model for the critical interface thickness. So far Tryggvason and coworkers have either used a given drainage time or a specified thickness of the film as criteria for coalescence. It occurs that an advantage of front tracking is that it is possible to control the distance at which interfaces merge and study the effect of varying coalescence criteria, unlike front capturing methods where there is no active control over topological changes. In the EI method the interface is explicitly tracked by connected marker points, so such changes in topology are accounted for by changing the connectivity of the points in an appropriate way. Tryggvason and coworkers state that this numerical operation is very time consuming and represents the greatest disadvantage of front-tracking methods. However, in methods like VOF and LS which identify the phase boundary by a marker function, topology changes take place automatically whenever two interfaces, or different parts of the same interface, come closer than about one grid cell spacing. Coalescence is apparently related to the drainage of the fluid between the coalescing interfaces in a complex manner, and a method that is simply connecting parts of the interface that are close certainly give an incorrect solution because these films supposedly rupture as a result of short-range molecular forces. Therefore, to calculate the draining of these films prior to rupture a prohibitive fine grid resolution is required. However, performing EI model simulations using feasible grid resolutions Tryggvason and co-workers have confirmed that the flow in the film between two colliding droplets is commonly so simple that the drainage process can be accomplished by analytical lubrication models [99, 213].

The embedded interface method has not been applied describing industrial scale chemical reactor operation. However, the EI method has been applied examining numerous multi-fluid phenomena relevant to reactor analysis. Unverdi and Tryggvason [242] and Tryggvason et al. [235] investigated the interactions of two 2D and 3D bubbles. The impact of variations in viscosity and the effects of surface tension were illustrated. They further stated that the model can be used to inspect the validity of the classical model simplifications (e.g., inviscidness, Stokes flow, two-dimensionality or axisymmetry) and to confirm the applicability of these idealizations for specific problems. The motion of a few 2D bubbles at low Reynolds numbers was simulated by Esmaeeli and Tryggvason [74], indicating that in such bubbly flows there is an inverse energy cascade. Esmaeeli et al. [73] and Ervin and Tryggvason [72] computed the rise of a single bubble in a vertical shear flows and showed that the lift force changes sign when the bubble deforms. Nobari et al. [170] and Han and Tryggvason [101] simulated binary collisions of axisymmetric drops, predicting the breakage after initial coalescence in reasonable agreement with experimental data. Juric and Tryggvason [135] developed a front tracking or EI method for the solidification of pure materials and used it to examine the growth of dendrites. The EI model has been extended and used to elucidate the motion of a premixed flame by Qian et al. [183]. The EI method has also been extended to simulate boiling flows [75, 76, 136, 239]. The variety of applications clearly demonstrate that the EI method has the potential of resolving many problem aspects in reactor technology. However, it is noted that the EI concept is not primarily intended for multicomponent reactive flow analyzes, but still interfacial heat- and mass transfer fluxes and variations in

the surface tension have been considered [238]. Nevertheless, in most cases the bulk phases are considered incompressible.

No direct model intercomparisons between the EI, VOF and LS methods have been performed, so it is difficult to evaluate which method are preferable regarding computational costs and accuracy for different applications. However, it seems that the VOF method is faster but suffers from lower accuracy. The LS methods are usually more accurate than VOF methods, but suffers from higher computational costs and problems regarding mass conservation. The EI method is quite accurate, but is probably the most time consuming one comparing these methods. However, although the LS model predictions can be very good for fluid particle collision simulations, the EI method has the advantage of controlling the coalescence process explicitly provided that a proper coalescence criterion is available. Notwithstanding, the VOF technique is still generally preferred in engineering research and industrial practice, whereas the LS and EI methods are regarded as academic research tools.

### 3.3.2.5 The Phase-Field Method

Phase field (PF) models are usually constructed in order to reproduce a given interfacial dynamics. The nature of the interface between two fluids has been the subject of extensive investigation for over two centuries [9]. Young [259], Laplace [147] and Gauss [87], in the early part of the 1800s, considered the interface between two fluids to be represented as a surface of zero thickness endowed with physical properties such as surface tension. In these investigations, which were based on static or mechanical equilibrium arguments, it was assumed that physical quantities, such as density were discontinuous across the interface. Physical processes such as capillarity occurring at the interface were represented by boundary conditions. Poisson [176], Maxwell [159] and Gibbs [88] recognized that the interface actually represented a rapid but smooth transition of physical quantities between the bulk fluid values. Gibbs introduced the notion of a dividing surface of discontinuity and surface excess quantities in order to develop the equilibrium thermodynamics of interfaces. The idea that the interface has a non-zero thickness and being diffuse was developed by Lord Rayleigh [153] and by van der Waals [243], who proposed gradient theories for the interface based on thermodynamic principles. Korteweg [138] built on these ideas and proposed a constitutive law for the *capillary stress tensor* in terms of the density and its spatial gradients. These original ideas have been developed further and refined over the past century. Diffuse interface models provide an alternative description of the interface physics. Quantities which in the surface of discontinuity formulation are localized to the interfacial surface are recognized to be distributed throughout the interfacial region.

Anderson and McFadden [8] listed a representative (but relatively simple) model that have been considered by a number of authors. The hydrodynamic equations governing inviscid, compressible flow of a single component fluid near its critical point are described by conservation equations for mass, momentum, and entropy (energy),

$$\frac{D\rho}{Dt} = -\rho \nabla \cdot \mathbf{v}, \quad (3.51)$$

$$\rho \frac{D\mathbf{v}}{Dt} = -\nabla p - \rho g \mathbf{e}_z + K \nabla \cdot \mathbf{T}, \quad (3.52)$$

$$\frac{Ds}{Dt} = 0, \quad (3.53)$$

where  $s(T, \rho)$  and  $p(T, \rho)$  are the entropy per unit mass and the pressure specified by an appropriate equation of state, respectively,  $K$  is the gradient energy coefficient which for simplicity is assumed constant, and  $\mathbf{T}$  is the capillary tensor.

A continuum theory of the interface was developed where the reversible part of the stress tensor,  $\mathbf{T}$ , that is associated with surface tension was expressed in its simplest form as (e.g., [164]):

$$\mathbf{T} = \left[ \left( \frac{1}{2} |\nabla \rho|^2 + \rho \nabla^2 \rho \right) \mathbf{e} - \nabla \rho \nabla \rho \right], \quad (3.54)$$

where  $\mathbf{e}$  is the unit tensor. The derivatives of the density that appear in the stress tensor arise from the non-local interaction of the molecules within the interface.

This formulation constitute a whole domain formulation as the presence of the capillary tensor allows these equations to apply over the entire domain, including the interfacial region. In this case, the density  $\rho$  is the variable which distinguishes the bulk fluids and the intervening interface. In this role, the density is known as the order parameter. In contrast, for a binary fluid the composition  $\omega$  plays the role of an order parameter [31]. It is possible that neither the density or the composition can be a convenient order parameter. Then it is possible to introduce an alternative order parameter, the so-called PF  $\Phi$ , to characterize the phases. The phase-field  $\Phi$  assumes distinct constant values in each bulk phase and undergoes rapid but smooth variation in the interfacial region. The phase-field is thus a mathematical device that allows a reformulation of free-boundary problems. Normally, the phase-field is spanning the range  $[-1, 1]$  having a constant value in each of the bulk phases equal to  $\Phi = -1$  and  $\Phi = +1$ , respectively. Between these phases in the interfacial region, the PF,  $\Phi$ , changes steeply but smoothly from  $-1$  to  $+1$ . In numerical solutions, the interface is located at  $\Phi = 0$ . The origins of the phase field equations lie in the works of Cahn and Hilliard [31] on the free energy of non-uniform systems.

Theoretical developments on the phase field models occurred in the 1980s and led to the modern use of phase field methods in material science. Early works investigated dendritic solidification of pure and binary materials. The model was rapidly considered as promising for the study of crystallization phenomena due to the fact that the crystallization length scales are comparable to the interface length scale [207]. The work of Fix [81] was one of the first to introduce a phase field model for a first-order phase transition. The models based on this theory consist in the transport of both a phase parameter and an energy parameter. While the energy is diffused in the system, the phase parameter is changing giving origin to solidification or melting. The model was further developed for fluid flow problem from the 1990s (e.g., Nadiga

and Zaleski [164], Anderson and McFadden [8] Jacqmin [126], Dupuy [66]) where either the density, concentration or an order parameter is transported. Conversely, the phase field name has been applied to both solidification and fluid flow problems. These numerical models are based on thermodynamics theory. In relation to the main variable tracked by the method, various variables have been used. The transport variable has been found to be either the density, concentration or phase-field parameter. This suggests that there are a family of equations equally valid within the phase-field approach. The ambiguity comes because any state variable can be obtained from others for a given temperature. Thus, the model gives the same results when using as order parameter the mass, molar or molecular density, or a normalization of the density spanning the range  $[-1, 1]$  for each bulk density. The present difficulty of these approaches relates to the computational costs due to the scale differences between the interface (nanometers) and the engineering equipment (of a wide range of scales from microns to meters).

### 3.4 Basic Principles and Derivation of Multi-Fluid Models

In the following chapters on multiphase modeling we first present the underlying principles used developing the microscopic two-fluid model. Then we introduce the averaging theorems and learned about the detailed mathematical manipulations required formulating the macroscopic multi-fluid transport equations. The concepts of averaging are employed to overcome the scale disparity dealing with the complex flow regimes occurring in multiphase chemical reactors.

An introductory summary of the basic ideas underlying the conventional single phase modeling concepts is given to emphasize the inherent limitations reflected by the different continuum model formulations [186]. It is generally accepted that solids, liquids, and gases are composed of distinct molecules or atoms. Therefore, in single phase flow there is numerous modeling approaches available that can be taken depending upon the application in question. These include the atomistic simulation of the behavior at the molecular level, kinetic theory, local instantaneous continuum modeling and averaged macro-scale modeling. It is further noticed that the evolution of these modeling approaches starts with a particle formulation at the atomic level. Then, by Maxwellian averaging over systems of particles, a local instant continuum model in the form of partial differential equations (PDEs) can be derived from kinetic theory, as shown in chap. 2. In the context of kinetic theory it is essential to point out the conceptual ideas that each macroscopic point in the continuum description represents a mean value for a large number of discrete molecules (although the exact number is not explicitly specified). In the particular cases in which very fine scales are considered as basis for the PDE model formulation (e.g., for micro channel analysis), the basic continuum assumption might become questionable as each macroscopic point only represent a limited number of molecules so no reliable weighted mean values can be determined as the representativity of the distribution function is questionable. The macro-scale model is obtained by

still another averaging of the local instantaneous continuum model. These modeling approaches applied to single PF dynamics yield the Boltzmann equation, the Navier-Stokes equations, and the Reynolds averaged Navier-Stokes equations, respectively. In most engineering models materials are conveniently treated as continuous media instead of individual molecules or atoms. This is because engineers are mostly concerned about the averaged features of material, represented by primitive variables like density, velocity, pressure, temperature, and mass fractions, which vary continuously in space and time. The only approach that is numerically tractable even for the single phase case, considering the current state of computer capability, is the averaged macro-scale model. In kinetic theory the macroscopic transport equations that correspond to the local instantaneous conservation laws are derived in terms of moments of invariant quantities by use of the Boltzmann equation. It is noted that the local instantaneous equations deduced from kinetic theory are inherently closed, so no additional constitutive relations are required. In continuum mechanics, on the other hand, the governing equations are formulated directly on macroscopic scales adopting the continuum hypothesis. In this approach closure laws are required, as the inherent characteristics of the molecular or atomic movement are ignored in this framework. In fluid mechanics the Newton's law of viscosity, the Fourier's law of conduction, and the Fick's law of diffusion constitute the closure laws for momentum, energy, and mass, respectively. Nevertheless, introducing the constitutive relations in the continuum mechanical approach, the resulting local instantaneous equations deduced from the two concepts coincide. It is thus apparent that the given PDEs in both formulations are not exact, they are merely very useful approximations. However, the partial differential descriptions typically break down at very short length and time scales in the sense that the underlying model assumptions are violated so no physical solution can be ensured. The length and time scales below which continuum descriptions become inaccurate are on the order of the characteristic lengths and times associated with the micro-structure of the medium. Only for lengths and times much larger than characteristic molecular lengths and times do the Navier-Stokes equations provide a quantitatively correct description of fluid dynamic behavior. In gas dynamics the importance of rarefaction effects is assessed in terms of the magnitude of the *Knudsen number* which is defined as the ratio of the mean free path  $l$  of the molecules to the characteristic length of the flow  $L$ , thus  $Kn = l/L$ . The characteristic scale of the gradients of the macroscopic magnitudes is  $L = \psi/(d\psi/dx)$ . The failure of the continuum model occurs when the shear stress, species mass- and the heat fluxes in the continuum equations of momentum, mass and energy conservation transport coefficients are no longer valid [36]. This happens when the scale length of the gradients of the macroscopic quantities becomes so small that it is comparable with the molecular mean free path of the gas. Generally, when  $Kn > 0.1$ , the continuum model is no longer valid. In such cases the number of molecules in the gas is not large enough to ensure that the average property of the gas is not influenced by the number concentration of molecules. In many of the multiphase models employed for engineering purposes, the characteristic scales of the internal structure being described are themselves macroscopic in nature. In such situations the desired separation between the calculated and modeled scales is much less clear cut, and

one must be careful not to attribute quantitative significance to any predicted solution features with scales comparable to the internal micro-scale. When a continuum description is pushed to far, i.e. applied on scales too small, one can only hope that such inaccuracies are not catastrophic in nature.

The local instant behavior of Newtonian multiphase flow is considered accurately described by the continuum equations with the addition of interfaces across which appropriate jump conditions hold. Nevertheless, just as for single phase flows, the application of the local instantaneous equations to large-scale engineering problems is numerically intractable. Therefore, to obtain macro-scale solutions we must resort to further averaging and seek solutions for the average values of the system dependent variables. In essence there are three approaches to averaging the continuous phase equations, these are time, volume and ensemble averaging. Considering time and volume averaging a central point is that the length and time scales associated with the detailed flow structures are not always widely separated from the macroscopic length and time scales on which one would like to predict the average behavior. Therefore, the continuum description rely on proper separation of scales. However, proper separation of scales rarely occurs in multiphase flows, as the scales of the internal structures over which we desire to average may be comparable to the macroscopic scales over which the desired averaged quantities vary. This is precisely the sort of situation in which a simple partial differential description may be expected to break down as the field variables are not sufficiently smooth to be considered continuous functions [118, 186]. Thus, in these particular flow regimes, it is somewhat doubtful whether the PDEs for the averaged flow variables can accurately predict the rate of change on the length and time scales of interest. The second averaging operation also introduces the need for additional closure models, and the details of the averaging methods have been the subjects of debate. It is important to note that the characteristic lengths and times over which these averages are performed clearly define lower limits for the scales over which the equations accurately represent differential variations. Nevertheless, the resulting PDEs can still be accurately solved to ensure reliable predictions of the physics inherently accounted for by the closed set of model equations, since the numerical approximations and the physical closure models are not coupled. Of course, the resulting numerical solution doesn't reflect any small scale physics which was not taken into account formulating the closure laws.

Considering multiphase LES simulations, on the other hand, the situation is very different as the numerical representation and the physical model can be directly coupled. To perform a LES simulation a differential model is formulated, discretized and implemented in a program code. In this particular case careful considerations are required as the length and time scales of the eventual discretization may not be compatible with those in which the interfacial model closures were based. Besides, in many situations of single phase simulations having wide spread of scales the discretization errors reflected by the finite difference and finite volume methods can be separately analyzed and dealt with by conventional techniques such as convergence and truncation-error analysis based on the Taylor series expansions. That is, from a mathematical point of view, the PDEs resulting from the volume averaging or

filtering procedures are based on the continuous function assumption, and thus they can in principle be solved with finer and finer numerical resolution in time and space intending to improve the accuracy of the numerical representation of the proposed PDEs. On the other hand, from a physical point of view, if the numerical resolution becomes finer than the cut off filtering scales (in time and space) determining the basis for the interfacial closure formulation, severe physical interpretation problems occur (strictly not defined). Proper model validation can then only be performed on scales larger than the filtered scales. In multiphase flow one is thus hardly ever in a position to keep on refining the resolution until the solution no longer changes (i.e., basically because no adaptive interfacial closures are available), and one must seek other means of obtaining the most accurate results possible under the circumstances. In any case, there is clearly no point in examining the behavior of the system in the limit of infinitely fine resolution when the interfacial closures do not apply on scales less than those considered in their parameterization. Therefore, ensemble averaging is frequently used intending to avoid the shortcomings of time and volume averaging, as ensemble averaging is not limited by any volume or time constraints [42, 63] (i.e., still limited by the continuum hypothesis adopted formulating the underlying single phase equations). Ensemble averaging is based on the probability of the flow field being in a particular configuration at a given time. That is, theoretically an ensemble denotes an infinite set of replicas of the same system that are identical in all respects apart from being in different microscopic multiphase system states at a particular instant in time. Nevertheless, in a more practical view a useful conceptualization of the ensemble average assumes that the flow is deterministic, but the randomness arises through uncertainty in the initial conditions itself, the physical transport coefficients or the empirical model parameters and the chaotic behavior of the evolving flow [62, 63]. Let a realization of the flow denote a possible motion that could have happened. An ensemble average is then taken over many different flow realizations that have the same initial and boundary conditions. In the limit that the number of realizations is going to infinity, the ensemble average approaches the ensemble mean which may be a function of both time and space. In numerical weather prediction a similar ensemble average is computed by averaging over many different forecasts for the same domain and time period, but starting from slightly different initial conditions or using different numerical models or parameterizations. In this sense an ensemble average is a generalization of the simple principle of adding the values of the variables for each realization, and dividing by the number of observations. It is further emphasized that ensemble averaging does not require that any representative volume contains a large number of particles in any given realization [62]. Besides, the interfacial coupling terms can in principle be considered representative for an ensemble of identical multiphase system states, thus they do not restrict the ensemble average in terms of a representative volume in their fundamental form. Nevertheless, the interface closures adopted in all continuum model formulations are conveniently derived per unit volume based on simple volume averaging considering one single particle in a relatively large volume of the continuous phase so that the particle can be considered a point mass. The interfacial constitutive relations may also be parameterized in terms of the relevant time scales for the problem in question. Therefore,

these characteristic length and time scales obviously define limitations for the scales over which the closed ensemble average equations accurately represent differential variations. In effect all the closed macro-scale model formulations reflect similar restrictions for their applications. In a conceptual interpretation the time and volume averages are representative measures for one realization only, so these averages rely on an implicit assumption that the statistics are the same for any one realization [62]. In a theoretical sense the ensemble average is thus considered fundamental, and time and space averages can only be used to approximate the ensemble average in special situations. That is, the ergodic hypothesis states that for statistically stationary and homogeneous flows the ensemble, time and volume averages are identical, otherwise the ergodic hypothesis is to be considered a rough approximation [111]. On the other hand, the experimental data used for model validation is normally obtained in a time or volume averaged framework [230]. Moreover, the accuracy limitations in performing experiments and the implicit assumptions related to the time and volume averaging techniques make the link between purely theoretical model considerations and practical applications difficult. In most applications it is thus referred to the ergodic hypothesis assuming that experimental data determined using any averaging procedure can be used validating any model formulation. However, such a model validation procedure is only approximate (at best) and indicates the accuracy that can be achieved using any of these modeling concepts. Based on the considerations presented above, it was found necessary to carry out a critical evaluation of the various model formulations available aiming to achieve a proper description of the multiphase flow regimes occurring in chemical reactors.

### 3.4.1 *Local Instantaneous Transport Equations*

In this section we apply the *control volume approach* to derive the governing equations for two-phase flows in the Eulerian framework. The mathematical formulation of the local instantaneous equations starts with the integral balance principle written for a fixed control volume (CV), through which the fluid flows, containing two continuous phases separated by an interface across which the physical properties are discontinuous and may jump. The integral equations are then transformed by means of the Leibniz rule and the Gauss theorems to obtain a sum of two volume integrals and a surface integral. The volume integrals lead to the local instantaneous PDEs valid in each of the continuous phases whereas the surface integral denotes the local instantaneous jump conditions valid on the interface only. Literature cited [11, 15, 26–28, 44–47, 51, 52, 68, 71, 86, 118, 125, 156, 157, 198, 211–213].

By definition a phase interface is the region in space separating two immiscible phases in which the system properties differ from those of the contiguous phases. When a physical phase interface is investigated on a sufficiently fine length scale, the transition zone is characterized as a highly inhomogeneous 3D region over which rapid changes and steep normal gradients in the continuum mechanical fields and material properties occur [86]. Several modeling approaches have been proposed

describing the interfacial transport processes, yet the results are not in complete agreement. Basically, the physical nature of such a phase interface allows two different views to be taken formulating continuum models for the interface region. Hence the interface region is either regarded as a *microscopic* 3D diffuse transition region or a *macroscopic* 2D dividing surface as observed over an experimental length scale that is large relative to the thickness of the physical interfacial transition zone.

From an academic viewpoint one might assume that on microscopic scales the system properties are continuous functions across the interface region as well as throughout the bulk phases, the phase interface might be regarded as a *3D region with finite thickness*. Applying the general balance principle to a material CV containing two phases, in a similar manner as we did for a continuous 3D media in Chap. 1, the governing balance equations can be cast in the generic form:

$$\frac{D}{Dt} \int_{V(t)} (\rho\psi) dv = - \int_{A(t)} \mathbf{J} \cdot \mathbf{n} da + \int_{V(t)} \sum_c \rho_c \phi_c dv \quad (3.55)$$

where  $\mathbf{n}$  is the outward directed normal unit vector to the surface of the control volume  $A$ ,  $D/Dt$  is the substantial time derivative,  $\mathbf{v}$  is the velocity,  $\rho$  is the density,  $\psi$  is the conserved quantity,  $\mathbf{J}$  is the diffusive flux and  $\phi_c$  is the source term. The given system balance can be transformed into an Eulerian control volume balance formulation by use of an extended form of the generalized transport theorem, which takes the discontinuous interface into consideration, in a similar manner as described in Chap. 1 for single phase flow. When the specific field variables indicated in Table 1.1 are substituted, the familiar local instantaneous balance equations are obtained governing the transport of mixture mass, species mass, mixture momentum, mixture energy, temperature and entropy etc. for the continuous media.

Although it is appealing from a scientific point of view to regard the interface as a 3D region of finite thickness, the computational difficulties involved considering the implicit numerical grid resolution requirements make the application of this concept infeasible. From a practical viewpoint instrumentation size limitations enable only indirect observations of the interfacial properties through their influence upon the surrounding bulk phases. Therefore, in engineering applications an interface has traditionally been viewed as a *singular 2D dividing surface* separating two immiscible homogeneous bulk phases.<sup>8</sup> In this concept the cumulative effects of the interface upon the adjoining phases are taken into account by the assignment to the dividing surface of any excess properties not accounted for by the homogeneous bulk phases [1]. Adopting these ideas describing two-phase flows it is essential to note that the conventional single phase differential balance equations can be applied to each bulk phase up to the interface, but not across it. Therefore, in the presence of a discontinuous interface the governing equations must be supplemented by appropriate boundary conditions or *jump conditions* at the interface. This is accomplished by writing separate conservation and constitutive equations for each of the two bulk

---

<sup>8</sup> The 2D dividing surface model was originally proposed by Gibbs [89] (p. 219).

fluids and the dividing surface. Furthermore, adopting the macro scale viewpoint several alternative modeling approaches are proposed in the literature for deriving the jump conditions. Moreover, coinciding results are achieved from independent thermodynamical and mechanical derivations, since the surface tension is equivalently defined from energy and force considerations [161]. The relevant concepts can be briefly summarized as follows. In a series of papers a general balance principle in which the interface is represented by a 2D dividing surface of no thickness was formulated for a generic quantity associated with a two-phase material body [45, 46, 52, 198, 208, 211, 213, 214]. A second group of interface model formulations applied a very similar balance principle in which the interface was represented by a 3D region over an infinitesimal CV of negligible thickness which was fixed to and spans the interface [144]. Ishii [118] derived an alternative interfacial balance equation based on a CV analysis, introducing surface mean properties which were averaged over a thin layer in the neighborhood of the interface. A third group of methods is proposed deriving the macro-scale interfacial conservation and constitutive equations from knowledge of the underlying micro-scale equations and thermodynamic principles [28, 68, 86, 156, 157, 161, 162]. Matched asymptotic expansion techniques are used for systematically reconciling the macro- and micro scale views.

In this book the generic balance equations for discontinuous 3D media are formulated adopting the generic surface excess concept [1, 68, 89]. The physical interface view adopted admits the use of two disparate length scales, so the physical variables are decomposed into the sum of a bulk phase quantity and an interface quantity. The bulk quantities represent the macro scale view that we are not resolving distances of the order of the thickness of the interfacial region. In the micro scale viewpoint, on the other hand, a more physical field density becomes apparent which is fully continuous throughout  $dV$ . It is only in the vicinity of the fluid interface that differences between the interface and bulk properties emerge, and these differences are attributable to large normal gradients in  $\psi$  existing within the interfacial transition zone. Thus, as a means of reconciling the usual discontinuous macro-scale view of fluid interfaces with the more physical continuous micro-scale view, the residual difference is assigned to the macroscopic surface  $A_I$  as representing the total surface excess amount of the property  $\psi$  in  $A_I$ . Therefore, the generic area field density  $\psi_I$  is connected to the excess amount of the property per unit area at the points of the 2D interfacial continuum.

Consider a joint material control volume (CV) containing two phases with phase index  $k (= 1, 2)$  and an interface with area  $A_I(t)$  moving with the velocity  $\mathbf{v}_I$ , as illustrated in Fig. 3.3. The macroscopic volume occupied by the CV is denoted by  $V = V_1(t) + V_2(t)$ , and  $A = A_1(t) + A_2(t)$  is the closed macroscopic surface of the CV. Hence it follows that for each phase  $k$  separately, an arbitrary non-material control volume  $V_k(t)$  bounded by a closed surface having partly an external CV surface  $A_k(t)$  and partly an interface surface  $A_I(t)$  is employed.  $l_I(t)$  is the line formed by the intersection of  $A_I()$  with  $A(t)$ . It is emphasised that the interface is not a material surface because mass transfer may occur between the volumes  $V_1(t)$  and  $V_2(t)$  through  $A_I(t)$ .

**Fig. 3.3** A material control volume containing two phases with a moving non-material interface

With the use of the excess property relations, the first term on the LHS of (3.55) is written as:

$$\frac{D}{Dt} \int_{V(t)} (\rho\psi) dv = \frac{d}{dt} \int_{V_1(t)+V_2(t)} (\rho\psi) dv + \frac{d_I}{dt} \int_{A_I(t)} (\rho_I\psi_I) da \quad (3.56)$$

in which the quantities  $\psi$ ,  $\rho$  and  $\mathbf{v}$  are assumed to be continuously differentiable in the regions  $V_1(t)$  and  $V_2(t)$ , and the surface quantities  $\psi_I$ ,  $\rho_I$  and  $\mathbf{v}_I$  are assumed to be continuously differentiable on the surface  $A_I(t)$ . Since in general the dividing surface  $A_I(t)$  is non-material, the regions  $V_1(t)$  and  $V_2(t)$  are not material.

The molecular (diffusive) fluxes of the property  $\psi$  through the boundaries of the macroscopically discontinuous CV depicted by  $V$  are rewritten in a similar manner, in which we are led to define the surface excess lineal flux of  $\psi$  through  $A_I$  [68]:

$$- \int_{A(t)} \mathbf{J} \cdot \mathbf{n} da = - \int_{A_1(t)+A_2(t)} \mathbf{J} \cdot \mathbf{n} da - \int_{l_I(t)} \varphi_I \cdot \mathbf{N}_I dl \quad (3.57)$$

The volume source relation adopts the form:

$$\int_{V(t)} \sum_c \rho_c \phi_c dv = \int_{V_1(t)+V_2(t)} \sum_c \rho_c \phi_c dv + \int_{A_I(t)} \sum_c \rho_{I,c} \phi_{I,c} da \quad (3.58)$$

By substituting these macro-scale excess property relations (3.56)–(3.58) into the generic microscopic transport equation (3.55), the macroscopic balance principle, as applied to the overall material CV for an arbitrary property  $\psi$  (per unit mass) associated with a two-phase system, is by definition expressed as a balance of the rate of change of the property within the two volumes  $V_k(t)$  ( $k = 1, 2$ ) and the interface  $A_I(t)$ , net inflow fluxes by diffusion through  $A_k(t)$ , production within the bulk volumes  $dV_k$  and the interface surface  $A_I(t)$ , and net inflow fluxes through the interface  $A_I$  (per unit length of line). The resulting generic macroscopic balance

equation is expressed on the form<sup>9</sup>:

$$\begin{aligned} \sum_{k=1}^2 \left( \frac{d}{dt} \int_{V_k(t)} (\rho_k \psi_k) dv \right) + \frac{d_I}{dt} \int_{A_I(t)} \rho_I \psi_I da = - \sum_{k=1}^2 \int_{A_k(t)} \mathbf{J}_k \cdot \mathbf{n}_k da \\ + \sum_{k=1}^2 \int_{V_k(t)} \sum_c \rho_{k,c} \phi_{k,c} dv + \int_{A_I(t)} \sum_c \rho_{I,c} \phi_{I,c} da - \oint_{l_I(t)} \varphi_I \cdot \mathbf{N}_I dl \quad (3.59) \end{aligned}$$

in which  $t$  is the time coordinate,  $A(t)$  is the closed surface bounding the whole body,  $l_I(t)$  is the line formed by the intersection of  $A_I(t)$  with  $A(t)$ ,  $\rho_k \psi_k$  is the density of the property per unit volume within the bulk phase  $k$ ,  $\frac{d_I}{dt}$  is the surface material derivative following a multi-component surface particle moving with the mass-averaged surface velocity  $\mathbf{v}_I$ ,  $\rho_I \psi_I$  is the density of the quantity per unit area on  $A_I(t)$ ,  $\rho_I$  is the mass density per unit area on  $A_I(t)$ ,  $\mathbf{J}_k$  is the diffusive flux of the quantity  $\psi_k$  (per unit area) through  $A_k(t)$ ,  $\mathbf{n}_k$  is the unit vector normal and outward directed with respect to the closed surfaces constituted by  $A_k(t)$ ,  $\phi_{k,c}$  is the rate of production of the quantity  $\psi_k$  per unit mass at each point within the bulk phases,  $\phi_{I,c}$  is the rate of production of the quantity  $\psi_k$  per unit mass at each point on  $A_I$ , and  $\varphi_I$  is the flux of the quantity  $\psi_I$  (per unit length of line) through  $l_I(t)$ ,  $\mathbf{N}_I$  is the unit vector normal to  $l_I(t)$  that is both tangent to and outwardly directed with respect to  $A_I(t)$ .

For the purpose of describing interfacial transport phenomena it is convenient to describe the 2D surface geometry using a 3D reference system with origo located outside the surface in the CV in which the surface is embedded (e.g., [68], Chap. 3; [231], Sect. 11.4; [67], pp. 486–492). This framework is named *extrinsic* and connects the 2D surface and the ambient 3D bulk phases. The *intrinsic* perspective of an observer located internally within the surface is then used as a component part providing a simpler description of the interface in terms of a 2D representation which is independent of the 3D space in which the interface is embedded. Due to the mathematical complexity involved, the notation of the 2D differential geometry is examined briefly. A more comprehensive introduction can be found in, for instance, Refs. [1, 27, 32, 67, 68, 100, 137, 213, 231, 247, 256]. Let us consider surfaces in a Cartesian frame, whence these results can be generalized to any set of three coordinates  $\mathbf{x}$  in an arbitrary coordinate system fixed in space. A surface in 3D space can generally be defined in several different ways. Explicitly,  $z = F(x, y)$ , implicitly,  $f(x, y, z) = 0$  or parametrically by defining a set of parametric equations of the form  $x = x(\zeta, \eta)$ ,  $y = y(\zeta, \eta)$ ,  $z = z(\zeta, \eta)$  which contain two independent parameters  $\zeta, \eta$  called surface coordinates or curvilinear coordinates of a point on the surface. In this coordinate system a curve on the surface is defined by a

<sup>9</sup> The notation used in the generic equation is strictly only valid for scalar properties. In the particular case when a vector property is considered the tensor order of the corresponding variables is understood to be adjusted accordingly. Hence, the quantities  $\psi_k$ ,  $\phi_k$  and  $\phi_I$  may be vectors or scalars, while  $\mathbf{J}_k$  and  $\varphi_I$  may be vectors, or second order tensors.

relation  $f(\zeta, \eta) = 0$  between the curvilinear coordinates. By eliminating the parameters  $\zeta, \eta$  one can derive the implicit form of the surface and by solving for  $z$  one obtains the explicit form of the surface. Moreover, using the parametric form of the surface we can define the position vector to a point on the surface which is then represented in terms of the parameters  $\zeta, \eta$  as  $\mathbf{r}_I = \mathbf{r}(x(\zeta, \eta), y(\zeta, \eta), z(\zeta, \eta))$ . The curves  $\mathbf{r}(\zeta, c_2)$  and  $\mathbf{r}(c_1, \eta)$  with  $c_1, c_2$  constants define two surface curves called coordinate curves, which intersect at the surface coordinates  $(c_1, c_2)$ . The family of curves with equally spaced constant values define a surface coordinate grid system. The vectors  $\mathbf{a}_\zeta = \frac{\partial \mathbf{r}}{\partial \zeta}$  and  $\mathbf{a}_\eta = \frac{\partial \mathbf{r}}{\partial \eta}$  evaluated at the surface coordinates  $(c_1, c_2)$  on the surface, are tangent vectors to the coordinate curves through the point and basis vectors for any vector lying in the surface. The position vector is then expressed in the form  $\mathbf{r}_I = x(\zeta, \eta)\mathbf{e}_x + y(\zeta, \eta)\mathbf{e}_y + z(\zeta, \eta)\mathbf{e}_z$ . From the basis vectors we may construct a unit normal vector to the surface at the point  $P$  by calculating the cross product of the tangent vectors  $\mathbf{n}_I(\zeta, \eta) = \mathbf{a}_\zeta \times \mathbf{a}_\eta / |\mathbf{a}_\zeta \times \mathbf{a}_\eta|$ , denoting a right handed system of coordinates. In this frame a vector  $\mathbf{c}$  associated with points in the surface can be expressed by  $\mathbf{c} = c^\alpha \mathbf{a}_\alpha + c_n \mathbf{n}_I = c_\alpha \mathbf{a}^\alpha + c_n \mathbf{n}_I$ , where  $c^\alpha$  ( $\alpha = 1, 2$ ) are the contra-variant components of  $\mathbf{c}$  and  $c_\alpha$  ( $\alpha = 1, 2$ ) are the covariant components of  $\mathbf{c}$ . For orthogonal coordinate systems, a set of unit vectors  $\mathbf{i}_\alpha = \mathbf{a}_\alpha / |\mathbf{a}_\alpha|$  can be defined. Hence, at each point  $P$  on  $A_I$  one can define a set of orthonormal basis vectors  $(\mathbf{i}_1, \mathbf{i}_2, \mathbf{n}_I)$ , where  $\mathbf{i}_1$  and  $\mathbf{i}_2$  are lying in the tangent plane and  $\mathbf{n}_I$  is the unit normal to  $A_I$ . In this frame the vector  $\mathbf{c}$  associated with points in the surface can be expressed by  $\mathbf{c} = \hat{c}_\alpha \mathbf{i}_\alpha + c_n \mathbf{n}_I$ .

Let the position  $(\zeta, \eta)$  of a moving particle in the surface be represented by the position vector  $\mathbf{r}_I = \mathbf{r}_I(\zeta, \eta, t) = x(\zeta, \eta, t)\mathbf{e}_x + y(\zeta, \eta, t)\mathbf{e}_y + z(\zeta, \eta, t)\mathbf{e}_z$ . The velocity of the surface point  $(\zeta, \eta)$  is then defined by:

$$\mathbf{v}_I = \left( \frac{\partial \mathbf{r}_I}{\partial t} \right)_{\zeta, \eta} \quad (3.60)$$

A rigorous model formulation must consider all the relevant interfacial transport phenomena. By constructing a moving coordinate system at each point on the interface one can describe the geometry in terms of a *curvature* which is a measure of how the tangent vector to the coordinate curves in the surface are changing along the curves. To compute the curvature we parameterize a curve in the surface in yet another way in terms of the arc length parameter  $s$ , thus  $\mathbf{r}_I = \mathbf{r}_I(s)$  where  $\zeta = \zeta(s)$  and  $\eta = \eta(s)$ . Thereafter we design a moving frame of orthogonal unit vectors traveling along a curve in space consisting of three vectors, the unit tangent vector, the unit normal vector and a bi-normal vector which is perpendicular to both the tangent and normal vectors.<sup>10</sup> From these prerequisites the method for determining the curvature proceeds with the construction of a unit normal  $\mathbf{n}_I$  at a general point  $P$  on the surface, and the design of a plane which contains the unit surface normal vector  $\mathbf{n}_I$ . Let  $\mathbf{r}_{I,1} = \mathbf{r}_{I,1}(s_1)$  denote the position vector defining a curve 1 which is the intersection of the selected plane with the surface, where  $s_1$  is the arc length along

<sup>10</sup> This frame is named the *Frenet frame* after Jean-Frédéric Frenet (1816–1900).

the curve measured from the point  $P$ . The curve's unit tangent vector evaluated at the point  $P$  is then given by:

$$\mathbf{t}_1 = \frac{d\mathbf{r}_{I,1}}{ds_1} = \frac{d\mathbf{r}_{I,1}/dt}{ds_1/dt} = \frac{d\mathbf{r}_{I,1}/dt}{|d\mathbf{r}_{I,1}/dt|} \quad (3.61)$$

Differentiating  $\mathbf{t}_1 \cdot \mathbf{t}_1 = 1$ , with respect to arc length  $s_1$  we find  $\mathbf{t}_1 \cdot d\mathbf{t}_1/ds_1 = 0$  which implies that the vector  $d\mathbf{t}_1/ds_1$  is perpendicular to the tangent vector  $\mathbf{t}_1$ . Therefore, if we divide  $d\mathbf{t}_1/ds_1$  by the length  $|d\mathbf{t}_1/ds_1|$ , we obtain a unit vector which is orthogonal to  $\mathbf{t}_1$ .

Hence, the principal unit normal vector to the space curve  $\mathbf{n}_{s_1}$  is defined by:

$$\mathbf{n}_{s_1} = \pm \frac{1}{|d\mathbf{t}_1/ds_1|} \frac{d\mathbf{t}_1}{ds_1} \quad (3.62)$$

in which we normally choose the sign of  $\mathbf{n}_{s_1}$  so that  $\mathbf{n}_{s_1}$  points in the direction in which the curve is bending [67]. In other words, the unit normal vector  $\mathbf{n}_{s_1}$  is positive pointing into the concave side of the curve.

The bi-normal unit vector of a space curve  $\mathbf{b}_1 = \mathbf{t}_1 \times \mathbf{n}_I$  is perpendicular to both the surface tangent vector  $\mathbf{t}_1$  and the surface normal vector  $\mathbf{n}_I$ , such that the vectors  $(\mathbf{t}_1, \mathbf{n}_I, \mathbf{b}_1)$  form a right handed system. It is noted that the vector  $\mathbf{n}_{s_1}$  lies in the plane which contains the vectors  $\mathbf{n}_I$  and  $\mathbf{b}_1$ , yet the direction of the two normal vectors in this plane generally differ by an angle  $\theta$ .

For curve 2 a consistent orthogonal Frenet frame is defined by  $(\mathbf{t}_2, \mathbf{n}_I, \mathbf{b}_2)$ . Therefore, for each of the two Frenet frames the curvature vectors  $\kappa_1 = \frac{d\mathbf{t}_1}{ds_1}$  and  $\kappa_2 = \frac{d\mathbf{t}_2}{ds_2}$  denote the rate at which the unit tangent vectors to the two curves turn with respect to the arc length  $s_1$  and  $s_2$ , respectively, along these curves. Since  $\mathbf{t}_1$  and  $\mathbf{t}_2$  are unit vectors, the length remain constant and only the direction changes as the particles move along the curves. The curvature vectors can be written in the component form as:

$$\kappa_1 = \frac{d\mathbf{t}_1}{ds_1} = \kappa_1 \mathbf{n}_{s_1} = \kappa_{n_1} \mathbf{n}_I + \kappa_{g_1} \mathbf{b}_{s_1} = \kappa_{n_1} + \kappa_{g_1} \quad (3.63)$$

$$\kappa_2 = \frac{d\mathbf{t}_2}{ds_2} = \kappa_2 \mathbf{n}_{s_2} = \kappa_{n_2} \mathbf{n}_I + \kappa_{g_2} \mathbf{b}_{s_2} = \kappa_{n_2} + \kappa_{g_2} \quad (3.64)$$

where  $\kappa_n$  is called the normal curvature and  $\kappa_g$  is called the geodesic curvature. The curvatures along  $s_1$  and  $s_2$  are conventionally defined by:

$$\kappa_1 = \left| \frac{d\mathbf{t}_1}{ds_1} \right| \quad \text{and} \quad \kappa_2 = \left| \frac{d\mathbf{t}_2}{ds_2} \right| \quad (3.65)$$

for curve 1 and 2, respectively.

To determine how much a curve is curving near a point on the surface the normal curvature components suffice, since the geodesic curvature rather concerns a property

of curves in a metric space which reflects the deviance of the curve from following the shortest arc length distance along each infinitesimal segment of its length. So far the two perpendicular planes containing the unit normal were arbitrarily selected. If we vary the plane containing the unit surface normal  $\mathbf{n}_I$  at  $P$  we get different curves of intersection with the surface, in which each curve has a curvature associated with it. By examining all such planes we can identify the maximum and minimum normal curvatures associated with the surface point  $P$ . The values of these normal curvatures are called the principal curvatures  $\kappa_{n1}$  and  $\kappa_{n2}$ . We omit details here, making only loose statements about the results of differential geometry of surfaces.

The local geometry of a surface is generally characterized by two surface tensors, the metric tensor and curvature tensor. Letting  $(\zeta, \eta) = (\zeta^1, \zeta^2)$ , the tangent vectors to each of the coordinate curves at a point  $P$  can be represented as the basis vectors  $\mathbf{a}_\alpha = \frac{\partial \mathbf{r}_I}{\partial \zeta^\alpha}$  ( $\alpha = 1, 2$ ) where the partial derivatives are to be evaluated where the coordinate curves on the surface intersect. It follows that an element of arc length with respect to the surface coordinates is represented by:

$$ds^2 = d\mathbf{r}_I \cdot d\mathbf{r}_I = \frac{\partial \mathbf{r}_I}{\partial \zeta^\alpha} \cdot \frac{\partial \mathbf{r}_I}{\partial \zeta^\beta} d\zeta^\alpha d\zeta^\beta = g_{\alpha\beta} d\zeta^\alpha d\zeta^\beta \quad (3.66)$$

where the components of the local metric tensor is defined by

$g_{\alpha\beta} = \mathbf{a}_\alpha \cdot \mathbf{a}_\beta$  ( $\alpha, \beta = 1, 2$ ) in terms of the basis vectors. It has an inverse  $g^{\alpha\beta}$  which satisfies by definition  $\mathbf{a}_\alpha \cdot \mathbf{a}^\beta = g^{\alpha\beta} g_{\alpha\beta} = \delta_\alpha^\beta$  ( $\alpha, \beta = 1, 2$ ), where  $\delta_\alpha^\beta$  is the Kronecker delta and the repeated Greek superscript-subscript indices imply summation following the Einstein summation convention. The metric tensor and its inverse are used to raise and lower Greek indices as in the following example:  $\mathbf{a}^\alpha = g^{\alpha\beta} \mathbf{a}_\beta$  and  $\mathbf{a}_\alpha = g_{\alpha\beta} \mathbf{a}^\beta$  ( $\alpha, \beta = 1, 2$ ). It is noted that the quadratic form of (3.66) is called *the first fundamental form of the surface*. Many important local properties of a surface can be expressed only in terms of this fundamental form. The study of these properties is called the *intrinsic geometry* of the surface.

The normal curvature which is determined from the dot product relation  $\kappa_n = \mathbf{n}_I \cdot \boldsymbol{\kappa} = \mathbf{n}_I \cdot \frac{d\mathbf{t}}{ds}$ . From the orthogonality condition  $\mathbf{n}_I \cdot \mathbf{t} = 0$  we obtain by differentiation with respect to the arc length  $s$  the relation  $\mathbf{n}_I \cdot \frac{d\mathbf{t}}{ds} + \mathbf{t} \cdot \frac{d\mathbf{n}_I}{ds} = 0$ , so the normal curvature can be rewritten as  $\kappa_n = -\mathbf{t} \cdot \frac{d\mathbf{n}_I}{ds} = -\frac{d\mathbf{r}_I}{ds} \cdot \frac{d\mathbf{n}_I}{ds}$ . We can then define the quadratic form:

$$\kappa_n ds^2 = -d\mathbf{r}_I \cdot d\mathbf{n}_I = K_{\alpha\beta} d\zeta^\alpha d\zeta^\beta \quad (3.67)$$

where the components of the curvature tensor (dyadic)  $K_{\alpha\beta}$  is defined via the second derivative of the surface shape function,  $K_{\alpha\beta} = \mathbf{n}_I \cdot \frac{\partial}{\partial \zeta^\alpha} \frac{\partial \mathbf{r}_I}{\partial \zeta^\beta}$ . The curvature tensor for the surface is defined by the relation  $\mathbf{K} = -\nabla_I \mathbf{n}_I$ , and the signed mean curvature  $H_I = -\frac{1}{2} g^{\alpha\beta} K_{\alpha\beta} = -\frac{1}{2} \nabla_I \cdot \mathbf{n}_I$  of the surface is positive<sup>11</sup> when the mean curvature is concave in the direction of  $\mathbf{n}_I$ . The surface gradient operator is defined as  $\nabla_I = \mathbf{e}_I \cdot \nabla = \mathbf{a}^\alpha \frac{\partial}{\partial \zeta^\alpha}$ . The quadratic form of (3.67) is called *the second fundamental form*

<sup>11</sup> Note that other sign conventions exist as well.

of the surface. The investigation of the properties of the surface expressible in terms of the second fundamental form are called extrinsic geometry of the surface.

Adopting an alternative interpretation of the second fundamental form of the surface the normal and mean curvatures can be computed from a procedure for determining the radii of curvature instead. In general, a curved surface is uniquely characterized by two radii of curvature. Again, to compute the curvature at a given point  $P$  of an arbitrary surface embedded in 3D space, one erects a normal to the surface at the point in question and then passes a plane through the surface and containing the normal. The line of intersection will in general be curved, so the local curvature at differential dimensions is approximated as the arc of a circle that is tangent to the curve at the given surface point. Thus, the first *radius of curvature* coincides with the radius of the imaginary circle. The second radius of curvature is obtained by passing a second plane through the surface, also containing the normal, but perpendicular to the first plane. The mean curvature,  $H_I$ , is then defined as the geometric mean value of the two radii of curvature,

$$H_I = \frac{1}{2} \left( \frac{1}{R_1} + \frac{1}{R_2} \right) \quad (3.68)$$

It is emphasized that the radii of curvature  $R_1$  and  $R_2$  obtained in this way are not necessarily the principal radii of curvature, but the geometric mean value of the reciprocals of the radii of curvature equals the mean curvature as this sum is independent of how the first plane is orientated [1]. On the other hand, if we rotate the first plane through a full circle, the first radius of curvature will go through a maximum, and its value at this maximum is called the *principal radius of curvature*. The second principal radius of curvature is then that in the second plane, yet kept fixed and perpendicular to the first. From the preceding discussion we conclude that the principle curvatures correspond to the reciprocals of the principal radii of curvature  $\kappa_1 = 1/R_1$  and  $\kappa_2 = 1/R_2$ . From a mathematical point of view this geometrical surface representation forms a rigorous basis for calculating the interfacial transport processes. The geometrical surface model can, for example, be adopted describing the macro-scale experimental observations that the normal surface tension force induces higher normal stresses in the fluid on the concave side of the interface than in the other fluid on the convex side of the interface. Nevertheless, in practice it is difficult to use these mathematical expressions for estimating the curvature of a surface in a numerical model, since it requires an algorithm for finding and choosing two convenient curves  $s_1$  and  $s_2$ , and calculating the mean curvature from these two curvatures. Instead, the mean curvature is expressed in terms of the unit normal that are determined based on so-called level curves as discussed in Sect. 3.3.2 presenting the VOF- and LS methods. A geometrical interpretation of the directional derivative shows that the gradient to a level curve at a given point on the surface determines a normal vector to the level surface. The normal vector is directed in the direction in which the level function increases most rapidly (corresponding to the direction of steepest ascent on a surface). The position of a point on a moving and deforming dividing surface may be described by the single scalar equation (e.g., [213], p. 24;

[231], Sect. 12.7):

$$f(\mathbf{r}, t) = 0 \quad (3.69)$$

upon differentiating this function with respect to time following a particular point on the surface  $(\zeta, \eta)$ , we find:

$$\frac{\partial f}{\partial t} + \mathbf{v}_I \cdot \nabla f = 0 \quad (3.70)$$

Since the interface is considered a level surface, the unit normal vector  $\mathbf{n}_I$  to  $A_I$  is defined by:

$$\mathbf{n}_I = \pm \frac{\nabla f}{|\nabla f|} \quad (3.71)$$

where the sign (+) is conventionally used for the normal directed outwards and (−) is used for  $\mathbf{n}_I$  directed inwards [261]. Nevertheless,  $\mathbf{n}_I$  can point in the same direction as  $\mathbf{n}_k$  or in the opposite direction depending on the choice of level function (i.e., the level function is usually set to be the volume fraction of either the continuous or dispersed phase). The unit normal of the dispersed phase, for example, is pointing outside the particle when it is defined from the spatial distribution of the volume fraction fields as follows:

$$\mathbf{n}_d = -\frac{\nabla \alpha_d}{|\nabla \alpha_d|} = \frac{\nabla \alpha_c}{|\nabla \alpha_c|} \quad (3.72)$$

The speed of displacement of the surface is defined as the scalar product of  $\mathbf{v}_I$  by  $\mathbf{n}_I$ . We then deduce, by use of (3.70) and (3.71):

$$\mathbf{v}_I \cdot \mathbf{n}_I = \mathbf{v}_I \cdot \frac{\nabla f}{|\nabla f|} = -\frac{\frac{\partial f}{\partial t}}{|\nabla f|} \quad (3.73)$$

The next task in our model derivation is to transform the system description (3.59) into an *Eulerian control volume formulation* by use of an extended form of the generalized transport theorem (see Appendix A). For phase  $k$  the generalized Leibnitz theorem is written:

$$\begin{aligned} \frac{d}{dt} \int_{V_k(t)} (\rho_k \psi_k) dv &= \int_{V_k(t)} \frac{\partial(\rho_k \psi_k)}{\partial t} dv + \int_{A_k(t)} \rho_k \psi_k \mathbf{v}_k \cdot \mathbf{n}_k da \\ &+ \int_{A_I(t)} \rho_k \psi_k \mathbf{v}_I \cdot \mathbf{n}_k da \end{aligned} \quad (3.74)$$

Likewise, the second term on the LHS of (3.59) is transformed using the Leibnitz theorem for the area  $A_I$  (see Appendix A). The surface theorem yields:

$$\frac{d_I}{dt} \int_{A_I(t)} (\rho_I \psi_I) da = \int_{A_I} \left( \frac{d_I(\rho_I \psi_I)}{dt} + \rho_I \psi_I \nabla_I \cdot \mathbf{v}_I \right) da \quad (3.75)$$

in which  $d_I/dt$  is the material derivative in the surface denoting the time derivative of a surface quantity following the motion of a surface particle (e.g., [213], p. 14; [62], p. 90; [68], Sect. 3.4). A material interface does not exchange mass at any point  $\mathbf{r}_I$  with the surrounding bulk phases, but moves and deforms with the mass averaged motion of the neighboring fluid phases [68], Sect. 3.5. In particular, the normal component of the velocity vector at some point  $\mathbf{r}_I$  of a material fluid interface, is identical to the actual normal surface velocity at that point. However, it is possible to allow for net solute or solvent molecular exchange to occur by molecular diffusion without violating the condition of no net mass exchange. Therefore, we often restrict the model derivation considering a material interface, with the interpretation that there are no convective transport across the interface, but we do not rule out the possibility of diffusive transport across the interface. This is possible because the molecular mass diffusion flux is measured relative to the mass averaged velocity, hence there is not net mass transport when there is no convective flux. That is, for a material surface, the velocity of a point lying permanently on the interface is the same as the mass-averaged velocity of the two 3D fluid continua lying on either sides of the interface. For a non-material interface the interface velocity will generally differ from the velocities of the two 3D fluid continua lying on either sides of the interface. However, the kinematical treatment of the interface as being a material surface may in many cases be a sufficiently accurate approximation for reactive systems. Nevertheless, to present a general description, we proceed assuming that the interface is non-material.

The convective and diffusive transport terms in (3.59) are rewritten as the sum of a volume and an interface surface integral using Gauss' theorem (see Appendix A).

For each bulk phase we get:

$$\int_{V_k(t)} \nabla \cdot \mathbf{J}_k dv = \int_{A_k(t)} \mathbf{J}_k \cdot \mathbf{n}_k da + \int_{A_I(t)} \mathbf{J}_k \cdot \mathbf{n}_k da \quad (3.76)$$

and

$$\int_{V_k(t)} \nabla \cdot (\rho_k \mathbf{v}_k \psi_k) dv = \int_{A_k(t)} (\rho_k \mathbf{v}_k \psi_k) \cdot \mathbf{n}_k da + \int_{A_I(t)} (\rho_k \mathbf{v}_k \psi_k) \cdot \mathbf{n}_k da \quad (3.77)$$

We can now combine the generalized transport theorem (3.74) and the Gauss' theorem (3.77) to obtain:

**Fig. 3.4** Diagram for Gauss surface theorem

$$\begin{aligned}
 \frac{d}{dt} \int_{V_k(t)} (\rho_k \psi_k) dv &= \int_{V_k(t)} \left[ \frac{\partial(\rho_k \psi_k)}{\partial t} + \nabla \cdot (\rho_k \mathbf{v}_k \psi_k) \right] dv \\
 &+ \int_{A_I(t)} \rho_k \psi_k (\mathbf{v}_I - \mathbf{v}_k) \cdot \mathbf{n}_k da
 \end{aligned} \quad (3.78)$$

We may refer to (3.78) as the transport theorem for a region where the closing control volume surface partly consists of a non-material phase interface.

Finally, the interfacial flux terms in (3.59) are transformed from a line integral into an interface surface integral using the surface divergence theorem (Appendix A). In the momentum equation the interfacial stress term involving surface tension appears as a line integral  $\int_{l_I(t)} \mathbf{N}_I \cdot \mathbf{T}_I dl$  over the curve  $l_I(t)$  which is the intersection of the fixed CV and  $A_I(t)$ .  $\mathbf{T}_I$  is the surface stress tensor and  $\mathbf{N}_I$  is the unit normal vector located in the tangent plane and directed outward the area  $A_I$  (Fig. 3.4). The surface fluid is normally assumed to be inviscid and thus isotropic, so this force reduces to  $\int_{l_I(t)} \mathbf{N}_I \sigma_I dl$ , where  $\sigma_I$  is the surface tension (a scalar). The Gauss theorem for a surface enable the transformation of a line integral into a surface integral, hence the surface tension term is conventionally written as:

$$\int_{l_I(t)} \mathbf{N}_I \sigma_I dl = \int_{A_I(t)} [\nabla_I \sigma_I - (\nabla_I \cdot \mathbf{n}_I) \sigma_I \mathbf{n}_I] da = \int_{A_I(t)} [\nabla_I \sigma_I + 2H_I \sigma_I \mathbf{n}_I] da \quad (3.79)$$

where  $\nabla_I$  is the surface del operator.

The surface divergence  $-(\nabla_I \cdot \mathbf{n}_I)$  is equal to twice the mean curvature,

$$-\nabla_I \cdot \mathbf{n}_I = 2H_I \quad (3.80)$$

The first term on the RHS of (3.79) is a force acting tangential to the interface toward regions of higher surface tension. The second term on the RHS of (3.79) is a force acting normal to the interface, proportional to the curvature  $H_I$ . The normal force tends to smooth regions of high curvature, whereas the tangential force tends to force fluid along the interface towards regions of higher surface tension.

Surface tension arises due to short range intermolecular forces. The most important ones are van der Waals forces, London dispersion forces, hydrogen and metallic bondings [1]. The contributions from the individual forces are assumed independent, and the effective surface tension are calculated as the linear sum of the individual force contributions. The different molecular attraction forces at the two sides of the interfaces induce a resulting attraction force at the interface. Imagine that the molecules at an interface between two fluids exist in a state different from that of the molecules in the interior of the fluid. The phase  $k$  molecules are (on the average) surrounded by phase  $k$  molecules on only one side within the interface, whereas the interior molecules are completely surrounded. Consequently, the configurational energy of the surface molecules differs from that of the interior molecules and the surface exists in a state of tension [249]. From a micro-scale point of view we may then say that the interfacial tension force is exerted by the interfacial material lying on the convex side of the surface upon the material lying on the concave side.

Two somewhat different definitions of the surface tension exist in the literature [1]. First, as discussed above, the surface tension can be viewed as a force per unit length intending to reduce the area of the interface. We can thus define it in accordance with the following interface force:

$$\int_{A_I(t)} \mathbf{F}_I da = - \oint_{l_I(t)} \mathbf{N}_I \sigma_I dl \quad (3.81)$$

where  $\sigma_I$  has units  $N/m$ . This interpretation is usually adopted for experimental determination of the surface tension.

Second, in thermodynamics it is more common to define surface tension in terms of work or the amount of energy needed to increase the surface with one unit area (i.e., the energy needed to bring a certain amount of molecules from the bulk to the surface). In this context the surface tension has a character of a surface free energy per unit area. The latter definition is in fact equivalent to the unit force per unit length (i.e.  $Nm/m^2 \equiv N/m$ ). The energy interpretation is by many researchers in thermodynamics considered the more fundamental one, and thus this interpretation

is usually adopted for theoretical derivations. The surface tension is then defined as [1, 179]:

$$\sigma_I = \left( \frac{d\hat{G}}{dA} \right)_{T,P,\mathbf{n}} = \left( \frac{d\hat{F}}{dA} \right)_{T,V,\mathbf{n}} \quad (3.82)$$

where  $dA$  determines the increase in surface area,  $d\hat{G}$  denotes the change of surface Gibbs free energy, and  $d\hat{F}$  denotes the change of surface Helmholtz energy. In this case  $\sigma_I$  has units  $Nm/m^2$ .

Further details on the force balance at an arbitrary curved fluid interface is given in Appendix A.

In the total energy and heat equations a similar line integral term appears  $\int_{l_I(t)} \mathbf{q}_I \cdot \mathbf{N}_I dl$  accounting for the heat flux entering the CV through  $l_I$ . Using another form of the Gauss theorem for a surface (Appendix A) transforming the line integral into a surface integral, the surface heat flux term is conventionally written as:

$$\int_{l_I(t)} \mathbf{q}_I \cdot \mathbf{N}_I dl = \int_{A_I(t)} \nabla_I \cdot \mathbf{q}_I da \quad (3.83)$$

For convenience, the generic interface flux  $\varphi_I$  of arbitrary tensorial order in (3.59) is split into two groups of contributions in accordance with their tensorial order (i.e., considering the mentioned surface tension and interfacial heat fluxes only). The first group represents flux vectors  $\varsigma_I$ , whereas the second group denotes fluxes of isotropic second order tensors  $\zeta_I \mathbf{e}_I$ .

The resulting surface terms are then written applying the different forms of the surface divergence theorem [68]:

$$\begin{aligned} - \oint_{l_I(t)} \varphi_I \cdot \mathbf{N}_I dl &= - \oint_{l_I(t)} \left( \varsigma_I \cdot \mathbf{N}_I + (\zeta_I \mathbf{e}_I) \cdot \mathbf{N}_I \right) dl \\ &= - \int_{A_I(t)} \nabla_I \cdot \varsigma_I da - \int_{A_I(t)} \nabla_I \cdot (\zeta_I \mathbf{e}_I) da \\ &= - \int_{A_I(t)} \nabla_I \cdot \varsigma_I da - \int_{A_I(t)} \left[ \nabla_I \zeta_I - (\nabla_I \cdot \mathbf{n}_I) \zeta_I \mathbf{n}_I \right] da \end{aligned} \quad (3.84)$$

where  $\nabla_I \cdot \mathbf{e}_I = 2H_I \mathbf{n}_I$ .  $\mathbf{e}_I$  denotes the *dyadic surface idemfactor* defined by  $\mathbf{e}_I = \mathbf{e} - \mathbf{n}_I \mathbf{n}_I$ , in which the dyadic  $\mathbf{e}$  is the 3D spatial idemfactor [68]. It is further noted that the  $\varsigma_I$  vector is tangent to the surface  $A_I$ .

Using these theorems and excess definitions, (3.59) takes the form:

$$\begin{aligned}
& \sum_{k=1}^2 \int_{V_k(t)} \left( \frac{\partial(\rho_k \psi_k)}{\partial t} + \nabla \cdot (\rho_k \mathbf{v}_k \psi_k) + \nabla \cdot \mathbf{J}_k - \sum_c \rho_{k,c} \phi_{k,c} \right) dv \\
&= - \int_{A_I(t)} \left( \frac{d_I(\rho_I \psi_I)}{dt} + \rho_I \psi_I \nabla_I \cdot \mathbf{v}_I - \sum_c \rho_{I,c} \phi_{I,c} \right. \\
&\quad - \sum_{k=1}^2 (\rho_k (\mathbf{v}_k - \mathbf{v}_I) \psi_k + \mathbf{J}_k) \cdot \mathbf{n}_k \\
&\quad \left. + \nabla_I \cdot \boldsymbol{\varsigma}_I - \nabla_I \zeta_I + (\nabla_I \cdot \mathbf{n}_I) \zeta_I \mathbf{n}_I \right) da
\end{aligned} \tag{3.85}$$

It is seen that the governing system Eq. (3.55) is transformed into a generic Eulerian control volume formulation (3.85) consisting of a volume integral determining the microscopic transport equations for the bulk phases and a surface integral determining the jump balance at the interface.

The balance (3.85) must be satisfied for any  $V_k(t)$  and  $A_I(t)$ , thus the arguments in the volume and surface integrals must all independently be equal to zero. The local instantaneous two-phase balance equations for a quantity  $\psi$  in the  $k$ th phase where  $\mathbf{J}_k$  and  $\phi_k$  are the fluxes and sources of  $\psi_k$  can then be expressed as:

$$\frac{\partial(\rho_k \psi_k)}{\partial t} + \nabla \cdot (\rho_k \mathbf{v}_k \psi_k) + \nabla \cdot \mathbf{J}_k - \sum_c \rho_{k,c} \phi_{k,c} = 0 \tag{3.86}$$

The balance principle applied to mass, momentum and energy for an interface is expressed by the jump condition:

$$\begin{aligned}
& \sum_{k=1}^2 \left( \rho_k (\mathbf{v}_k - \mathbf{v}_I) \psi_k + \mathbf{J}_k \right) \cdot \mathbf{n}_k \\
&= \frac{d_I(\rho_I \psi_I)}{dt} + \rho_I \psi_I \nabla_I \cdot \mathbf{v}_I - \sum_c \rho_{I,c} \phi_{I,c} + \nabla_I \cdot \boldsymbol{\varsigma}_I - \nabla_I \zeta_I + (\nabla_I \cdot \mathbf{n}_I) \zeta_I \mathbf{n}_I
\end{aligned} \tag{3.87}$$

### 3.4.1.1 Continuity

The mass balance is then found by substituting  $\psi = 1$ ,  $\mathbf{J}_k = 0$  and  $\phi_{k,c} = 0$  into (3.86):

$$\frac{\partial \rho_k}{\partial t} + \nabla \cdot (\rho_k \mathbf{v}_k) = 0 \tag{3.88}$$

This equation expresses the constraint of conservation of mass at every point within phase  $k$ .

Introducing the values for the interface parameters  $\varsigma_I = 0$ ,  $\phi_{I,c} = 0$  and  $\zeta_I = 0$  into (3.87), the jump mass balance for the dividing surface becomes (e.g., [213], p. 87; [46], p. 400; [219], p. 44):

$$\sum_{k=1}^2 \rho_k (\mathbf{v}_k - \mathbf{v}_I) \cdot \mathbf{n}_k = \frac{d_I \rho_I}{dt} + \rho_I \nabla_I \cdot \mathbf{v}_I \quad (3.89)$$

In practical applications one normally neglects the terms describing the interfacial effects, thus the jump mass balance may be written as:

$$\sum_{k=1}^2 \rho_k (\mathbf{v}_k - \mathbf{v}_I) \cdot \mathbf{n}_k = \sum_{k=1}^2 \dot{m}_k = 0. \quad (3.90)$$

### 3.4.1.2 Species Mass Balance

The species mass balance is established by substituting  $\psi = \omega_s$ ,  $\mathbf{J}_k = \mathbf{j}_{k,s}$  and  $\phi_{k,c} = R_{k,s}/\rho_{k,c}$  into the (3.86):

$$\frac{\partial \rho_{k,s}}{\partial t} + \nabla \cdot (\rho_{k,s} \mathbf{v}_k) = -\nabla \cdot \mathbf{j}_{k,s} + R_{k,s} \quad (3.91)$$

Introducing the values for the interface parameters  $\varsigma_I = 0$ ,  $\phi_{I,c} = -R_{I,s}/\rho_{I,c}$  and  $\zeta_I = 0$  into (3.87), the jump mass balance equation for the dividing surface becomes (e.g., [213], pp. 679–708):

$$\sum_{k=1}^2 \left( \rho_{k,s} (\mathbf{v}_k - \mathbf{v}_I) + \mathbf{j}_{k,s} \right) \cdot \mathbf{n}_k = \frac{d_I \rho_{I,s}}{dt} + \rho_{I,s} \nabla_I \cdot \mathbf{v}_I + R_{I,s} \quad (3.92)$$

where  $R_{k,s}$  is the rate at which species  $s$  is produced by homogeneous chemical reactions per unit volume, and  $R_{I,s}$  is the rate at which species  $s$  is produced by heterogeneous chemical reactions per unit area.

In practical applications one normally neglects the terms describing the interfacial transport phenomena, thus the jump component mass balance may be written as:

$$\sum_{k=1}^2 \left( \rho_{k,s} (\mathbf{v}_k - \mathbf{v}_I) + \mathbf{j}_{k,s} \right) \cdot \mathbf{n}_k = R_{I,s} \quad (3.93)$$

In line with single phase flows, the diffusive flux,  $\mathbf{j}_{k,s}$ , is commonly parameterized adopting Fick's law for binary systems,  $\mathbf{j}_{k,s} = -\rho_k D_s \nabla \omega_{k,s}$ .

### 3.4.1.3 Momentum Balance

The momentum balance is found by substituting  $\psi = \mathbf{v}$ ,  $\mathbf{J}_k = \mathbf{T}_k$  and  $\phi_{k,c} = \mathbf{g}_{k,c}$  into the generalized transport Eq. (3.86):

$$\frac{\partial}{\partial t}(\rho_k \mathbf{v}_k) + \nabla \cdot (\rho_k \mathbf{v}_k \mathbf{v}_k) = -\nabla \cdot \mathbf{T}_k + \sum_c \rho_{k,c} \mathbf{g}_{k,c} \quad (3.94)$$

This is Cauchy's first law for a multicomponent mixture (e.g., [213], p. 710).

Introducing the values for the interfacial parameters  $\sigma_I = 0$ ,  $\phi_{I,c} = \mathbf{g}_{I,c}$  and  $\zeta_I = \sigma_I$  into (3.87), the jump momentum balance for the dividing surface becomes<sup>12</sup> (e.g., [213], p. 710; [46], p. 400; [219], p. 44):

$$\begin{aligned} & \sum_{k=1}^2 \left( \rho_k \mathbf{v}_k (\mathbf{v}_k - \mathbf{v}_I) + \mathbf{T}_k \right) \cdot \mathbf{n}_k \\ &= \frac{d_I(\rho_I \mathbf{v}_I)}{dt} + \rho_I \mathbf{v}_I \nabla_I \cdot \mathbf{v}_I - \sum_c \rho_{I,c} \mathbf{g}_{I,c} - \nabla_I \sigma_I + (\nabla_I \cdot \mathbf{n}_I) \sigma_I \mathbf{n}_I \end{aligned} \quad (3.95)$$

where  $(\nabla_I \cdot \mathbf{n}_I) \sigma_I \mathbf{n}_I$  and  $\nabla_I \sigma_I$  denote the normal and tangential components of the surface force [27], respectively.

In practical applications considering fluid particles one normally neglects all the interface terms in (3.95), except the interfacial tension terms. Hence, the jump momentum balance is given by:

$$\sum_{k=1}^2 \left( \rho_k \mathbf{v}_k (\mathbf{v}_k - \mathbf{v}_I) + \mathbf{T}_k \right) \cdot \mathbf{n}_k = -\nabla_I \sigma_I + (\nabla_I \cdot \mathbf{n}_I) \sigma_I \mathbf{n}_I \quad (3.96)$$

Each of the two tangential unit vectors  $\mathbf{t}_i$  ( $i = 1, 2$ ) is perpendicular to  $\mathbf{n}_I$  and to the other vector,  $\mathbf{t}_1 \cdot \mathbf{t}_2 = 0$ . Therefore, the tangential components of the jump condition (3.96) can be expressed as:

$$\sum_{k=1}^2 \left( \mathbf{T}_k \cdot \mathbf{n}_k \right) \cdot \mathbf{t}_i = -\nabla_I \sigma_I \cdot \mathbf{t}_i \quad \text{for } i = 1, 2 \quad (3.97)$$

From this equality it follows that when the surface tension is constant, the tangential stress is continuous over the interface. In fluid mechanics it is thus frequently assumed that the tangential components of velocity are continuous across a phase interface [213]. With this simplification,  $v_{I,t} = v_{k,t}$ , the jump momentum balance yields:

<sup>12</sup> The surface tension parameter (a scalar) has the same role as the pressure term in the three dimensional case (e.g., [46], p. 398; [213], p. 163).

$$\begin{aligned}
& \sum_{k=1}^2 \left( \rho_k (\mathbf{v}_k \cdot \mathbf{n}_k - \mathbf{v}_I \cdot \mathbf{n}_k)^2 \mathbf{n}_k + \mathbf{T}_k \cdot \mathbf{n}_k \right) \\
&= \frac{d_I(\rho_I \mathbf{v}_I)}{dt} + \rho_I \mathbf{v}_I \nabla_I \cdot \mathbf{v}_I - \sum_c \rho_{I,c} \mathbf{g}_{I,c} - \nabla_I \sigma_I + (\nabla_I \cdot \mathbf{n}_I) \sigma_I \mathbf{n}_I \quad (3.98)
\end{aligned}$$

in which we have used a particular identity for a spatial vector field in a surface given on the next page.

The mentioned identity for a spatial vector field in a surface is defined by:

$$\mathbf{v} = (\mathbf{v} \cdot \mathbf{n}_I) \mathbf{n}_I + (\mathbf{e} - \mathbf{n}_I \mathbf{n}_I) \cdot \mathbf{v} = (\mathbf{v} \cdot \mathbf{n}_I) \mathbf{n}_I + \mathbf{e}_I \cdot \mathbf{v} = v_n \mathbf{n}_I + v_t \hat{\mathbf{t}} \quad (3.99)$$

where  $\mathbf{e}_I$  is the dyadic surface idem-factor which can be regarded as a tangential projector [261]. The tangential vector  $\hat{\mathbf{t}}$  can be written as linear combinations of the two basis vector fields associated with an orthogonal surface coordinate system  $\hat{\mathbf{t}} = \hat{t}_i \mathbf{t}_i$  [213].

The surface tension force is usually significant when one of the materials is a liquid and the other is either a gas, solid or a liquid. A computational methodology to determine the surface tension for solids in liquids are outlined by [64, 257]. In gas-solid particle flows the surface tension terms are commonly ignored, since these forces are usually very small compared to the viscous terms within the particle phase [61].

#### 3.4.1.4 Energy Balance Equation

The energy balance is found by substituting  $\psi = (e_k + \frac{1}{2} v_k^2)$ ,  $\mathbf{J}_k = \mathbf{T}_k \cdot \mathbf{v}_k + \mathbf{q}_k$  and  $\phi_{k,c} = \mathbf{v}_{k,c} \cdot \mathbf{g}_{k,c}$  into (3.86) (e.g., [213], pp. 715-723):

$$\frac{\partial \rho_k (e_k + \frac{1}{2} v_k^2)}{\partial t} + \nabla \cdot (\rho_k (e_k + \frac{1}{2} v_k^2) \mathbf{v}_k) = -\nabla \cdot \mathbf{T}_k \cdot \mathbf{v}_k + \sum_c \rho_{k,c} \mathbf{v}_{k,c} \cdot \mathbf{g}_{c,k} - \nabla \cdot \mathbf{q}_k \quad (3.100)$$

Introducing the values for the interfacial parameters  $\varsigma_I = \mathbf{q}_I - \sigma_I \mathbf{v}_I$  and  $\zeta_I = 0$  into (3.87), the jump energy balance equation for the dividing surface becomes (e.g., [46], pp. 400–401):

$$\begin{aligned}
& \sum_{k=1}^2 \left( \rho_k (e_k + \frac{1}{2} v_k^2) (\mathbf{v}_k - \mathbf{v}_I) + \mathbf{v}_k \cdot \mathbf{T}_k + \mathbf{q}_k \right) \cdot \mathbf{n}_k = \frac{d_I \rho_I (e_I + \frac{1}{2} v_I^2)}{dt} \\
& + \rho_I (e_I + \frac{1}{2} v_I^2) \nabla_I \cdot \mathbf{v}_I - \sum_c \rho_{I,c} \mathbf{v}_{I,c} \cdot \mathbf{g}_{c,I} + \nabla_I \cdot \mathbf{q}_I - \nabla_I \cdot (\sigma_I \mathbf{v}_I) \quad (3.101)
\end{aligned}$$

### 3.4.1.5 Internal Energy Balance

The differential transport equations for mechanical energy, internal energy, and temperature in the bulk phases are derived as described for the single phase equations in Chap. 1. The derivation of the corresponding jump balances, on the other hand, may need some further comments. To derive the jump internal energy balance we start with the jump total energy balance and subtract the jump kinetic (mechanical) energy balance, in a similar way as we did for the derivation of the transport equations for the bulk phases.

The jump kinetic energy balance is derived by taking the scalar product of the jump momentum balance (3.95) with  $\mathbf{v}_I$  (e.g., [213], p. 720; [46], p. 401):

$$\begin{aligned} & \sum_{k=1}^2 \left( \rho_k \mathbf{v}_I \cdot \mathbf{v}_k (\mathbf{v}_k - \mathbf{v}_I) + \mathbf{v}_I \cdot \mathbf{T}_k \right) \cdot \mathbf{n}_k \\ &= \frac{d_I}{dt} \left( \frac{1}{2} \rho_I v_I^2 \right) + \rho_I v_I^2 \nabla_I \cdot \mathbf{v}_I - \sum_c \rho_{I,c} \mathbf{v}_I \cdot \mathbf{g}_{c,I} - \mathbf{v}_I \cdot \nabla_I \sigma_I + (\nabla_I \cdot \mathbf{n}_I) \sigma_I \mathbf{v}_I \cdot \mathbf{n}_I \end{aligned} \quad (3.102)$$

Subtracting the jump kinetic energy balance (3.102) from the jump total energy balance (3.101), yields:

$$\begin{aligned} & \sum_{k=1}^2 \left( \rho_k (e_k + \frac{1}{2} v_k^2 - \mathbf{v}_k \cdot \mathbf{v}_I) (\mathbf{v}_k - \mathbf{v}_I) + (\mathbf{v}_k - \mathbf{v}_I) \cdot \mathbf{T}_k + \mathbf{q}_k \right) \cdot \mathbf{n}_k \\ &= \frac{d_I(\rho_I e_I)}{dt} + \rho_I (e_I - \frac{1}{2} v_I^2) \nabla_I \cdot \mathbf{v}_I + \nabla_I \cdot \mathbf{q}_I - \sum_c \rho_{I,c} \mathbf{j}_{I,c} \cdot \mathbf{g}_{c,I} \\ &\quad + \mathbf{v}_I \cdot \nabla_I \sigma_I - (\nabla_I \cdot \mathbf{n}_I) \sigma_I \mathbf{v}_I \cdot \mathbf{n}_I - \nabla_I \cdot (\sigma_I \mathbf{v}_I) \\ &= \frac{d_I(\rho_I e_I)}{dt} + \rho_I (e_I - \frac{1}{2} v_I^2) \nabla_I \cdot \mathbf{v}_I + \nabla_I \cdot \mathbf{q}_I - \sum_c \rho_{I,c} \mathbf{j}_{I,c} \cdot \mathbf{g}_{c,I} \\ &\quad - (\nabla_I \cdot \mathbf{n}_I) \sigma_I \mathbf{v}_I \cdot \mathbf{n}_I - \sigma_I \nabla_I \cdot \mathbf{v}_I \end{aligned} \quad (3.103)$$

Since our concern is primarily with interface energy transfer rather than with the energy associated with the dividing surface, we normally neglect all interfacial effects and write the jump internal energy balance (3.103) as:

$$\sum_{k=1}^2 \left( \rho_k (e_k + \frac{1}{2} v_k^2 - \mathbf{v}_k \cdot \mathbf{v}_I) (\mathbf{v}_k - \mathbf{v}_I) + (\mathbf{v}_k - \mathbf{v}_I) \cdot \mathbf{T}_k + \mathbf{q}_k \right) \cdot \mathbf{n}_k = 0 \quad (3.104)$$

There is no experimental evidence to suggest that the interfacial effects neglected in the jump energy balance significantly affect interface energy transfer ([213] p. 721). On the other hand, the interfacial effects in the jump momentum balance may affect the velocity distribution within the immediate neighborhood of the interface and in

this way indirectly influence the interface energy transfer. Nevertheless, even if the interfacial energy has no practical effect upon interface energy transfer, it is not zero, since interfacial tension is a derivative of  $e_I$  (see [213], Sect. 5.8.6). In engineering practice we normally neglect the effect of mass transfer upon the interchange of kinetic energy, and the work done at the phase interface with respect to its effect upon the interchange of internal energy at the interface. Adopting these simplifying assumptions the jump internal energy balance further reduces to (e.g., [219], p. 45):

$$\sum_{k=1}^2 \left( \rho_k e_k (\mathbf{v}_k - \mathbf{v}_I) + \mathbf{q}_k \right) \cdot \mathbf{n}_k = 0 \quad (3.105)$$

#### Jump Enthalpy Balance

Let the enthalpy be defined by  $h_k = e_k + p_k/\rho_k$ , the deviatoric stress tensor by  $\mathbf{T}_k = p_k \mathbf{e} + \boldsymbol{\sigma}_k$ , and the surface enthalpy  $h_I = e_I - \sigma_I/\rho_I$ , hence the jump internal energy balance (3.103) can be cast into the following form (e.g., [46, 219] p. 45):

$$\begin{aligned} & \sum_{k=1}^2 \left( \rho_k \left( h_k + \frac{1}{2} v_k^2 - \mathbf{v}_k \cdot \mathbf{v}_I \right) (\mathbf{v}_k - \mathbf{v}_I) + (\mathbf{v}_k - \mathbf{v}_I) \cdot \boldsymbol{\sigma}_k + \mathbf{q}_k \right) \cdot \mathbf{n}_k \\ &= \frac{d_I(\rho_I h_I)}{dt} + \rho_I \left( h_I - \frac{1}{2} v_I^2 \right) \nabla_I \cdot \mathbf{v}_I + \frac{d_I \sigma_I}{dt} + \nabla_I \cdot \mathbf{q}_I - \sum_c \rho_{I,c} \mathbf{j}_{I,c} \cdot \mathbf{g}_{c,I} \\ & \quad - (\nabla_I \cdot \mathbf{n}_I) \sigma_I \mathbf{v}_I \cdot \mathbf{n}_I \end{aligned} \quad (3.106)$$

where we have used the fact that  $(\mathbf{v}_k - \mathbf{v}_I) \cdot p_k \mathbf{e}_k \cdot \mathbf{n}_k = (\mathbf{v}_k - \mathbf{v}_I) \cdot \mathbf{n}_k p_k$ .

At catalytic surfaces chemical reaction engineers often prefer to use a heat jump formulation which contains an explicit term for the heat generation due to the heterogeneous chemical reactions. The reformulation of the surface enthalpy term in the above enthalpy jump condition follows the same principles as explained in Sect. 1.2.4 deriving the single phase temperature equations from the enthalpy equation. By use of the species mass jump condition (3.92) or its simplified form (3.93), the surface version of the complete differential (1.151) can be expressed as:

$$\begin{aligned} \frac{d_I h_I}{dt} &= C_{p,I} \frac{d_I T_I}{dt} + \left( \frac{1}{\rho_I} + \frac{T_I}{\rho_I^2} \left( \frac{\partial \rho_I}{\partial T_I} \right)_{p,\omega} \right) \frac{d_I p_I}{dt} \\ & \quad - \frac{1}{\rho_I} \left[ \sum_{c=1}^N \bar{h}_{I,c} \nabla_I \cdot \left( \frac{\mathbf{J}_{I,c}}{M_{w_c}} \right) + \sum_{r=1}^q r_{r,c_{\text{ref}},I} (-\Delta \bar{H}_{r,c_{\text{ref}},I}) \right] \end{aligned} \quad (3.107)$$

This result is then used to rewrite the surface enthalpy substantial derivative term in (3.106), and so the required form of the jump enthalpy balance is obtained. However, in practical applications of the jump condition for catalytic surfaces, one generally neglects the terms describing the interfacial transport phenomena and retains only the heat of reaction term. Therefore, the approximate jump heat balance is written

as:

$$\sum_{k=1}^2 \left( \rho_k h_k (\mathbf{v}_k - \mathbf{v}_I) + \mathbf{q}_k \right) \cdot \mathbf{n}_k \approx \sum_{r=1}^q r_{r,c_{\text{ref}},I} (-\Delta \bar{H}_{r,c_{\text{ref}},I}) \quad (3.108)$$

This jump enthalpy condition determines the basis for the derivation of the conventional temperature equation used in heterogeneous catalysis (3.209).

#### *Jump Entropy Balance*

In order to transform the enthalpy balance into a jump entropy balance, we introduce the Gibbs free enthalpies defined by ([46], p. 402):

$$g_k = h_k - T_k s_k \quad (3.109)$$

$$g_I = h_I - T_I s_I \quad (3.110)$$

The Gibbs equation, written for the interface, has the following form:

$$\frac{d_I h_I}{dt} = T_I \frac{d_I s_I}{dt} - \frac{1}{\rho_I} \frac{d_I \sigma_I}{dt} \quad (3.111)$$

Using these definitions, the jump enthalpy balance becomes:

$$\begin{aligned} & \sum_{k=1}^2 \left( \rho_k (g_k + T_k s_k + \frac{1}{2} v_k^2 - \mathbf{v}_k \cdot \mathbf{v}_I) (\mathbf{v}_k - \mathbf{v}_I) + (\mathbf{v}_k - \mathbf{v}_I) \cdot \boldsymbol{\sigma}_k + \mathbf{q}_k \right) \cdot \mathbf{n}_k \\ &= \frac{d_I \rho_I g_I}{dt} + \frac{d_I \rho_I T_I s_I}{dt} + \rho_I (g_I + T_I s_I - \frac{1}{2} v_I^2) \nabla_I \cdot \mathbf{v}_I + \frac{d_I \sigma_I}{dt} + \nabla_I \cdot \mathbf{q}_I \\ & \quad - \sum_c \rho_{I,c} \mathbf{j}_{I,c} \cdot \mathbf{g}_{c,I} - (\nabla_I \cdot \mathbf{n}_I) \sigma_I \mathbf{v}_I \cdot \mathbf{n}_I. \end{aligned} \quad (3.112)$$

#### **3.4.1.6 Summarizing the Governing Equations and Jump Balances**

The generic instantaneous transport equation for a balanced quantity  $\psi$  in the  $k$ th phase is expressed by (3.86), in which  $\mathbf{J}_k$  and  $\phi_k$  are the fluxes and source of  $\psi_k$ . It is noted that the bulk phase equation is identical to the single phase Eq. (1.3) presented in Chap. 1.

Ignoring the interface transport terms, the local instantaneous jump balances for a quantity  $\psi$  can be expressed in a generic form as:

$$\begin{aligned} \sum_{k=1}^2 \left( \rho_k (\mathbf{v}_k - \mathbf{v}_I) \psi_k + \mathbf{J}_k \right) \cdot \mathbf{n}_k &\approx - \sum_c \rho_{I,c} \phi_{I,c} + \nabla_I \cdot \zeta_I \\ &\quad - \nabla_I \zeta_I + (\nabla_I \cdot \mathbf{n}_I) \zeta_I \mathbf{n}_I \\ &\approx - M_I \end{aligned} \quad (3.113)$$

**Table 3.1** The definitions of  $\psi$ ,  $\mathbf{J}$  and  $M_I$ 

| Conservation Principle | $\psi$               | $\mathbf{J}$                               | $\phi$                              | $M_I$                                                |
|------------------------|----------------------|--------------------------------------------|-------------------------------------|------------------------------------------------------|
| Total mass             | 1                    | 0                                          | 0                                   | 0                                                    |
| Component mass         | $\omega_s$           | $\mathbf{J}_s$                             | $R_s$                               | $R_{I,s}$                                            |
| Momentum               | $\mathbf{v}$         | $\mathbf{T}$                               | $\mathbf{g}_c$                      | $-M_I^\sigma$                                        |
| Energy                 | $e + \frac{1}{2}v^2$ | $\mathbf{T} \cdot \mathbf{v} + \mathbf{q}$ | $(\mathbf{g}_c \cdot \mathbf{v}_c)$ | $-(\epsilon_I^\sigma + \nabla_I \cdot \mathbf{q}_I)$ |

where  $M_I$  denotes the relevant terms associated with  $\psi$  at the dividing surface.

The values for  $\psi$ ,  $\mathbf{J}$ ,  $\phi$  and  $M_I$  are given in Table 3.1:

where

- $\omega_s$  is the mass fraction of component  $s$ ;
- $\mathbf{J}_s$  is the molecular (diffusive) flux of component  $s$ ;
- $R_s$  is the rate of production of species  $s$  by homogeneous reactions;
- $R_{I,s}$  is the rate of production of species  $s$  by heterogeneous reactions;
- $\mathbf{T}$  is the total stress tensor ( $= p\mathbf{e} + \boldsymbol{\sigma}$ );
- $\mathbf{g}_c$  is the external forces per unit mass of component  $c$ ;
- $M_I$  is a net surface property term:
  - $\mathbf{M}_I^\sigma = -\nabla_I \sigma_I + (\nabla_I \cdot \mathbf{n}_I) \sigma_I \mathbf{n}_I$  is the surface tension force;
  - $\epsilon_I^\sigma = -\nabla_I \cdot (\sigma_I \mathbf{v}_I)$  is the surface energy associated with surface tension;
- $e$  is the internal energy of the multicomponent system;
- $\mathbf{q}$  is the multicomponent energy flux vector;
- $\boldsymbol{\sigma}$  is the viscous stress tensor;
- $\sigma_I$  is the surface tension;
- $\nabla_I$  is the surface del or nabla operator.

### 3.4.1.7 The Microscopic Transport Equations for a Finite Number of Dispersed Phases: The Multi-Fluid Model

The generic microscopic transport equation for a generalized quantity  $\psi$  can be formulated considering a material control volume  $V(t)$  containing  $N$  continuous phases separated by several interfaces across which the physical properties are discontinuous and may jump, as sketched in Fig. 3.5. This formulation represents a direct extension of the two-fluid modeling procedure described in the preceding section. Among the most rigorous model formulations proposed hitherto are those by Slattery [208, 211, 213] and Deemer and Slattery [45].

The generic balance equation for the variable  $\psi$  in  $V(t)$  is written as:

**Fig. 3.5** A material control volume  $V(t)$  containing  $N$  phases with moving interfaces. The closed surface bounding the CV is  $A(t)$ , and the dividing surfaces enclosed by  $A(t)$  are  $A_{I,jk}(t)$ . The lines formed by the intersection of  $A_{I,jk}(t)$  with  $A(t)$  are  $l_{jk}(t)$ . Any anomalous physical phenomena occurring in the union of all common lines formed by the intersection of the dividing surfaces are ignored [213]

$$\begin{aligned}
 & \sum_{k=1}^N \left( \frac{d}{dt} \int_{V_k(t)} \rho_k \psi_k dv \right) + \frac{1}{2} \sum_{k=1}^N \sum_{j=1}^N (1 - \delta_{jk}) \frac{d_{I,jk}}{dt} \int_{A_{I,jk}(t)} \rho_{I,jk} \psi_{I,jk} da = \\
 & - \sum_{k=1}^N \int_{A_k(t)} \mathbf{J}_k \cdot \mathbf{n}_k da \\
 & + \sum_{k=1}^N \int_{V_k(t)} \sum_c \rho_{k,c} \phi_{k,c} dv + \frac{1}{2} \sum_{k=1}^N \sum_{j=1}^N (1 - \delta_{jk}) \int_{A_{I,jk}(t)} \sum_c \rho_{I,jk,c} \phi_{I,jk,c} da \\
 & - \frac{1}{2} \sum_{k=1}^N \sum_{j=1}^N (1 - \delta_{jk}) \oint_{l_{I,jk}(t)} \boldsymbol{\varphi}_{I,jk} \cdot \mathbf{N}_{I,jk} dl
 \end{aligned} \tag{3.114}$$

where  $A_{I,jk}(t)$  denotes the interface between the  $j^{\text{th}}$  and  $k^{\text{th}}$  phases. Defining the location of the surface  $A_{I,jk}(t)$  as  $\mathbf{r}_{I,jk} = \mathbf{r}_{I,jk}(x(\zeta, \eta, t), y(\zeta, \eta, t), z(\zeta, \eta, t))$  the velocity of the surface point  $(\zeta, \eta)$  is defined by  $\mathbf{v}_{I,jk} = (\partial \mathbf{r}_{I,jk} / \partial t)_{\zeta, \eta}$ .

The two first terms on the LHS of (3.114) can be transformed into a volume and a surface integral using the Leibnitz's theorem:

$$\begin{aligned}
\frac{d}{dt} \int_{V_k(t)} \rho_k \psi_k dv &= \int_{V_k(t)} \frac{\partial}{\partial t} (\rho_k \psi_k) dv + \int_{A_k(t)} (\rho_k \mathbf{v}_k \psi_k) \cdot \mathbf{n}_k da \\
&\quad + \sum_{j=1}^N (1 - \delta_{jk}) \int_{A_{I,kj}(t)} \rho_k \psi_k \mathbf{v}_{I,kj} \cdot \mathbf{n}_{kj} da
\end{aligned} \quad (3.115)$$

The convective and diffusive terms can be written as a sum of a volume and a surface integral using the Gauss' theorem:

$$\begin{aligned}
&\int_{V_k(t)} \nabla \cdot (\rho_k \psi_k \mathbf{v}_k) dv \\
&= \int_{A_k(t)} \rho_k \psi_k \mathbf{v}_k \cdot \mathbf{n}_k da + \sum_{j=1}^N (1 - \delta_{jk}) \int_{A_{I,kj}(t)} \rho_k \psi_k \mathbf{v}_k \cdot \mathbf{n}_{kj} da
\end{aligned} \quad (3.116)$$

and

$$\int_{V_k(t)} \nabla \cdot \mathbf{J}_k dv = \int_{A_k(t)} \mathbf{J}_k \cdot \mathbf{n}_k da + \sum_{j=1}^N (1 - \delta_{jk}) \int_{A_{I,kj}(t)} \mathbf{J}_k \cdot \mathbf{n}_{kj} da \quad (3.117)$$

Accordingly, (3.114) can be rewritten as:

$$\begin{aligned}
&\sum_{k=1}^N \int_{V_k(t)} \left( \frac{\partial (\rho_k \psi_k)}{\partial t} + \nabla \cdot (\rho_k \mathbf{v}_k \psi_k) + \nabla \cdot \mathbf{J}_k - \sum_c \rho_{k,c} \phi_{k,c} \right) dv \\
&= - \sum_{k=1}^N \sum_{j=1}^N (1 - \delta_{ij}) \int_{A_{I,kj}(t)} \left( \frac{1}{2} \frac{d_{I,kj}}{dt} (\rho_{I,kj} \psi_{I,kj}) + \frac{1}{2} \rho_{I,kj} \psi_{I,kj} \nabla_{I,kj} \cdot \mathbf{v}_{I,kj} \right. \\
&\quad - \frac{1}{2} \sum_c \rho_{I,kj,c} \phi_{I,kj,c} - (\rho_k (\mathbf{v}_k - \mathbf{v}_{I,kj}) \psi_k + \mathbf{J}_k) \cdot \mathbf{n}_k \\
&\quad \left. + \frac{1}{2} \nabla_{I,kj} \cdot \boldsymbol{\varsigma}_{I,kj} - \frac{1}{2} \nabla_{I,kj} \zeta_{I,kj} + \frac{1}{2} (\nabla_{I,kj} \cdot \mathbf{n}_{I,kj}) \zeta_{I,kj} \mathbf{n}_{I,kj} \right) da
\end{aligned} \quad (3.118)$$

The balance (3.118) must be satisfied for any  $V_k(t)$  and  $A_{I,kj}(t)$ , thus the arguments in the volume and surface integrals must all independently be equal to zero. The local instantaneous multi-fluid balance equations for a quantity  $\psi$  in the  $k$ th phase where  $\mathbf{J}_k$  and  $\phi_k$  are the fluxes and sources of  $\psi_k$  can then be expressed as:

$$\frac{\partial (\rho_k \psi_k)}{\partial t} + \nabla \cdot (\rho_k \mathbf{v}_k \psi_k) + \nabla \cdot \mathbf{J}_k - \sum_c \rho_{k,c} \phi_{k,c} = 0 \quad (3.119)$$

The generic jump condition is expressed as:

$$\begin{aligned}
 & \dot{\mathbf{m}}_{I,kj}\psi_k + \dot{\mathbf{m}}_{I,jk}\psi_j + \mathbf{J}_k \cdot \mathbf{n}_{kj} + \mathbf{J}_j \cdot \mathbf{n}_{jk} \\
 &= \frac{d_{I,kj}(\rho_{I,kj}\psi_{I,kj})}{dt} + \rho_{I,kj}\psi_{I,kj}\nabla_{I,kj} \cdot \mathbf{v}_{I,kj} - \sum_c \rho_{I,kj,c}\phi_{I,kj,c} \\
 &+ \nabla_{I,kj} \cdot \boldsymbol{\varsigma}_{I,kj} - \nabla_{I,kj}\zeta_{I,kj} + (\nabla_{I,kj} \cdot \mathbf{n}_{I,kj})\zeta_{I,kj}\mathbf{n}_{I,kj}
 \end{aligned} \tag{3.120}$$

where  $\dot{\mathbf{m}}_{I,kj} = \rho_k(\mathbf{v}_k - \mathbf{v}_{I,kj}) \cdot \mathbf{n}_{I,kj}$  is the mass transfer per unit area of the interface and unit time from the  $k^{\text{th}}$  phase to the  $j^{\text{th}}$  phase through the interface.

The particular local instantaneous equations are specifically defined when the values for  $\psi$ ,  $\mathbf{J}$ ,  $\phi$  and  $M_I$  are given in accordance with Table 3.1 for multi-fluid systems.

### 3.4.2 The Purpose of Averaging Procedures

From the preceding discussion in this chapter, one can conclude that the pertinent modeling approaches to be applied in practice must involve some kind of average representation of the flow structure in the reactors. Starting out from the local instantaneous equations proper averaging is needed on the macroscopic scales to avoid solving the multiphase flow problem as a deterministic multi-boundary problem with the interface relations of mass, momentum, and energy as boundary conditions (e.g., [62, 71, 118, 219]). The purpose of averaging is thus to allow a coarser mesh and a longer time step to be used in the numerical simulation. Unfortunately, as a consequence of the averaging of the instantaneous jump conditions valid across the interface between the phases, new expressions that lack formal description are introduced. Closure models for such terms thus become necessary. These models are often formulated by recourse to approximate local flow field analysis and sometimes by recourse to empiricism. Usually, it is here that the approach loses some of the precision that is inherent in the derivation of the rigorous differential equations. In fact all the averaging methods have the important drawback that the resulting macroscopic equations have lost most of the topological information about the flow structure. For example, after averaging the governing equations for gas-liquid flows operating in the bubbly flow, stratified flow or slug flow regimes the resulting set of macroscopic equations are apparently identical. This means that all these flows are represented by the same set of governing equations, so for each particular flow regime the physical structure properties have to be re-introduced through the constitutive equations. Nevertheless, this framework is still the most rigorous concept that can be put to practice for performance optimization, scale-up and design of industrial scale reactors.

### 3.5 Averaging Procedures

This section deals with the formulation of proper transport equations representing some kind of averaged continuum mechanical description of the flow system. There are two main strategies that have been used deriving the existing macroscopic models, denoted the averaging and mixture approaches, respectively. The *Averaging approach* consist in the postulation of the local instantaneous conservation equations prior to the application of an averaging procedure deriving macroscopic Eulerian multi-fluid models. In the *mixture approach* the mixture properties are postulated directly at the macroscopic scales, and a set of macroscopic balance equations is formulated based on the conventional conservation laws and the mixture properties. So, in this particular modeling concept the control volume and the averaging volume coincide. The averaging approach might be considered fundamental and preferred compared to the mixture approach, because averaging provides certain advantages as the resulting macroscopic variables are explicitly related to the local variables. Nevertheless, averaging cannot circumvent the need to postulate constitutive equations, but it can give insight into the types of terms expected to be important in the constitutive relations. The major difference between the averaging and mixture approaches thus lies in the level at which we introduce the necessary postulates and empiricism. Moreover, embedded in the practice of using either average or mixture equations is the assumptions that, for the investigation of multiphase flows in reactor systems, the local microscopic details of the flow are not needed (eluding a multi-scale approach). However, even though it is the macroscopic characteristics that are of interest, the effect of the microscopic details on the macroscopic characteristics can be very important for particular multiphase systems. Depending on the mathematical formulation used to describe the multiphase problem in question, the different averaging procedures can be classified into three groups, the Eulerian averaging, the Lagrangian averaging and the Boltzmann statistical averaging [118]. In this section emphasis is placed on the Eulerian integral averaging operators since the main purpose is to smooth out instant and local variations of the local instantaneous variable fields. Besides, these averages are conventionally used in continuum mechanics and experimental analyzes. The philosophy taken in this book is that any understanding that can be gained from averaging is worthwhile, thus a general introduction to this topic is given before all the mathematical details are presented. Many mathematically different Eulerian averaging procedures for deriving the macroscopic equations and jump conditions for multiphase flows have been proposed in the literature. These are the *volume averaging*-, the *time averaging*- and the *ensemble averaging* techniques, as well as combinations of the basic single averaging operators. Besides, some researches also introduce mass- or phase averaged variables. The first step in a general averaging procedure is to form the average of the local instantaneous transport equations and the corresponding jump conditions. The resulting averaged equations cannot be solved directly, as they contain averages of products of the dependent variables. The second step in an averaging procedure is thus to obtain a solvable set of equations by relating the averages of products to expressions containing products of averaged variables.

**Fig. 3.6** General procedure for formulating a multi-fluid model

This has commonly been done either by employing concepts similar to conventional single phase Reynolds decomposition [190] or methods similar to single phase Favre decomposition before averaging [79, 80]. Note that the Reynolds and Favre decomposition and averaging rules are normally used in the field of single phase turbulence modeling in order to separate the fluctuating components of the variables from the averaged variables (separation of scales), whereas when applied to multiphase flow models the main purpose of these procedures is rather to separate the averages of product into products of average. Moreover, these procedures give rise to extra terms in the transport equations, containing covariances of the fluctuating components, analogous to the Reynolds stress terms obtained in the case of single phase turbulence modeling. A general procedure for formulating a multi-fluid model is sketched in Fig. 3.6. Finally, for completeness it ought to be mentioned that a lot of work has been focused on formulating multi-fluid models for dispersed phases based on kinetic theories [142, 188, 189], and on the kinetic theories of granular materials as outlined in Chap. 4. It is noted that the fundamental basis for such model formulations is related to dispersed particle statistics (Maxwellian averaging) rather than continuum mechanics.

From a mathematical point of view there are still no complete agreement on the properties of the different averaging operators and their suitability for deriving the macroscopic equations. In continuum mechanics a proper averaging procedure should lead to flow variables that are continuous [12]. Considering the pure time and space averages which were the first methods to appear around 1950 [58], some doubts or difficulties related to the continuity of the flow variables were pointed out by [12, 47, 51, 52, 219]. To deal with these matters the basic averages were thus

refined by weighting, by multiple application, and by various choices of averaging scales.

On the other hand, experimental techniques have been developed over the years exclusively to determine time- and volume average measures of the flow keeping the expenses as low as possible. Therefore, in the past the time averaging, volume averaging and time- or ensemble averaging after volume averaging solely have been used in the engineering sciences deriving multiphase models. In particular the time-after volume averaging operator was frequently used. In this method the purpose of the time averaging after volume averaging is to express averages of products in terms of products of averages and to account for the high frequency fluctuations retained by the instantaneous volume averages (separation of scales) [219]. A convenient consequence of this approach is that the conventional single phase Reynolds and Favre decomposition and time averaging concepts are considered appropriate, thus the established single phase turbulence models are often adopted closing the resulting model equations. However, detailed inspections of the flows in laboratory scale, pilot scale and industrial scale chemical reactors under typical operating conditions reveal that the validity conditions of the time- and volume averaging operators are frequently violated thus an ensemble average operator might be preferable. Therefore, in the last few years the mass-weighted ensemble averaging procedure has gained considerable interest. In the subsequent sections the averaging procedures most frequently used in multiphase reactor modeling are examined. Hence it follows that the basic principles of averaging are presented with emphasis on disperse two phase systems.

### 3.5.1 The Volume Averaging Procedure

In this section we assess the volume averaging technique. The literature cited considering different forms of *spatial averaging* (i.e., area or volume) are [2, 7, 12, 16, 19, 23, 26, 41, 42, 47, 48, 56, 58, 85, 95–97, 104–108, 116, 137, 144, 165, 166, 168, 169, 175, 178, 181, 184, 194, 205, 206, 208–214, 219, 220, 245, 248–250, 252–254, 258] which might be recommended for complementary studies.

The condition under which the volume averaging operators can be applied handling the scale disparity in a suitable manner<sup>13</sup> can be expressed as [95, 168, 219, 220, 250]:

$$\left\{ \begin{array}{l} \text{Characteristic} \\ \text{dimension of} \\ \text{phases, } d_p \end{array} \right\} \ll \left\{ \begin{array}{l} \text{Characteristic} \\ \text{dimension of} \\ \text{averaging volume, } l \end{array} \right\} \ll \left\{ \begin{array}{l} \text{Characteristic} \\ \text{dimension of} \\ \text{physical system, } L \end{array} \right\}$$

<sup>13</sup> It is noted that the requirement of proper separation of scales represents the main drawback of the volume averaging method. The constitutive equations used generally depend strongly on this assumption which is hardly ever fulfilled performing simulations of laboratory, pilot and industrial scale reactor units.

This means that we require that the averaging volume is sufficiently large so that the microscopic variations in  $\psi_k$  are essentially smoothed out and the averaged functions  $\langle\psi_k\rangle_V$  are continuous, and that the average of the average equals the average,  $\langle\langle\psi_k\rangle_V\rangle_V = \langle\psi_k\rangle_V$ . That is, when the averaging volume is very small the average quantities of the mixture fluctuates because portions of the phases included in the averaging volume are location-dependent. This fluctuation diminishes as the size of the volume increases, and within a certain characteristic size of  $V$  the average quantities become independent of  $V$ . However, the characteristic size of  $V$  should not be too large, otherwise it becomes dependent upon the global variations of the quantities and the dimensions of the system.

The *volume averaging operator* which can be applied to any scalar, vector or tensor valued property function  $\psi_k$  associated with phase  $k$ , is defined by:

$$\langle\psi_k\rangle_V = \frac{1}{V} \int_V X_k \psi_k dv = \frac{1}{V} \int_{V_k(t)} \psi_k dv \quad (3.121)$$

It is emphasized that  $\langle\psi_k\rangle_V$  is the average of the quantity  $\psi$  in phase  $k$  over the entire averaging volume  $V$ . This averaging operator is sometimes called the *extensive* or *superficial* volume average of  $\psi$  for phase  $k$ .

The  $X_k$  is the phase indicator function which equals 1 in phase  $k$  and zero elsewhere:

$$X_k(\mathbf{r}, t) = \begin{cases} 1 & \text{if location } \mathbf{r} \text{ pertains to phase } k, \\ 0 & \text{otherwise.} \end{cases} \quad (3.122)$$

The mathematical properties of the generalized function  $X_k$  ensure that the ordinary mathematical operations of vector calculus can be performed on the local variables. In particular, as the fluid properties is discontinuous across the 2D interface between the two bulk phases, the phase indicator function is used as a weighting function in forming averages of the local variables to ensure that the differentiation of the discontinuous variables within the integrals are performed in a valid manner [7, 62]. Besides, it is claimed that the introduction of the weighted averages leads to considerable mathematical simplification deriving the averaged equations [58, 184]. However, the trade-off for the simple derivation is that all the manipulations involve generalized functions. Hence it is emphasized that the conventional space averaging operator was defined avoiding the explicit use of the phase indicator function [26, 47, 51, 58, 219, 220, 254]. On the other hand, under certain conditions the  $X_k$ -weighted volume average coincides with the conventional single volume average operator [184].

The *intrinsic* volume average is defined as:

$$\langle\psi_k\rangle_{V_k} = \langle\psi_k\rangle_V^{X_k} = \frac{\frac{1}{V} \int_V X_k \psi_k dv}{\frac{1}{V} \int_V X_k dv} = \frac{1}{V_k(t)} \int_{V_k(t)} \psi_k dv \quad (3.123)$$

where the intrinsic volume average has been expressed as the  $X_k$ -weighted volume average. In other words, the  $X_k$ -weighted volume average as defined by (3.123) is assumed to coincide with  $\langle \psi_k \rangle_{V_k}$  which represents the averaged value of  $\psi$  in the phase  $k$  over the volume  $V_k(t)$ .

By comparing the averaging operators (3.121) and (3.123), we can see that:

$$\langle \psi_k \rangle_V = \frac{V_k}{V} \langle \psi \rangle_{V_k} = \alpha_k \langle \psi \rangle_{V_k} \quad (3.124)$$

in which the instantaneous *volume fraction*  $\alpha_k$  of phase  $k$  is given by:

$$\alpha_k = \frac{V_k}{V} \quad (3.125)$$

To derive a local volume average of the generic differential balance equation for phase  $k$  (3.86) is integrated over the phase  $k$  averaging volume  $V_k$ , and thereafter multiplied with the reciprocal averaging volume  $V$ . The resulting volume averaged equation is given by:

$$\frac{1}{V} \int_{V_k} \frac{\partial(\rho_k \psi_k)}{\partial t} dv + \frac{1}{V} \int_{V_k} \nabla \cdot (\rho_k \mathbf{v}_k \psi_k + \mathbf{J}_k) dv - \frac{1}{V} \int_{V_k} \sum_c \rho_{k,c} \phi_{k,c} dv = 0 \quad (3.126)$$

or, using a more compact notation:

$$\left\langle \frac{\partial(\rho_k \psi_k)}{\partial t} \right\rangle_V + \langle \nabla \cdot (\rho_k \mathbf{v}_k \psi_k + \mathbf{J}_k) \rangle_V - \left\langle \sum_c \rho_{k,c} \phi_{k,c} \right\rangle_V = 0 \quad (3.127)$$

The first, second and third terms in (3.127) have to be reformulated using the conventional volume averaging theorems. The volume averaging theorems have been derived rigorously by several researchers [42, 95–97, 116, 208, 213, 214, 248, 250–252, 254]. The first theorem one makes use of relates the spatial average of a time derivative to the time derivative of a spatial average, and is called the *Leibnitz rule* for volume averaging:

$$\frac{1}{V} \int_{V_k} \frac{\partial \psi_k}{\partial t} dv = \frac{\partial}{\partial t} \left[ \frac{1}{V} \int_{V_k} \psi_k dv \right] - \frac{1}{V} \int_{A_I} \psi_k \mathbf{v}_I \cdot \mathbf{n}_k da \quad (3.128)$$

or, using the compact notation:

$$\left\langle \frac{\partial \psi_k}{\partial t} \right\rangle_V = \frac{\partial}{\partial t} \langle \psi_k \rangle_V - \frac{1}{V} \int_{A_I} \psi_k \mathbf{v}_I \cdot \mathbf{n}_k da \quad (3.129)$$

In this theorem  $A_I$  is the area of the interface between phase  $k$  and the other phase,  $\mathbf{n}_k$  is the outward unit normal of the infinitesimal element of area  $a$  of phase  $k$ , and  $\mathbf{v}_I$  is the velocity of the local interface. The theorem, which was originally derived by [251], represents a special form of the Leibnitz rule which is necessary for the particular case when the time derivative is discontinuous and reflects a Dirac delta function like character [62, 96, 254].

For the particular case when  $\psi_k = 1$  it is recognized that (3.121), (3.123) and (3.129) can be manipulated and expressed as

$$\langle 1 \rangle_V = \frac{1}{V} \int_V X_k dv = \frac{1}{V} \int_{V_k} dv = \alpha_k \quad (3.130)$$

and

$$0 = \frac{\partial \alpha_k}{\partial t} - \frac{1}{V} \int_{A_I} \mathbf{v}_I \cdot \mathbf{n}_k da \quad (3.131)$$

in accordance with the work of [104, 105, 219, 254], among others.

The second theorem we utilize relates the average of a spatial derivative to the spatial derivative of the average, and is called the *Gauss rule* for volume averaging:

$$\frac{1}{V} \int_{V_k} (\nabla \psi_k) dv = \nabla \left[ \frac{1}{V} \int_{V_k} \psi_k dv \right] + \frac{1}{V} \int_{A_I} \psi_k \mathbf{n}_k da \quad (3.132)$$

or

$$\langle \nabla \psi_k \rangle = \nabla \langle \psi_k \rangle + \frac{1}{V} \int_{A_I} \psi_k \mathbf{n}_k da \quad (3.133)$$

This spatial averaging theorem was independently derived by Anderson and Jackson [7], Slattery [208] and Whitaker [248] applying three different methods [116]. In the method of Slattery [208] the theorem is elegantly deduced from the three dimensional Leibnitz's theorem using advanced mathematics and a compact notation for the geometry [42, 210]. The three dimensional Leibnitz theorem is also referred to as the *general transport theorem*. On the other hand, the use of weighted averages emerged from the work of Anderson and Jackson [7].

A special case of (3.133) is the theorem for the volume average of a divergence:

$$\langle \nabla \cdot \psi_k \rangle_V = \nabla \cdot \langle \psi_k \rangle_V + \frac{1}{V} \int_{A_I} \psi_k \cdot \mathbf{n}_k da \quad (3.134)$$

where  $\psi_k$  is interpreted as a vector or a second order tensor field [214]. The theorems (3.133) and (3.134) represent special forms of the Gauss rule which are necessary in

the particular case when the spatial derivatives are discontinuous and reflect a Dirac delta function like character [62].

For the particular case when  $\psi_k = 1$  it is recognized that (3.133) reduces to:

$$0 = \nabla \alpha_k + \frac{1}{V} \int_{A_I} \mathbf{n}_k da \quad (3.135)$$

This is an important relationship frequently utilized manipulating the averaged terms [219, 254].

This completes the list of the mathematical tools required to reformulate the volume averaged Eq. (3.126) into a more practically useful form.

Applying the Leibnitz's rule (3.128) to the first term in (3.126) yields:

$$\frac{1}{V} \int_{V_k} \frac{\partial(\rho_k \psi_k)}{\partial t} dv = \frac{\partial}{\partial t} \left[ \frac{1}{V} \int_{V_k} \rho_k \psi_k dv \right] - \frac{1}{V} \int_{A_I} \rho_k \psi_k \mathbf{v}_I \cdot \mathbf{n}_k da \quad (3.136)$$

or, in the compact notation:

$$\left\langle \frac{\partial(\rho_k \psi_k)}{\partial t} \right\rangle_V = \frac{\partial}{\partial t} \langle \rho_k \psi_k \rangle_V - \frac{1}{V} \int_{A_I} \rho_k \psi_k \mathbf{v}_I \cdot \mathbf{n}_k da \quad (3.137)$$

Applying the Gauss' rule (3.134) to the second and the third terms gives:

$$\frac{1}{V} \int_{V_k} \nabla \cdot (\rho_k \mathbf{v}_k \psi_k) dv = \nabla \cdot \left[ \frac{1}{V} \int_{V_k} (\rho_k \mathbf{v}_k \psi_k) dv \right] + \frac{1}{V} \int_{A_I} (\rho_k \mathbf{v}_k \psi_k) \cdot \mathbf{n}_k da \quad (3.138)$$

for the convective terms.

In the compact notation we may write:

$$\langle \nabla \cdot (\rho_k \mathbf{v}_k \psi_k) \rangle_V = \nabla \cdot \langle \rho_k \mathbf{v}_k \psi_k \rangle_V + \frac{1}{V} \int_{A_I} (\rho_k \mathbf{v}_k \psi_k) \cdot \mathbf{n}_k da \quad (3.139)$$

Likewise, the diffusive terms are written:

$$\frac{1}{V} \int_{V_k} \nabla \cdot \mathbf{J}_k dv = \nabla \cdot \left[ \frac{1}{V} \int_{V_k} \mathbf{J}_k dv \right] + \frac{1}{V} \int_{A_I} \mathbf{J}_k \cdot \mathbf{n}_k da \quad (3.140)$$

and, in the compact notation:

$$\langle \nabla \cdot \mathbf{J}_k \rangle_V = \nabla \cdot \langle \mathbf{J}_k \rangle_V + \frac{1}{V} \int_{A_I} \mathbf{J}_k \cdot \mathbf{n}_k da \quad (3.141)$$

The fourth term is given directly by use of the volume average operator:

$$\frac{1}{V} \int_{V_k} \sum_c \rho_{k,c} \phi_{k,c} dv = \langle \sum_c \rho_{k,c} \phi_{k,c} \rangle_V \quad (3.142)$$

Substituting the novel relations (3.137), (3.139), (3.141) and (3.142) into the generic equation (3.127), the volume averaged equation becomes:

$$\begin{aligned} \frac{\partial \langle \rho_k \psi_k \rangle_V}{\partial t} + \nabla \cdot \langle \rho_k \mathbf{v}_k \psi_k \rangle_V + \nabla \cdot \langle \mathbf{J}_k \rangle_V \\ = -\frac{1}{V} \int_{A_I} (\psi_k \rho_k (\mathbf{v}_I - \mathbf{v}_k) + \mathbf{J}_k) \cdot \mathbf{n}_k da + \langle \sum_c \rho_{k,c} \phi_{k,c} \rangle_V \end{aligned} \quad (3.143)$$

Introducing the phase  $k$  volume fraction (3.125) and the intrinsic volume average operator (3.123), we get:

$$\begin{aligned} \frac{\partial (\alpha_k \langle \rho_k \psi_k \rangle_{V_k})}{\partial t} + \nabla \cdot (\alpha_k \langle \rho_k \mathbf{v}_k \psi_k \rangle_{V_k}) + \nabla \cdot (\alpha_k \langle \mathbf{J}_k \rangle_{V_k}) \\ = -\frac{1}{V} \int_{A_I} (\dot{m}_k \psi_k + \mathbf{J}_k \cdot \mathbf{n}_k) da + \alpha_k \langle \sum_c \rho_c \phi_c \rangle_{V_k} \end{aligned} \quad (3.144)$$

where  $\dot{m}_k$  is the interface mass transfer rate defined by:

$$\dot{m}_k = \rho_k (\mathbf{v}_k - \mathbf{v}_I) \cdot \mathbf{n}_k \quad (3.145)$$

The local jump conditions are averaged in a similar manner. Integrating the local jump condition (3.113) over the interfacial area  $A_I$  and then multiplying the result with the reciprocal averaging volume  $V$ , the averaged jump condition becomes:

$$\frac{1}{V} \int_{A_I} \left( \sum_k [\dot{m}_k \psi_k + \mathbf{J}_k \cdot \mathbf{n}_k] + M_I \right) da = 0 \quad (3.146)$$

The averaged equations governing each phase and the corresponding jump conditions are then achieved defining the specific values of the generic variables in (3.144) and (3.146) in accordance with Table 3.1.

The governing instantaneous volume averaged equations are examined next with focus on the principal approximations normally applied to the interfacial integral terms.

*Mass:*

The volume averaged continuity equation appears by substituting  $\psi_k = 1$ ,  $\mathbf{J}_k = 0$  and  $\phi_{c,k} = 0$  into (3.144):

$$\frac{\partial(\alpha_k \langle \rho_k \rangle_{V_k})}{\partial t} + \nabla \cdot (\alpha_k \langle \rho_k \mathbf{v}_k \rangle_{V_k}) = -\frac{1}{V} \int_{A_I} \dot{m}_k da \quad (3.147)$$

Introducing the values for the interface properties  $M_I = 0$  into (3.146), yields:

$$\sum_k \Gamma_{Vk} = 0 \quad (3.148)$$

where the interfacial mass transfer terms due to phase change is defined by:

$$\Gamma_{Vk} = \frac{1}{V} \int_{A_I} \rho_k (\mathbf{v}_I - \mathbf{v}_k) \cdot \mathbf{n}_k da = -\frac{1}{V} \int_{A_I} \dot{m}_k da = a_I \langle \dot{m}_k \rangle_{A_I} \quad (3.149)$$

in which  $\langle \dot{m}_k \rangle_{A_I} = -\int_{A_I} \dot{m}_k da / A_I$  denotes the interfacial area averaged mass transfer rate [118]. The interfacial area density is defined by:

$$a_I = A_I / V \quad (3.150)$$

*Momentum:*

The volume averaged momentum equation appears by substituting  $\psi_k = \mathbf{v}_k$ ,  $\mathbf{J}_k = \mathbf{T}_k$  and  $\phi_{c,k} = \mathbf{g}_{c,k}$  into (3.144):

$$\begin{aligned} \frac{\partial(\alpha_k \langle \rho_k \mathbf{v}_k \rangle_{V_k})}{\partial t} + \nabla \cdot (\alpha_k \langle \rho_k \mathbf{v}_k \mathbf{v}_k \rangle_{V_k}) + \nabla \cdot (\alpha_k \langle \mathbf{T}_k \rangle_{V_k}) \\ = -\frac{1}{V} \int_{A_I} (\dot{m}_k \mathbf{v}_k + \mathbf{T}_k \cdot \mathbf{n}_k) da + \alpha_k \langle \sum_c \rho_c \mathbf{g}_c \rangle_{V_k} \end{aligned} \quad (3.151)$$

Introducing the values for the interface properties  $\mathbf{M}_I = 2\sigma_I H_I \mathbf{n}_I + \nabla_I \sigma_I$  into (3.146), yields:

$$\sum_k (\mathbf{M}_k^F + \mathbf{M}_k^T) = \frac{1}{V} \int_{A_I} \mathbf{M}_I da \quad (3.152)$$

The interfacial momentum transfer due to phase change is defined by:

$$\mathbf{M}_k^F = \frac{1}{V} \int_{A_I} \rho_k \mathbf{v}_k (\mathbf{v}_I - \mathbf{v}_k) \cdot \mathbf{n}_k da = -\frac{1}{V} \int_{A_I} \dot{m}_k \mathbf{v}_k da = \Gamma_{Vk} \langle \mathbf{v}_k \rangle_{A_I}^{\Gamma_{Vk}} \quad (3.153)$$

in which the mass transfer weighted interfacial area averaged velocity  $\langle \mathbf{v}_k \rangle_{A_I}^{\Gamma_{Vk}}$  is defined in analogy to the mass-weighted averaged variables known from turbulence theory [118] (p. 133).

The interfacial momentum stresses yield:

$$\mathbf{M}_k^T = -\frac{1}{V} \int_{A_I} \mathbf{T}_k \cdot \mathbf{n}_k da = -\frac{1}{V} \int_{A_I} (p_k \mathbf{e} + \boldsymbol{\sigma}_k) \cdot \mathbf{n}_k da \quad (3.154)$$

where the total stress tensor of both phases has been modeled using the Newtonian strain-stress formulation.

It has become customary to rewrite the interfacial momentum transfer term  $\mathbf{M}_k^T$  in terms of the interfacially averaged pressure  $\langle p_k \rangle_{A_I}$  and shear stresses  $\langle \boldsymbol{\sigma}_k \rangle_{A_I}$  of phase  $k$  to separate the mean field effects from local effects [58, 60, 118, 165, 166, 206, 208, 248]. In the volume averaging approach the interfacial area averaged pressure is defined by:

$$\langle p_k \rangle_{A_I} = \frac{1}{A_I} \int_{A_I} p_k da \quad (3.155)$$

and the interfacial area averaged viscous stress term is defined by:

$$\langle \boldsymbol{\sigma}_k \rangle_{A_I} = \frac{1}{A_I} \int_{A_I} \boldsymbol{\sigma}_k da \quad (3.156)$$

The deviation between the local instantaneous pressure and the interfacial area averaged pressure is defined as:

$$\widehat{p}_{k,I} = p_k - \langle p_k \rangle_{A_I} \quad (3.157)$$

and similarly, the interfacial stress deviation yields:

$$\widehat{\boldsymbol{\sigma}}_{k,I} = \boldsymbol{\sigma}_k - \langle \boldsymbol{\sigma}_k \rangle_{A_I} \quad (3.158)$$

Using these definitions of the interfacial quantities, the stress terms in (3.151) can be expressed as:

$$\begin{aligned} & -\nabla \cdot (\alpha_k \langle \mathbf{T}_k \rangle_{V_k}) - \frac{1}{V} \int_{A_I} (p_k \mathbf{e} + \boldsymbol{\sigma}_k) \cdot \mathbf{n}_k da \\ &= -\left[ \nabla (\alpha_k \langle p_k \rangle_{V_k}) + \nabla \cdot (\alpha_k \langle \boldsymbol{\sigma}_k \rangle_{V_k}) \right] \\ & - \left[ \langle p_k \rangle_{A_I} \mathbf{e} \cdot \frac{1}{V} \int_{A_I} \mathbf{n}_k da + \langle \boldsymbol{\sigma}_k \rangle_{A_I} \cdot \frac{1}{V} \int_{A_I} \mathbf{n}_k da \right] \\ & + \frac{1}{V} \int_{A_I} (\widehat{p}_{k,I} \mathbf{e} + \widehat{\boldsymbol{\sigma}}_{k,I}) \cdot \mathbf{n}_k da \end{aligned} \quad (3.159)$$

Besides, by making use of (3.135), introducing the interfacial momentum transfer term  $\mathbf{M}_k^T$  given by (3.154), and defining the generalized drag term by:

$$\mathbf{F}_k = \frac{1}{V} \int_{A_I} (\widehat{p}_{k,I} \mathbf{e} + \widehat{\boldsymbol{\sigma}}_{k,I}) \cdot \mathbf{n}_k da \quad (3.160)$$

we can further manipulate the stress terms in (3.159) in the following manner:

$$\begin{aligned} & -\nabla \cdot (\alpha_k \langle \mathbf{T}_k \rangle_{V_k}) + \mathbf{M}_k^T \\ &= -\left[ \nabla (\alpha_k \langle p_k \rangle_{V_k}) + \nabla \cdot (\alpha_k \langle \boldsymbol{\sigma}_k \rangle_{V_k}) \right] \\ & \quad - \left[ -\langle p_k \rangle_{A_I} \nabla \alpha_k - \langle \boldsymbol{\sigma}_k \rangle_{A_I} \cdot \nabla \alpha_k - \mathbf{F}_k \right] \\ &= -\alpha_k \nabla \langle p_k \rangle_{V_k} + (\langle p_k \rangle_{A_I} - \langle p_k \rangle_{V_k}) \nabla \alpha_k \\ & \quad - \nabla \cdot (\alpha_k \langle \boldsymbol{\sigma}_k \rangle_{V_k}) + \langle \boldsymbol{\sigma}_k \rangle_{A_I} \cdot \nabla \alpha_k + \mathbf{F}_k \\ &\approx -\alpha_k \nabla \langle p_k \rangle_{V_k} - \nabla \cdot (\alpha_k \langle \boldsymbol{\sigma}_k \rangle_{V_k}) + \mathbf{F}_k = -\alpha_k \nabla \langle p_k \rangle_{V_k} + \mathbf{M}_k^d \end{aligned} \quad (3.161)$$

where

$$\mathbf{M}_k^d = \langle p_k \rangle_{A_I} \nabla \alpha_k + \langle \boldsymbol{\sigma}_k \rangle_{A_I} \cdot \nabla \alpha_k + \mathbf{F}_k \quad (3.162)$$

The terms  $(\langle p_k \rangle_{A_I} - \langle p_k \rangle_{V_k}) \nabla \alpha_k + \langle \boldsymbol{\sigma}_k \rangle_{A_I} \cdot \nabla \alpha_k$  are referred to as the interfacial pressure difference effect (or the concentration gradient effect) and the combined interfacial shear and volume fraction gradient effect [71, 121], respectively. The interfacial pressure difference effect is normally assumed to be insignificant for the two-fluid model [4, 58, 127, 133]. That is, for two-phase flows one generally assumes that  $\langle p_k \rangle_{A_I} = \langle p_k \rangle_{V_k} = \langle p_l \rangle_{A_I} = \langle p_l \rangle_{V_l}$  for phases  $k$  and  $l$ , respectively. Moreover, for separated flows the combined interfacial shear and volume fraction gradient effect normally dominates over the generalized drag  $\mathbf{F}_k$ , whereas this combined effect is generally ignored for dispersed flows [121].

The generalized drag force per unit mixture volume which is acting on the dispersed phases of mean diameter  $d$  is commonly formulated as [4, 58, 61, 62, 118–121, 127, 128, 166, 181]:

$$\begin{aligned} \mathbf{F}_d &= -\frac{1}{V} \int_{A_I} (\widehat{p}_{d,I} \mathbf{e} + \widehat{\boldsymbol{\sigma}}_{d,I}) \cdot \mathbf{n}_d da = N_d (\mathbf{f}_D + \mathbf{f}_V + \mathbf{f}_B + \mathbf{f}_L) \\ &= \frac{6\alpha_d}{\pi d^3} (\mathbf{f}_D + \mathbf{f}_V + \mathbf{f}_B + \mathbf{f}_L) \end{aligned} \quad (3.163)$$

where the  $\mathbf{f}$ -terms in the bracket denote the forces acting on a single sphere in a dilute mixture (assuming no particle-particle interactions) which are normally including the steady drag, virtual mass, Basset history and the lift forces. The  $N_d$  denotes the number of particles per unit volume and is defined by  $N_d = \frac{6\alpha_d}{\pi d^3}$ . The generalized drag force hypothesis is assumed valid for dilute flows provided that the different forces are independent. Further details on the modeling of the interfacial coupling terms are discussed in the Sect. 5.1.

For wall bounded flows the wall interaction forces have a similar origin as the interfacial momentum transfer terms [137]. These terms are assessed in further details in Sect. 3.5.6.

For the surface tension forces we can utilize (3.135) and the mean value theorem for integrals, hence the term on the RHS of (3.152) can be expressed as [118, 137]:

$$\begin{aligned}
 \frac{1}{V} \int_{A_I} \mathbf{M}_I da &= \frac{1}{V} \int_{A_I} (2\sigma_I H_I \mathbf{n}_I + \nabla_I \sigma_I) da \\
 &\approx 2\langle \sigma_I H_I \rangle_{A_I} \frac{1}{V} \int_{A_I} \mathbf{n}_I da + \frac{1}{V} \int_{A_I} \nabla_I \sigma_I da \\
 &\approx 2\langle \sigma_I \rangle_{A_I} \langle H_I \rangle_{A_I} \nabla \alpha_2 + a_I \langle \nabla_I \sigma_I \rangle_{A_I}
 \end{aligned} \tag{3.164}$$

where  $\langle H_I \rangle_{A_I}$  is the interfacial area averaged curvature [58, 118, 137]. In this relation we adopt the sign convention defined by  $\mathbf{n}_I = \mathbf{n}_1$ . The mean curvature is still defined in accordance with (3.80).

For dispersed flows containing very small fluid particles the interfacial tension effects have occasionally been considered significant [137]. In this case, the average momentum jump condition (3.152) becomes [58, 118, 137]:

$$\begin{aligned}
 &\Gamma_{Vk} \langle \mathbf{v}_k \rangle_{A_I}^{\Gamma_{Vk}} + \langle p_k \rangle_{A_I} \nabla \alpha_k + \langle \boldsymbol{\sigma}_k \rangle_{A_I} \cdot \nabla \alpha_k + \mathbf{F}_k \\
 &\quad + \Gamma_{Vl} \langle \mathbf{v}_l \rangle_{A_I}^{\Gamma_{Vl}} + \langle p_l \rangle_{A_I} \nabla \alpha_l + \langle \boldsymbol{\sigma}_l \rangle_{A_I} \cdot \nabla \alpha_l + \mathbf{F}_l \\
 &= 2\sigma_I \langle H_I \rangle_{A_I} \nabla \alpha_l + a_I \langle \nabla_I \sigma_I \rangle_{A_I}
 \end{aligned} \tag{3.165}$$

Nevertheless, it is common to neglect the variations in surface tension at the interfaces, and the interfacial pressures are generally related by the Young-Laplace equation [58, 147, 259]:

$$\langle p_k \rangle_{A_I} - \langle p_l \rangle_{A_I} \approx -2\sigma_I \langle H_I \rangle_{A_I} = -\sigma_I \left( \frac{1}{R_1} + \frac{1}{R_1} \right) \tag{3.166}$$

in which the curvature radii is defined in accordance with (3.68).

In this case the averaged momentum jump condition can be expressed by:

$$\Gamma_{Vk} (\langle \mathbf{v}_k \rangle_{A_I}^{\Gamma_{Vk}} - \langle \mathbf{v}_l \rangle_{A_I}^{\Gamma_{Vl}}) + (\langle \boldsymbol{\sigma}_k \rangle_{A_I} - \langle \boldsymbol{\sigma}_l \rangle_{A_I}) \cdot \nabla \alpha_k + \mathbf{F}_k + \mathbf{F}_l \approx 0 \tag{3.167}$$

Provided that the interfacial area averaged velocities are parameterized in a consistent manner (i.e.,  $\Gamma_{Vk} (\langle \mathbf{v}_k \rangle_{A_I}^{\Gamma_{Vk}} - \langle \mathbf{v}_l \rangle_{A_I}^{\Gamma_{Vl}}) = 0$ ), this condition shows that the introduction of the surface tension force is in accordance with Newton's third law. In practice, however, it is difficult to parameterize the interfacial area averaged velocity so in the momentum equation it's often set equal to the bulk velocity and in the momentum jump condition the mass transfer terms are simply neglected enabling a closure relation for the interfacial drag terms which are in agreement with Newton's third

law. Hence,

$$(\langle \sigma_k \rangle_{A_I} - \langle \sigma_I \rangle_{A_I}) \cdot \nabla \alpha_k + \mathbf{F}_k + \mathbf{F}_I \approx 0 \quad (3.168)$$

For dispersed systems the interfacial tension terms are generally more important in the high resolution models simulating details of the local flow close to each individual interface.

*Energy:*

The volume averaged energy equation appears by substituting  $\psi_k = e_k + \frac{1}{2}v_k^2$ ,  $\mathbf{J}_k = \mathbf{T}_k \cdot \mathbf{v}_k + \mathbf{q}_k$  and  $\phi_{c,k} = \mathbf{v}_k \cdot \mathbf{g}_{c,k}$  into (3.144):

$$\begin{aligned} & \frac{\partial}{\partial t} \left( \alpha_k \langle \rho_k (e_k + \frac{1}{2}v_k^2) \rangle_{V_k} \right) + \nabla \cdot \left( \alpha_k \langle \rho_k \mathbf{v}_k (e_k + \frac{1}{2}v_k^2) \rangle_{V_k} \right) \\ & + \nabla \cdot \left( \alpha_k \langle \mathbf{T}_k \cdot \mathbf{v}_k \rangle_{V_k} \right) + \nabla \cdot \left( \alpha_k \langle \mathbf{q}_k \rangle_{V_k} \right) \\ & = -\frac{1}{V} \int_{A_I} \left( \dot{m}_k (e_k + \frac{1}{2}v_k^2) + (\mathbf{T}_k \cdot \mathbf{v}_k + \mathbf{q}_k) \cdot \mathbf{n}_k \right) da \\ & + \alpha_k \left\langle \sum_c \rho_{k,c} \mathbf{v}_{k,c} \cdot \mathbf{g}_{k,c} \right\rangle_{V_k} \end{aligned} \quad (3.169)$$

Introducing the values for the interface properties

$M_I = \nabla_I \cdot \mathbf{q}_I - \nabla_I \cdot (\sigma_I \mathbf{v}_I)$  into (3.146), yield:

$$\sum_k (E_k^E + E_k^W + E_k^I) = -\frac{1}{V} \int_{A_I} M_I da \quad (3.170)$$

The interfacial energy transfer due to phase change is defined by:

$$\begin{aligned} E_k^I &= \frac{1}{V} \int_{A_I} \rho_k (e_k + \frac{1}{2}v_k^2) (\mathbf{v}_I - \mathbf{v}_k) \cdot \mathbf{n}_k da = -\frac{1}{V} \int_{A_I} \dot{m}_k (e_k + \frac{1}{2}v_k^2) da \\ &= \Gamma_{V_k} \langle (e_k + \frac{1}{2}v_k^2) \rangle_{A_I}^{\Gamma_{V_k}} \end{aligned} \quad (3.171)$$

in which  $\langle (e_k + \frac{1}{2}v_k^2) \rangle_{A_I}^{\Gamma_{V_k}}$  denotes the mass transfer weighted interfacial (internal and mechanical) energy [118] (p. 137).

The interfacial heat transfer is given by:

$$E_k^E = -\frac{1}{V} \int_{A_I} \mathbf{q}_k \cdot \mathbf{n}_k da = a_I \langle \mathbf{q}_k \cdot \mathbf{n}_k \rangle_{A_I}, \quad (3.172)$$

in which  $\langle \mathbf{q}_k \cdot \mathbf{n}_k \rangle_{A_I}$  denotes the interfacial area averaged heat transfer flux.

The interfacial work by viscous and pressure forces yields:

$$E_k^W = -\frac{1}{V} \int_{A_I} (\mathbf{T}_k \cdot \mathbf{v}_k) \cdot \mathbf{n}_k da \quad (3.173)$$

The surface energy sources are expressed as the product of the interfacial area concentration and the averaged interfacial fluxes:

$$\begin{aligned} \frac{1}{V} \int_{A_I} M_I da &= -\frac{1}{V} \int_{A_I} (-\nabla_I \cdot (\sigma_I \mathbf{v}_I) + \nabla_I \cdot \mathbf{q}_I) da \\ &= \langle \nabla_I \cdot (\sigma_I \mathbf{v}_I) \rangle_{A_I} a_I - \langle \nabla_I \cdot \mathbf{q}_I \rangle_{A_I} a_I \end{aligned} \quad (3.174)$$

where  $-\langle \nabla_I \cdot \mathbf{q}_I \rangle_{A_I}$  and  $\langle \nabla_I \cdot (\sigma_I \mathbf{v}_I) \rangle_{A_I}$  are the interfacial area averaged interfacial energy fluxes.

*Internal Energy:*

It is not convenient to use (3.144) averaging the internal energy balance, as some of the terms do not fit within the generalized framework. Instead the averaged form of the internal energy equation is obtained by averaging (1.135). The resulting volume averaged internal energy equation is given by [205, 219]:

$$\begin{aligned} &\frac{\partial}{\partial t} (\alpha_k \langle \rho_k e_k \rangle_{V_k}) + \nabla \cdot (\alpha_k \langle \rho_k \mathbf{v}_k e_k \rangle_{V_k}) \\ &= -\alpha_k \langle \mathbf{T}_k : \nabla \mathbf{v}_k \rangle_{V_k} - \nabla \cdot (\alpha_k \langle \mathbf{q}_k \rangle_{V_k}) \\ &\quad - \frac{1}{V} \int_{A_I} (\dot{m}_k e_k + \mathbf{q}_k \cdot \mathbf{n}_k) da + \alpha_k \langle \sum_c \mathbf{j}_{k,c} \cdot \mathbf{g}_{k,c} \rangle_{V_k} \\ &= -\alpha_k \langle \boldsymbol{\sigma}_k : \nabla \mathbf{v}_k \rangle_{V_k} - \alpha_k \langle p_k \nabla \cdot \mathbf{v}_k \rangle_{V_k} - \nabla \cdot (\alpha_k \langle \mathbf{q}_k \rangle_{V_k}) \\ &\quad - \frac{1}{V} \int_{A_I} (\dot{m}_k e_k + \mathbf{q}_k \cdot \mathbf{n}_k) da + \alpha_k \langle \sum_c \mathbf{j}_{k,c} \cdot \mathbf{g}_{k,c} \rangle_{V_k} \end{aligned} \quad (3.175)$$

Alternatively, the internal energy balance can be deduced from the averaged counterparts of the kinetic energy Eq. (1.133) and the total energy Eq. (1.121).

The averaged form of the internal energy jump balance (3.105) can be written as

$$\sum_k (E_k^E + e_k^\Gamma) \approx 0 \quad (3.176)$$

and from (3.171) it is seen that  $e_k^\Gamma = \Gamma_{V_k} \langle e_k \rangle_{A_I}^{\Gamma_{V_k}}$ .

*Enthalpy:*

It is not convenient use (3.144) averaging the enthalpy equation as some of the terms do not fit within the generalized framework. Instead the averaged form of the enthalpy equation can be obtained by averaging (1.138) directly or from (3.175) and the enthalpy definition (1.137).

The volume averaged enthalpy equation is given by [205, 219]:

$$\begin{aligned}
 & \frac{\partial}{\partial t} (\alpha_k \langle \rho_k h_k \rangle_{V_k}) + \nabla \cdot (\alpha_k \langle \rho_k \mathbf{v}_k h_k \rangle_{V_k}) \\
 &= \frac{\partial (\alpha_k \langle p_k \rangle_{V_k})}{\partial t} + \nabla \cdot (\alpha_k \langle \mathbf{v}_k p_k \rangle_{V_k}) \\
 & - \alpha_k \langle \boldsymbol{\sigma}_k : \nabla \mathbf{v}_k \rangle_{V_k} - \alpha_k \langle p_k \nabla \cdot \mathbf{v}_k \rangle_{V_k} - \nabla \cdot (\alpha_k \langle \mathbf{q}_k \rangle_{V_k}) \\
 & - \frac{1}{V} \int_{A_I} \left( \dot{m}_k (h_k - \frac{p_k}{\rho_k}) + \mathbf{q}_k \cdot \mathbf{n}_k \right) da + \alpha_k \langle \sum_c \mathbf{j}_{k,c} \cdot \mathbf{g}_{k,c} \rangle_{V_k}
 \end{aligned} \tag{3.177}$$

The averaged form of the simplified enthalpy jump balance (3.106) can be written as:

$$\sum_k (E_k^E + h_k^\Gamma) \approx 0 \tag{3.178}$$

in which we have neglected the interfacial tension and heat flux effects. Besides, the additional interfacial jump condition term which occurs within the averaging process:

$$\frac{1}{V} \int_{A_I} p_k (\mathbf{v}_I - \mathbf{v}_k) \cdot \mathbf{n}_k da \approx 0 \tag{3.179}$$

since the effect of wave propagation is assumed to be negligible [205, 213].

The interfacial heat transfer due to phase change is expressed as

$$h_k^\Gamma = \Gamma_{V_k} \langle h_k \rangle_{A_I}^{\Gamma_{V_k}} \tag{3.180}$$

#### *Temperature:*

The averaging of the temperature equation for multiphase reactive systems is not straight forward and numerous forms of the averaged equation can be found in the literature. It is obviously not convenient to use (3.144) averaging the temperature equation, as the terms in the equation do not fit within the generalized framework. Instead the averaged form of the temperature equation might be deduced by averaging (1.159).

The volume averaged temperature equation is then given by:

$$\begin{aligned}
& \alpha_k \langle \rho_k C_{p,k} \frac{\partial T_k}{\partial t} \rangle_{V_k} + \alpha_k \langle \rho_k C_{p,k} \mathbf{v}_k \cdot \nabla T_k \rangle_{V_k} \\
& = -\nabla \cdot (\alpha_k \langle \mathbf{q}_k \rangle_{V_k}) - \alpha_k \langle \frac{T}{\rho} (\frac{\partial \rho}{\partial T})_{p,\omega} \frac{Dp}{Dt} \rangle_{V_k} \\
& \quad - \nabla \cdot (\alpha_k \langle \boldsymbol{\sigma}_k : \nabla \mathbf{v}_k \rangle_{V_k}) + \alpha_k \langle \sum_c \mathbf{J}_{k,c} \cdot \mathbf{g}_{k,c} \rangle_{V_k} \\
& \quad + \alpha_k \langle \sum_{c=1}^N \bar{h}_c \nabla \cdot (\frac{\mathbf{j}_c}{M_{w_c}}) \rangle_{V_k} + \alpha_k \langle \sum_{r=1}^q r_{r,c_{\text{ref}}} (-\Delta \bar{H}_{r,c_{\text{ref}}}) \rangle_{V_k} \\
& \quad - \frac{1}{V} \int_{A_I} \mathbf{q}_k \cdot \mathbf{n}_k da
\end{aligned} \tag{3.181}$$

To achieve the solvable temperature equation frequently used in reactor analysis it is necessary to assume that  $C_{p,k}$  is constant within the averaging volume. In this particular case the continuity equation can be used manipulating the terms on the LHS of (3.181). In addition, in this approach the interfacial heat transfer term due to phase change has to be included by postulation.

Alternatively, a similar result is obtained from (3.177) by use of the complete differential (1.151). This method seems more appropriate as the derivation of the interfacial terms for example is in accordance with the standard averaging theorems, hence this method might be more rigorous. The alternative form of the averaged temperature is given in (3.209). However, the choice of model approximations should of course always be determined by comparison with physical observations.

*Chemical species:*

The volume averaged species mass balance appears by substituting  $\psi_k = \omega_{k,s}$ ,  $\mathbf{J}_k = \mathbf{j}_{k,s}$  and  $\phi_{c,k} = -R_{k,s}/\rho_{k,c}$  into (3.144):

$$\begin{aligned}
& \frac{\partial(\alpha_k \langle \rho_{k,s} \rangle_{V_k})}{\partial t} + \nabla \cdot (\alpha_k \langle \rho_{k,s} \mathbf{v}_k \rangle_{V_k}) + \nabla \cdot (\alpha_k \langle \mathbf{j}_{k,s} \rangle_{V_k}) \\
& = -\frac{1}{V} \int_{A_I} (\dot{m}_k \omega_{k,s} + \mathbf{j}_{k,s} \cdot \mathbf{n}_k) da + \alpha_k \langle R_{k,s} \rangle_{V_k}
\end{aligned} \tag{3.182}$$

Introducing the values for the interface properties  $M_I = R_{I,s}$  into (3.146), yields:

$$\sum_k (\mathbf{J}_{k,s}^I + \mathbf{J}_{k,s}^j) = \frac{1}{V} \int_{A_I} R_{I,s} da \tag{3.183}$$

The interfacial species mass transfer due to phase change is defined by:

$$\begin{aligned}
\mathbf{J}_{k,s}^\Gamma &= \frac{1}{V} \int_{A_I} \rho_k \omega_{k,s} (\mathbf{v}_I - \mathbf{v}_k) \cdot \mathbf{n}_k da = -\frac{1}{V} \int_{A_I} \dot{m}_k \omega_{k,s} da \\
&= \Gamma_{V_k} \langle \omega_{k,s} \rangle_{A_I}^{\Gamma_{V_k}}
\end{aligned} \tag{3.184}$$

in which the  $\langle \omega_{k,s} \rangle_{A_I}^{\Gamma_{V_k}}$  denotes the mass transfer weighted interfacial species  $s$  mass fraction [118] (p. 133).

The other interfacial mass transfer fluxes are given by:

$$\mathbf{J}_{k,s}^j = -\frac{1}{V} \int_{A_I} \mathbf{j}_{k,s} \cdot \mathbf{n}_k da = a_I \langle \mathbf{j}_{k,s} \cdot \mathbf{n}_k \rangle_{A_I} \tag{3.185}$$

in which  $\langle \mathbf{j}_{k,s} \cdot \mathbf{n}_k \rangle_{A_I}$  denotes the interfacial area averaged mass transfer flux.

The interfacial production term due to heterogeneous reactions is normally rewritten as:

$$\frac{1}{V} \int_{A_I} M_I da = \frac{1}{V} \int_{A_I} R_{I,s} da = \langle R_{I,s} \rangle_{A_I} a_I = \rho_{\text{Bulk}} \langle R_{I,s} \rangle^m \tag{3.186}$$

in which the interfacial reaction rate per unit interface area is commonly substituted by the more practical reaction rate per unit mass  $\langle R_{I,s} \rangle^m = \langle R_{I,s} \rangle_{A_I} a_I / \rho_{\text{Bulk}}$  ( $kg/kg, cat \times s$ ) in which  $\rho_{\text{Bulk}}$  denotes the bulk density of the catalyst ( $kg, cat/m^3$ ).

In order to carry out computations with the volume averaged equations on the form (3.143) or (3.144), we need to relate the average of products to products of averages and derive constitutive equations for the interfacial coupling terms. The first problem is generally solved by introducing mass- and phase weighted volume averaged variables and the concept of *spatial decomposition* of these variables [85, 104].

The mass-weighted volume average of the quantity  $\psi_k$  is defined by:

$$\langle \psi_k \rangle_V^{X_k \rho_k} = \frac{\frac{1}{V} \int_V \rho_k \psi_k X_k dv}{\frac{1}{V} \int_V \rho_k X_k dv} = \frac{\langle \rho_k \psi_k \rangle_V}{\langle \rho_k \rangle_V} = \frac{\langle \rho_k \psi_k \rangle_{V_k}}{\langle \rho_k \rangle_{V_k}}, \tag{3.187}$$

in which the intrinsic volume average coincides with the  $X_k$ -weighted average as defined by (3.123).

We can now adopt the concept of *spatial decomposition* of the mass-weighted variables to relate the average of products to products of average.

Let  $\widehat{\psi}_k$  represent the spatial deviation of the point variable  $\psi_k$  from the mass-weighted volume average value  $\langle \psi_k \rangle_V^{X_k \rho_k}$ , as defined by:

$$\widehat{\psi}_k = \psi_k - \langle \psi_k \rangle_V^{X_k \rho_k} \tag{3.188}$$

where  $\psi_k$  represents the local variable at a point in space  $\mathbf{r}$ . The concept of spatial decomposition of the volume averaged variables was initially proposed by Whitaker [248, 250, 251] for applications in multiphase flow models in analogy to the conventional temporal decomposition of the instantaneous variables used in the study of turbulent transport phenomena [79, 140]. The spatial decomposition concept was later slightly modified by Gray and co-workers [95, 97, 104, 105] to eliminate an inherent inconsistency for modeling dispersion as a diffusive mechanism. Introducing (3.188) into (3.187) we obtain the important result:

$$\begin{aligned} \langle \rho_k \rangle_V \langle \psi_k \rangle_V^{X_k \rho_k} &= \langle \rho_k \psi_k \rangle_V \\ &= \langle \rho_k (\langle \psi_k \rangle_V^{X_k \rho_k} + \widehat{\psi}_k) \rangle_V \\ &= \langle \rho_k \rangle_V \langle \psi_k \rangle_V^{X_k \rho_k} + \langle \rho_k \widehat{\psi}_k \rangle_V \\ &= \langle \rho_k \rangle_V \langle \psi_k \rangle_V^{X_k \rho_k}, \end{aligned} \quad (3.189)$$

in which we have shown that  $\langle \rho_k \widehat{\psi}_k \rangle_V = \alpha_k \langle \rho_k \widehat{\psi}_k \rangle_{V_k} = \langle \widehat{\psi}_k \rangle_V^{X_k \rho_k} = 0$  because  $\langle \psi_k \rangle_V^{X_k \rho_k}$  is constant within  $V$ .

Moreover, utilizing (3.189) the convective term in the averaged Eq. (3.144) can be rewritten as:

$$\begin{aligned} \langle \rho_k \mathbf{v}_k \psi_k \rangle_{V_k} &= \langle \rho_k \mathbf{v}_k \psi_k \rangle_V^{X_k} \\ &= \langle \rho_k (\langle \mathbf{v}_k \rangle_V^{X_k \rho_k} + \widehat{\mathbf{v}}_k) (\langle \psi_k \rangle_V^{X_k \rho_k} + \widehat{\psi}_k) \rangle_{V_k} \\ &= \langle \rho_k \rangle_{V_k} \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \langle \psi_k \rangle_V^{X_k \rho_k} + \langle \rho_k \widehat{\psi}_k \widehat{\mathbf{v}}_k \rangle_{V_k} \end{aligned} \quad (3.190)$$

Introducing the mass-weighted variables (3.187) and manipulating the convective terms by use of the concept of spatial decomposition (3.188), the averaged Eq. (3.144) can be written as:

$$\begin{aligned} &\frac{\partial (\alpha_k \langle \rho_k \rangle_{V_k} \langle \psi_k \rangle_V^{X_k \rho_k})}{\partial t} + \nabla \cdot (\alpha_k \langle \rho_k \rangle_{V_k} \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \langle \psi_k \rangle_V^{X_k \rho_k}) + \nabla \cdot (\alpha_k \langle \mathbf{J}_k \rangle_{V_k}) \\ &= -\frac{1}{V} \int_{A_I} (\dot{m}_k \psi_k + \mathbf{J}_k) \cdot \mathbf{n}_k da + \alpha_k \sum_c \langle \rho_{k,c} \phi_c \rangle_{V_k} \\ &\quad - \nabla \cdot (\alpha_k \langle \rho_k \widehat{\mathbf{v}}_k \widehat{\psi}_k \rangle_{V_k}) \end{aligned} \quad (3.191)$$

It is easily seen that the principal closure problem is maintained since three undetermined terms appear in the volume averaged Eq. (3.191). The first term,  $-\nabla \cdot (\alpha_k \langle \rho_k \widehat{\mathbf{v}}_k \widehat{\psi}_k \rangle_{V_k})$ , is called the microscopic deviation term. In principle these terms correspond to the single phase SGS turbulence fluxes and might be modeled adopting a single phase turbulence model. In LES these covariance terms are normally modeled as sub-grid scale turbulence fluxes adopting the Smagorinsky model. On the other hand, in connection with the double averaging operators (i.e., adopting the time

or ensemble after volume averaging procedures) these terms are normally neglected [12, 258]. The second term,  $-\frac{1}{V} \int_{A_I} \mathbf{J}_k \cdot \mathbf{n}_k da$ , accounts for the effects of interfacial stress, heat and species mass transfer, whereas the third term,  $\frac{1}{V} \int_{A_I} \dot{m}_k \psi_k da$ , accounts for the interfacial transfer due to phase change.

To illustrate the remaining covariance modeling task required closing the model, the fairly rigorous instantaneous volume averaged equations expressed in terms of mass-weighted quantities are listed below.

*Mass:*

The modified volume averaged continuity equation deduced from (3.147) can be written as:

$$\frac{\partial}{\partial t} \left( \alpha_k \langle \rho_k \rangle_{V_k} \right) + \nabla \cdot \left( \alpha_k \langle \rho_k \rangle_{V_k} \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \right) = \Gamma_{Vk} \quad (3.192)$$

The interfacial mass transfer flux  $\Gamma_{Vk}$  needs to be approximated providing parameterizations for the unknown quantities in (3.149).

*Momentum:*

The modified volume averaged momentum equation deduced from (3.151) can be written as:

$$\begin{aligned} & \frac{\partial}{\partial t} \left( \alpha_k \langle \rho_k \rangle_{V_k} \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \right) + \nabla \cdot \left( \alpha_k \langle \rho_k \rangle_{V_k} \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \right) \\ &= -\nabla \cdot \left( \alpha_k (\langle \mathbf{T}_k \rangle_{V_k} + \langle T_k \rangle_{V_k}^{Re}) \right) + \mathbf{M}_k^T \\ &+ \Gamma_{Vk} \langle \mathbf{v}_k \rangle_{A_I}^{\Gamma_{Vk}} + \alpha_k \left\langle \sum_c \rho_{k,c} \mathbf{g}_c \right\rangle_{V_k} \\ &\approx -\alpha_k \nabla \langle p_k \rangle_{V_k} - \nabla \cdot \left( \alpha_k (\langle \boldsymbol{\sigma}_k \rangle_{V_k} + \langle T_k \rangle_{V_k}^{Re}) \right) + \mathbf{F}_k \\ &+ \Gamma_{Vk} \langle \mathbf{v}_k \rangle_{A_I}^{\Gamma_{Vk}} + \alpha_k \left\langle \sum_c \rho_{k,c} \mathbf{g}_c \right\rangle_{V_k} \end{aligned} \quad (3.193)$$

in which  $\langle T_k \rangle_{V_k}^{Re} = \langle \rho_k \widehat{\mathbf{v}}_k \widehat{\mathbf{v}}_k \rangle_{V_k}$ . In addition, closure relations are needed for the interfacial terms (3.153), (3.163) and (3.164).

*Energy:*

The modified volume averaged energy equation deduced from (3.169) can be written as:

$$\begin{aligned} & \frac{\partial}{\partial t} \left( \alpha_k \langle \rho_k \rangle_{V_k} (\langle e_k \rangle_V^{X_k \rho_k} + \frac{1}{2} (\langle v_k \rangle_V^{X_k \rho_k})^2 + \frac{1}{2} \langle \widehat{\mathbf{v}}_k \cdot \widehat{\mathbf{v}}_k \rangle_V^{X_k \rho_k}) \right) \\ &+ \nabla \cdot \left( \alpha_k \langle \rho_k \rangle_{V_k} \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \langle e_k \rangle_V^{X_k \rho_k} + \langle \rho_k \widehat{\mathbf{v}}_k \widehat{e}_k \rangle_{V_k} \right) \\ &+ \frac{1}{2} \nabla \cdot \left( \alpha_k \langle \rho_k \rangle_{V_k} \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} ((\langle v_k \rangle_V^{X_k \rho_k})^2 + \langle \widehat{\mathbf{v}}_k \cdot \widehat{\mathbf{v}}_k \rangle_V^{X_k \rho_k}) \right) \end{aligned}$$

$$\begin{aligned}
& + \nabla \cdot \left( \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \cdot (\alpha_k \langle \rho_k \widehat{\mathbf{v}}_k \widehat{\mathbf{v}}_k \rangle_{V_k}) \right) \\
& + \frac{1}{2} \nabla \cdot \left( \alpha_k \langle \rho_k \rangle_{V_k} \langle \widehat{\mathbf{v}}_k (\widehat{\mathbf{v}}_k \cdot \widehat{\mathbf{v}}_k) \rangle_V^{X_k \rho_k} \right) + \nabla \cdot \left( \alpha_k \langle \mathbf{q}_k \rangle_{V_k} \right) \\
& + \nabla \cdot \left( \alpha_k (\langle \mathbf{T}_k \rangle_{V_k} \cdot \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} + \langle \mathbf{T}_k \cdot \widehat{\mathbf{v}}_k \rangle_{V_k}) \right) \\
& = \Gamma_{V_k} \left( \langle e_k \rangle_{A_I}^{\Gamma_{V_k}} + \frac{1}{2} (\langle \mathbf{v}_k \rangle_{A_I}^{\Gamma_{V_k}})^2 \right) + E_k^W + E_k^E \\
& + \alpha_k \left\langle \sum_c \rho_{k,c} \mathbf{v}_{k,c} \cdot \mathbf{g}_{k,c} \right\rangle_{V_k}
\end{aligned} \tag{3.194}$$

The interfacial work by viscous and pressure forces (3.173) can be rearranged decomposing the velocity as:

$$\begin{aligned}
E_k^W & = -\frac{1}{V} \int_{A_I} (\mathbf{T}_k \cdot \mathbf{v}_k) \cdot \mathbf{n}_k da \\
& = -\frac{1}{V} \int_{A_I} (\mathbf{T}_k \cdot (\langle \mathbf{v}_k \rangle_V^{X_k \rho_k} + \widehat{\mathbf{v}}_k)) \cdot \mathbf{n}_k da \\
& = \mathbf{M}_k^T \cdot \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} + E_k^{\widehat{W}}
\end{aligned} \tag{3.195}$$

where  $E_k^{\widehat{W}}$  is called the interfacial extra work [60].

Besides, constitutive equations are required for the unknown quantities in (3.171), (3.172) and (3.174).

#### *Mechanical Energy:*

The volume averaged kinetic energy equation can be derived by taking the scalar product of the averaged velocity with the momentum Eq. (3.193). Without introducing the normal simplifications assumed valid for dispersed flows, the result is:

$$\begin{aligned}
& \frac{\partial}{\partial t} \left( \alpha_k \langle \rho_k \rangle_{V_k} \frac{1}{2} (\langle v_k \rangle_V^{X_k \rho_k})^2 \right) + \nabla \cdot \left( \alpha_k \langle \rho_k \rangle_{V_k} \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \frac{1}{2} (\langle v_k \rangle_V^{X_k \rho_k})^2 \right) \\
& = -\langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \cdot \nabla \cdot \left( \alpha_k (\langle \mathbf{T}_k \rangle_{V_k} + \langle \mathbf{T}_k \rangle_{V_k}^{Re}) \right) + \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \cdot \mathbf{M}_k^T \\
& + \Gamma_{V_k} \langle \mathbf{v}_k \rangle_{A_I}^{\Gamma_{V_k}} \cdot \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} + \alpha_k \left\langle \sum_c \rho_{k,c} \mathbf{g}_c \right\rangle_{V_k} \cdot \langle \mathbf{v}_k \rangle_V^{X_k \rho_k}
\end{aligned} \tag{3.196}$$

A simplified formulation of the volume averaged mechanical energy equation supposedly valid for dispersed flows only can be expressed as:

$$\begin{aligned}
& \frac{\partial}{\partial t} \left( \alpha_k \langle \rho_k \rangle_{V_k} \frac{1}{2} (\langle v_k \rangle_V^{X_k \rho_k})^2 \right) \\
& + \nabla \cdot \left( \alpha_k \langle \rho_k \rangle_{V_k} \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \frac{1}{2} (\langle v_k \rangle_V^{X_k \rho_k})^2 \right) \\
& = -\alpha_k \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \cdot \nabla \langle p_k \rangle_{V_k} \\
& - \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \cdot \nabla \cdot \left( \alpha_k (\langle \sigma_k \rangle_{V_k} + \langle T_k \rangle_{V_k}^{Re}) \right) + \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \cdot \mathbf{F}_k \\
& + \Gamma_{V_k} \langle \mathbf{v}_k \rangle_{A_I}^{V_k} \cdot \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} + \alpha_k \left\langle \sum_c \rho_{k,c} \mathbf{g}_c \right\rangle_{V_k} \cdot \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \quad (3.197)
\end{aligned}$$

In which the identity:

$$\begin{aligned}
& \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \cdot \left( \frac{\partial}{\partial t} (\alpha_k \langle \rho_k \rangle_{V_k} \langle \mathbf{v}_k \rangle_V^{X_k \rho_k}) + \nabla \cdot (\alpha_k \langle \rho_k \rangle_{V_k} \langle \mathbf{v}_k \rangle_V^{X_k \rho_k}) \right) \\
& = \frac{\partial}{\partial t} \left( \alpha_k \langle \rho_k \rangle_{V_k} \frac{1}{2} (\langle v_k \rangle_V^{X_k \rho_k})^2 \right) \\
& + \nabla \cdot \left( \alpha_k \langle \rho_k \rangle_{V_k} \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \frac{1}{2} (\langle v_k \rangle_V^{X_k \rho_k})^2 \right) \quad (3.198)
\end{aligned}$$

has been used [60, 118].

An apparent internal energy equation can be derived by subtracting (3.198) from (3.194). The result is:

$$\begin{aligned}
& \frac{\partial}{\partial t} \left( \alpha_k \langle \rho_k \rangle_{V_k} \langle e_k \rangle_V^{X_k \rho_k} + \frac{1}{2} \langle \widehat{\mathbf{v}}_k \cdot \widehat{\mathbf{v}}_k \rangle_V^{X_k \rho_k} \right) \\
& + \nabla \cdot \left( \alpha_k (\langle \rho_k \rangle_{V_k} \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \langle e_k \rangle_V^{X_k \rho_k} + \langle \rho_k \widehat{\mathbf{v}}_k \widehat{e}_k \rangle_{V_k}) \right) \\
& + \frac{1}{2} \nabla \cdot \left( \alpha_k \langle \rho_k \rangle_{V_k} \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \langle \widehat{\mathbf{v}}_k \cdot \widehat{\mathbf{v}}_k \rangle_V^{X_k \rho_k} \right) \\
& + \frac{1}{2} \nabla \cdot \left( \alpha_k \langle \rho_k \rangle_{V_k} \langle \widehat{\mathbf{v}}_k (\widehat{\mathbf{v}}_k \cdot \widehat{\mathbf{v}}_k) \rangle_V^{X_k \rho_k} \right) + \nabla \cdot \left( \alpha_k \langle \mathbf{q}_k \rangle_{V_k} \right) \\
& + \alpha_k \left( \langle \sigma_k \rangle_{V_k} + \langle T_k \rangle_{V_k}^{Re} \right) : \nabla \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} + \nabla \cdot \left( \alpha_k \langle T_k \cdot \widehat{\mathbf{v}}_k \rangle_{V_k} \right) \\
& + \alpha_k \langle p_k \rangle_{V_k} \nabla \cdot \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \\
& = \Gamma_{V_k} \left( \langle e_k \rangle_{A_I}^{V_k} + \frac{1}{2} (\langle \mathbf{v}_k \rangle_{A_I}^{V_k})^2 - \langle \mathbf{v}_k \rangle_{A_I}^{V_k} \cdot \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \right) \\
& + E_k^{\widehat{W}} + E_k^E + \alpha_k \left( \left\langle \sum_c \rho_{k,c} \mathbf{v}_{k,c} \cdot \mathbf{g}_{k,c} \right\rangle_{V_k} - \left\langle \sum_c \rho_{k,c} \mathbf{g}_c \right\rangle_{V_k} \cdot \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \right) \quad (3.199)
\end{aligned}$$

For the particular systems where gravity is the only external force considered, the corresponding energy source terms vanish.

*Internal Energy:*

The modified volume averaged internal energy equation can be deduced from (3.175) introducing a spatial decomposition of the velocity variable. The result is:

$$\begin{aligned}
 & \frac{\partial}{\partial t} \left( \alpha_k \langle \rho_k \rangle_{V_k} \langle e_k \rangle_V^{X_k \rho_k} \right) + \nabla \cdot \left( \alpha_k \langle \rho_k \rangle_{V_k} \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \langle e_k \rangle_V^{X_k \rho_k} \right) \\
 &= -\alpha_k \langle \boldsymbol{\sigma}_k \rangle_{V_k} : \nabla \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} - \alpha_k \langle p_k \rangle_{V_k} \nabla \cdot \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \\
 & \quad - \alpha_k \langle \boldsymbol{\sigma}_k : \nabla \widehat{\mathbf{v}}_k \rangle_{V_k} - \alpha_k \langle p_k \nabla \cdot \widehat{\mathbf{v}}_k \rangle_{V_k} - \nabla \cdot (\alpha_k \langle \mathbf{q}_k \rangle_{V_k}) \\
 & \quad + \Gamma_k \langle e_k \rangle_{A_I}^{\Gamma_{V_k}} + E_k^E - \nabla \cdot (\alpha_k \langle \rho_k \widehat{\mathbf{v}}_k \widehat{e}_k \rangle_{V_k}) + \alpha_k \left\langle \sum_c \mathbf{j}_{k,c} \cdot \mathbf{g}_{k,c} \right\rangle_{V_k} \quad (3.200)
 \end{aligned}$$

The averaged form of the internal energy jump balance (3.105) can be written as:

$$\sum_k (E_k^E + e_k^\Gamma) \approx 0 \quad (3.201)$$

From (3.170) we observe that  $e_k^\Gamma = \Gamma_{V_k} \langle e_k \rangle_{A_I}^{\Gamma_{V_k}}$ .

Subtracting the equation for the averaged internal energy (3.200) from the apparent internal energy Eq. (3.199) gives an equation for the spatial covariance expressing an average deviating kinetic energy:

$$\begin{aligned}
 & \frac{\partial}{\partial t} \left( \alpha_k \langle \rho_k \rangle_{V_k} \left( \frac{1}{2} \langle \widehat{\mathbf{v}}_k \cdot \widehat{\mathbf{v}}_k \rangle_V^{X_k \rho_k} \right) \right) \\
 & \quad + \nabla \cdot \left( \alpha_k \langle \rho_k \rangle_{V_k} \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \left( \frac{1}{2} \langle \widehat{\mathbf{v}}_k \cdot \widehat{\mathbf{v}}_k \rangle_V^{X_k \rho_k} \right) \right) \\
 & \quad + \nabla \cdot \left( \alpha_k \langle \rho_k \rangle_{V_k} \left( \frac{1}{2} \langle \widehat{\mathbf{v}}_k (\widehat{\mathbf{v}}_k \cdot \widehat{\mathbf{v}}_k) \rangle_V^{X_k \rho_k} \right) \right) \\
 & \quad + \alpha_k \langle \mathbf{T}_k \rangle_{V_k}^{Re} : \nabla \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} + \nabla \cdot \left( \alpha_k \langle \mathbf{T}_k \cdot \widehat{\mathbf{v}}_k \rangle_{V_k} \right) \\
 &= \Gamma_{V_k} \left( \frac{1}{2} (\langle \mathbf{v}_k \rangle_{A_I}^{\Gamma_{V_k}})^2 - \langle \mathbf{v}_k \rangle_{A_I}^{\Gamma_{V_k}} \cdot \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \right) \\
 & \quad + \alpha_k \left( \left\langle \sum_c \rho_{k,c} \mathbf{v}_{k,c} \cdot \mathbf{g}_{k,c} \right\rangle_{V_k} - \left\langle \sum_c \rho_{k,c} \mathbf{g}_{k,c} \right\rangle_{V_k} \cdot \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \right) \\
 & \quad - \alpha_k \left\langle \sum_c \mathbf{j}_{k,c} \cdot \mathbf{g}_{k,c} \right\rangle_{V_k} + E_k^{\widehat{W}} \quad (3.202)
 \end{aligned}$$

*Enthalpy:*

The modified volume averaged enthalpy equation can be deduced from (3.177) or alternatively from (3.200) and the relations between the averaged internal energy and the enthalpy:

$$\langle e_k \rangle_V^{X_k \rho_k} = \langle h_k \rangle_V^{X_k \rho_k} - \langle p_k \rangle_{V_k} / \langle \rho_k \rangle_{V_k} \quad (3.203)$$

$$\langle e_k \rangle_{A_I}^{\Gamma_{V_k}} = \langle h_k \rangle_{A_I}^{\Gamma_{V_k}} - \langle p_k \rangle_{A_I}^{\Gamma_{V_k}} / \langle \rho_k \rangle_{A_I}^{\Gamma_{V_k}} \quad (3.204)$$

The result is:

$$\begin{aligned} & \frac{\partial}{\partial t} (\alpha_k \langle \rho_k \rangle_{V_k} \langle h_k \rangle_V^{X_k \rho_k}) \\ & + \nabla \cdot \left( \alpha_k \langle \rho_k \rangle_{V_k} \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \langle h_k \rangle_V^{X_k \rho_k} \right) \\ & = \frac{\partial (\alpha_k \langle p_k \rangle_{V_k})}{\partial t} + \nabla \cdot (\alpha_k \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \langle p_k \rangle_{V_k}) + \nabla \cdot (\alpha_k \langle \widehat{\mathbf{v}}_k p_k \rangle_{V_k}) \\ & - \alpha_k \langle \sigma_k \rangle_{V_k} : \nabla \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} - \alpha_k \langle p_k \rangle_{V_k} \nabla \cdot \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \\ & - \alpha_k \langle \sigma_k : \nabla \widehat{\mathbf{v}}_k \rangle_{V_k} - \alpha_k \langle p_k \nabla \cdot \widehat{\mathbf{v}}_k \rangle_{V_k} - \nabla \cdot (\alpha_k \langle \mathbf{q}_k \rangle_{V_k}) \\ & - \nabla \cdot (\alpha_k \langle \rho_k \widehat{\mathbf{v}}_k \widehat{h}_k \rangle_{V_k}) + \alpha_k \left\langle \sum_c \mathbf{j}_{k,c} \cdot \mathbf{g}_{k,c} \right\rangle_{V_k} \\ & + \Gamma_{V_k} \langle h_k \rangle_{A_I}^{\Gamma_{V_k}} + E_k^E \end{aligned} \quad (3.205)$$

The averaged form of the enthalpy jump balance (3.105) can be written as:

$$\sum_k (E_k^E + h_k^\Gamma) \approx 0 \quad (3.206)$$

in which  $h_k^\Gamma = \Gamma_{V_k} \langle h_k \rangle_{A_I}^{\Gamma_{V_k}}$ .

*Temperature:*

The averaged temperature equation can be derived from the averaged enthalpy Eq. (3.205) by use of the complete differential (1.151). In this case the averaged enthalpy equation is first reformulated by use of the averaged continuity equation (3.192). The intermediate result is:

$$\begin{aligned} & \alpha_k \langle \rho_k \rangle_{V_k} \left( \frac{\partial \langle h_k \rangle_V^{X_k \rho_k}}{\partial t} + \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \cdot \nabla \langle h_k \rangle_V^{X_k \rho_k} \right) \\ & = \frac{\partial (\alpha_k \langle p_k \rangle_{V_k})}{\partial t} + \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \cdot \nabla (\alpha_k \langle p_k \rangle_{V_k}) + \nabla \cdot (\alpha_k \langle \widehat{\mathbf{v}}_k p_k \rangle_{V_k}) \\ & - \alpha_k \langle p_k \nabla \cdot \widehat{\mathbf{v}}_k \rangle_{V_k} - \alpha_k \langle \sigma_k \rangle_{V_k} : \nabla \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} - \alpha_k \langle \sigma_k : \nabla \widehat{\mathbf{v}}_k \rangle_{V_k} \\ & - \nabla \cdot (\alpha_k \langle \rho_k \widehat{\mathbf{v}}_k \widehat{h}_k \rangle_{V_k}) + \alpha_k \left\langle \sum_c \mathbf{j}_{k,c} \cdot \mathbf{g}_{k,c} \right\rangle_{V_k} - \nabla \cdot (\alpha_k \langle \mathbf{q}_k \rangle_{V_k}) \\ & + \Gamma_{V_k} \langle h_k \rangle_{A_I}^{\Gamma_{V_k}} + E_k^E - \Gamma_{V_k} \langle h_k \rangle_V^{X_k \rho_k} \end{aligned} \quad (3.207)$$

The volume averaged form of the complete differential (1.151) can be approximated as:

$$\begin{aligned}
\frac{D\langle h_k \rangle_V^{X_k \rho_k}}{Dt} &= \langle C_{p,k} \rangle_{V_k} \frac{D\langle T_k \rangle_{V_k}}{Dt} \\
&+ \left( \frac{1}{\langle \rho_k \rangle_{V_k}} + \frac{\langle T_k \rangle_{V_k}}{\langle \rho_k \rangle_{V_k}^2} \left( \frac{\partial \langle \rho_k \rangle_{V_k}}{\partial \langle T_k \rangle_{V_k}} \right)_{p,\omega} \right) \frac{D\langle p_k \rangle_{V_k}}{Dt} \\
&- \frac{1}{\langle \rho_k \rangle_{V_k}} \left[ \left\langle \sum_{c=1}^N \bar{h}_c \nabla \cdot \left( -\frac{\mathbf{j}_c}{M_{w_c}} \right) \right\rangle_{V_k} + \left\langle \sum_{r=1}^q r_{r,c_{\text{ref}}} (-\Delta \bar{H}_{r,c_{\text{ref}}}) \right\rangle_{V_k} \right]
\end{aligned} \quad (3.208)$$

in which the average of products are assumed equal to the product of averages. By substitution the temperature equation yields:

$$\begin{aligned}
&\alpha_k \langle \rho_k \rangle_{V_k} \langle C_{p,k} \rangle_{V_k} \left( \frac{\partial \langle T_k \rangle_{V_k}}{\partial t} + \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} \cdot \nabla \langle T_k \rangle_{V_k} \right) \\
&= -\alpha_k \frac{\langle T \rangle_{V_k}}{\langle \rho \rangle_{V_k}} \left( \frac{\partial \langle \rho \rangle_{V_k}}{\partial \langle T_k \rangle_{V_k}} \right)_{p,\omega} \frac{D\langle p_k \rangle_{V_k}}{Dt} + \langle p_k \rangle_{V_k} \frac{D\alpha_k}{Dt} \\
&\quad - \alpha_k \langle \sigma_k \rangle_{V_k} : \nabla \langle \mathbf{v}_k \rangle_V^{X_k \rho_k} - \alpha_k \langle \sigma_k : \widehat{\nabla \mathbf{v}_k} \rangle_{V_k} \\
&\quad + \alpha_k \left( \left\langle \sum_{c=1}^N \bar{h}_c \nabla \cdot \left( -\frac{\mathbf{j}_c}{M_{w_c}} \right) \right\rangle_{V_k} + \left\langle \sum_{r=1}^q r_{r,c_{\text{ref}}} (-\Delta \bar{H}_{r,c_{\text{ref}}}) \right\rangle_{V_k} \right) \\
&\quad - \nabla \cdot (\alpha_k \langle \mathbf{q}_k \rangle_{V_k}) + \Gamma_{V_k} (\langle h_k \rangle_{A_I}^{\Gamma_{V_k}} - \langle h_k \rangle_V^{X_k \rho_k}) + E_k^E \\
&\quad + \alpha_k \left\langle \sum_c \mathbf{j}_{k,c} \cdot \mathbf{g}_{k,c} \right\rangle_{V_k}
\end{aligned} \quad (3.209)$$

The interfacial heat transfer flux involves the interfacial heat which can be related to the heat of vaporization or condensation and the heat flux of the phase on the  $k$  side of the interface [118].

For incompressible and porous media flows we may follow the approaches of [214, 254] wherein the variations of the factor  $\rho_k C_{p,k}$  within the averaging volume are neglected to enable application of the Leibnitz' and Gauss' averaging rules on the temperature and apparent flux terms. For this particular case the modified volume averaged enthalpy equation in terms of temperature can be deduced from (3.181) as follows:

$$\begin{aligned}
&\rho_k C_{p,k} \left( \frac{\partial (\alpha_k \langle T_k \rangle_{V_k})}{\partial t} + \langle \mathbf{v}_k \rangle_{V_k} \cdot \nabla (\alpha_k \langle T_k \rangle_{V_k}) \right) \\
&= -\nabla \cdot (\alpha_k \langle \mathbf{q}_k \rangle_{V_k}) - \nabla \cdot (\alpha_k \langle \sigma_k \rangle_{V_k} : \nabla \langle \mathbf{v}_k \rangle_{V_k}) \\
&\quad + \alpha_k \left\langle \sum_{c=1}^N \bar{h}_c \nabla \cdot \left( -\frac{\mathbf{j}_c}{M_{w_c}} \right) \right\rangle_{V_k} + \alpha_k \left\langle \sum_{r=1}^q r_{r,c_{\text{ref}}} (-\Delta \bar{H}_{r,c_{\text{ref}}}) \right\rangle_{V_k} \\
&\quad + \Gamma_{V_k} \langle C_{p,k} T_k \rangle_{A_I}^{\Gamma_{V_k}} + E_k^E + \alpha_k \left\langle \sum_c \mathbf{j}_{k,c} \cdot \mathbf{g}_{k,c} \right\rangle_{V_k} \\
&\quad - \nabla \cdot (\rho_k C_{p,k} \langle \widehat{\mathbf{v}_k T_k} \rangle_{V_k})
\end{aligned} \quad (3.210)$$

in which the terms on the LHS are manipulated by use of the continuity equation. Moreover, the average of products resulting from the convective term is reformulated using spatial decomposition of the temperature and velocity variables.

The procedure can be summarized in three steps:

$$\begin{aligned}
 & \left\langle \frac{\partial T_k}{\partial t} \right\rangle_V + \langle \mathbf{v}_k \cdot \nabla T_k \rangle_V \\
 & \approx \frac{\partial}{\partial t} (\alpha_k \langle T_k \rangle_{V_k}) + \nabla \cdot (\alpha_k \langle \mathbf{v}_k T_k \rangle_{V_k}) - \frac{\Gamma_{Vk}}{\rho_k C_{p,k}} \langle C_{p,k} T_k \rangle_{A_I}^{\Gamma_{Vk}} \\
 & = \frac{\partial}{\partial t} (\alpha_k \langle T_k \rangle_{V_k}) + \langle \mathbf{v}_k \rangle_{V_k} \cdot \nabla (\alpha_k \langle T_k \rangle_{V_k}) + \nabla \cdot (\langle \widehat{\mathbf{v}}_k \widehat{T}_k \rangle_{V_k}) \\
 & \quad - \frac{\Gamma_{Vk}}{\rho_k C_{p,k}} \langle C_{p,k} T_k \rangle_{A_I}^{\Gamma_{Vk}}
 \end{aligned} \tag{3.211}$$

*Chemical species:*

The modified volume averaged species mass balance deduced from (3.182) can be expressed as:

$$\begin{aligned}
 & \frac{\partial}{\partial t} \left( \alpha_k \langle \rho_k \rangle_{V_k} \langle \omega_{k,s} \rangle_V^{\alpha_k \rho_k} \right) \\
 & + \nabla \cdot \left( \alpha_k \langle \langle \rho_k \rangle_{V_k} \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \langle \omega_{k,s} \rangle_V^{\alpha_k \rho_k} + \langle \rho_k \widehat{\mathbf{v}}_k \widehat{\omega}_k \rangle_{V_k} \right) \\
 & + \nabla \cdot \left( \alpha_k \langle \mathbf{j}_{k,s} \rangle_{V_k} \right) = \Gamma_{Vk} \langle \omega_{k,s} \rangle_{A_I}^{\Gamma_{Vk}} - \mathbf{J}_{k,s}^j + \alpha_k \langle R_{k,s} \rangle_{V_k}
 \end{aligned} \tag{3.212}$$

in which constitutive equations are needed for the unknown quantities in (3.184), (3.185) and (3.186).

For *incompressible* flows the fluid properties (e.g.,  $\rho_k$ ,  $\mu_k$ ) are constants so the covariances between the fluctuating components of  $\rho_k$  and  $\psi_k$ , i.e.,  $\langle \widehat{\rho}_k \widehat{\psi}_k \rangle_{V_k}$ , vanish. The density variable is thus conveniently denoted by  $\rho_k$  and simply moved outside the averaging bracket. Therefore, for constant density flows the mass-weighted variables coincide with the phase-weighted or intrinsic variables, thus the Favre like mass-weighted variable procedure used above can be replaced by a simpler method resembling the conventional Reynolds averaging procedure used in turbulence analysis [165, 166, 206].

Since the spatially averaged model for incompressible systems is used occasionally in chemical engineering practice, we will briefly outline the Reynolds like spatial decomposition and averaging procedure for completeness. In this case the  $\psi_k$  represents the spatial deviation of the point variable  $\psi_k$  from the intrinsic volume average value  $\langle \psi_k \rangle_{V_k}$ , and is defined by:

$$\widehat{\psi}_k = \psi_k - \langle \psi_k \rangle_{V_k} \tag{3.213}$$

where  $\psi_k$  represents the local variable at a point in space  $\mathbf{r}$ .

The average of the spatial deviation  $\widehat{\psi}_k$  is computed applying the intrinsic average operator (3.123) on (3.213). The obvious result is:

$$\langle \widehat{\psi}_k \rangle_{V_k} = \langle \psi_k \rangle_{V_k} - \langle \langle \psi_k \rangle_{V_k} \rangle_{V_k} = \langle \psi_k \rangle_{V_k} - \langle \psi_k \rangle_{V_k} = 0 \quad (3.214)$$

It follows that the average of the product of the two local variables  $\psi_k$  and  $\phi_k$  can be written as the product of the averaged variables plus a covariance term, as follows:

$$\langle \psi_k \phi_k \rangle_{V_k} = \langle \psi_k \rangle_{V_k} \langle \phi_k \rangle_{V_k} + \langle \widehat{\psi}_k \widehat{\phi}_k \rangle_{V_k} \quad (3.215)$$

Having related the average of products to the products of averages, the averaged Eq. (3.144) becomes:

$$\begin{aligned} & \frac{\partial(\alpha_k \rho_k \langle \psi_k \rangle_{V_k})}{\partial t} + \nabla \cdot (\alpha_k \rho_k \langle \mathbf{v}_k \rangle_{V_k} \langle \psi_k \rangle_{V_k}) + \nabla \cdot (\alpha_k \langle \mathbf{J}_k \rangle_{V_k}) \\ &= -\frac{1}{V} \int_{A_I} (\dot{m}_k \psi_k + \mathbf{J}_k) \cdot \mathbf{n}_k da - \nabla \cdot (\alpha_k \rho_k \langle \widehat{\mathbf{v}}_k \widehat{\psi}_k \rangle_{V_k}) + \alpha_k \sum_c \rho_{k,c} \langle \phi_c \rangle_{V_k} \end{aligned} \quad (3.216)$$

The averaging approach for incompressible flows has been applied describing solidification processes in metallurgy [16, 85, 165, 206]. For example, for the modeling of materials solidification Shyy et al. [206] did derive a set of macroscopic transport equations intended to be valid in solid, liquid, and mushy zones. In particular, since the volume averaged covariance terms can be interpreted as sub-grid stresses they adopted the LES concept developing a microscopic deviation model and constitutive equations based on the Smagorinsky eddy viscosity coefficient hypothesis. The suggested models have their limitations as the constitutive relations are not generally valid, thus experimental data is always required to fit the unknown model parameters and for model validation. The conventional constitutive equations are discussed in Chap. 5.

### 3.5.2 The Time Averaging Procedure

In this section we assess the single time averaging technique. Pure *time averaging* has been examined by [26, 47, 49, 51, 52, 57, 58, 118, 122, 123, 169, 244]. These investigations are recommended for complementary studies.

The conditions under which the time averaging procedure can be applied for multiphase flows coincide with those for which time averaging can be used for

single phase turbulence flows,<sup>14</sup> and can be expressed as [47, 51, 118]:

$$\left\{ \begin{array}{l} \text{Characteristic} \\ \text{time scale of} \\ \text{the turbulent} \\ \text{fluctuations in} \\ \text{the flow, } \tau_t \end{array} \right\} \ll \left\{ \begin{array}{l} \text{Characteristic} \\ \text{time period of} \\ \text{averaging, } T \end{array} \right\} \ll \left\{ \begin{array}{l} \text{Characteristic} \\ \text{time scale of} \\ \text{the overall} \\ \text{variations in} \\ \text{the flow, } \tau_L \end{array} \right\}$$

In this averaging procedure we imagine that at any point  $\mathbf{r}$  in a two-phase flow, phase  $k$  passes intermittently so a function  $\psi_k$  associated with phase  $k$  will be a piecewise continuous function. However, the interfaces are not stationary so they do not occupy a fixed location for finite time intervals. For this reason the average macroscopic variables are expected to be continuous functions (but this hypothesis has been questioned as it can be shown that the first order time derivative might be discontinuous which is not physical, hence an amended double time averaging operator was later proposed as a way of dealing with this problem [47, 51]). Since  $T$  is the overall time period over which the time averaging is performed, phase  $k$  is observed within a subset of residence time intervals so that  $T = \sum_k T_k$  for all the phases in the system. In this context the time averaged equations are established treating the interfaces as discontinuous jumps with no thickness [47, 51], in contrast to the interface model used by Ishii [118].

In the conventional averaging procedure a phase indicator function  $X_k$  is defined by:

$$X_k(\mathbf{r}, t) = \begin{cases} 1 & \text{if location } \mathbf{r} \text{ pertains to phase } k, \\ 0 & \text{otherwise.} \end{cases} \quad (3.122)$$

The mathematical properties of  $X_k$  ensure that the ordinary mathematical operations of vector calculus can be performed on the local instantaneous variables which are discontinuous [62, 118].

The local instantaneous equations can be time averaged over a defined time interval  $[t - T/2; t + T/2]$ . The *single time averaging operator* which can be applied to any scalar, vector or tensor valued property function  $\psi_k$  associated with phase  $k$ , is defined by:

$$\langle \psi_k \rangle_T = \frac{1}{T} \int_{t-T/2}^{t+T/2} X_k \psi_k dt' = \frac{1}{T} \int_{t_k-T_k/2}^{t_k+T_k/2} \psi_k dt' \quad (3.217)$$

It is emphasized that  $\langle \psi_k \rangle_T$  is by definition the time average of the quantity  $\psi_k$  over the entire time averaging period  $T$ .

The corresponding time average of  $\psi_k$  over the time interval  $T_k$ , which coincides with the  $X_k$ -weighted average of  $\psi_k$  over the entire time period  $T$ , is defined by:

<sup>14</sup> It is noted that the requirement of proper separation of scales represents the main drawback of the time averaging method. The constitutive equations used generally depend strongly on this assumption which is hardly ever fulfilled performing simulations of turbulent reactive flows.

$$\langle \psi_k \rangle_{T_k} = \langle \psi_k \rangle_T^{X_k} = \frac{\frac{1}{T} \int_{t-T/2}^{t+T/2} X_k \psi_k dt'}{\frac{1}{T} \int_{t-T/2}^{t+T/2} X_k dt'} = \frac{1}{T_k} \int_{t_k-T_k/2}^{t_k+T_k/2} \psi_k dt' \quad (3.218)$$

By comparing the averaging operators (3.217) and (3.218), the following relationship is achieved:

$$\langle \psi_k \rangle_T = \frac{T_k}{T} \langle \psi_k \rangle_{T_k} = \beta_k \langle \psi_k \rangle_{T_k} \quad (3.219)$$

The *time fraction*  $\beta_k$  of phase  $k$  is defined by:

$$\beta_k = \frac{T_k}{T} \quad (3.220)$$

To derive a time average of the generic differential balance equation for phase  $k$  (3.86) is multiplied with  $X_k$ , integrated over the entire averaging time interval  $T$ , and thereafter multiplied with the fixed reciprocal overall time averaging period  $T$ . The resulting time averaged equation is given by:

$$\frac{1}{T} \int_{t-T/2}^{t+T/2} \left( X_k \frac{\partial(\rho_k \psi_k)}{\partial t} + X_k \nabla \cdot (\rho_k \mathbf{v}_k \psi_k + \mathbf{J}_k) - X_k \sum_c \rho_{k,c} \phi_{k,c} \right) dt' = 0 \quad (3.221)$$

or, by using a more compact notation:

$$\left\langle \frac{\partial(\rho_k \psi_k)}{\partial t} \right\rangle_T + \langle \nabla \cdot (\rho_k \mathbf{v}_k \psi_k + \mathbf{J}_k) \rangle_T - \left\langle \sum_c \rho_{k,c} \phi_{k,c} \right\rangle_T = 0 \quad (3.222)$$

The first, second and third terms in (3.222) have to be reformulated using the conventional time averaging theorems [51, 118]. The first theorem one makes use of relates the average of a time derivative to the time derivative of an average quantity, and is called the *Leibnitz's rule* for time averaging:

$$\frac{1}{T} \int_{t-T/2}^{t+T/2} X_k \frac{\partial \psi_k}{\partial t} dt' = \frac{\partial}{\partial t} \left[ \frac{1}{T} \int_{t-T/2}^{t+T/2} X_k \psi_k dt' \right] - \frac{1}{T} \sum_{t_I^k \in (t-\frac{T}{2}; t+\frac{T}{2})} \frac{\mathbf{v}_I \cdot \mathbf{n}_I}{|\mathbf{v}_I \cdot \mathbf{n}_I|} \psi_k(t_I^k) \quad (3.223)$$

or, expressed in the compact notation

$$\begin{aligned}
\left\langle \frac{\partial \psi_k}{\partial t} \right\rangle_T &= \frac{\partial}{\partial t} \langle \psi_k \rangle_T - \frac{1}{T} \sum_{t_I^k \in (t - \frac{T}{2}; t + \frac{T}{2})} \frac{1}{|\mathbf{v}_I \cdot \mathbf{n}_I|} \psi_k(t_I^k) \mathbf{v}_I \cdot \mathbf{n}_I \\
&= \frac{\partial}{\partial t} (\beta_k \langle \psi_k \rangle_{T_k}) - \frac{1}{T} \sum_{t_I^k \in (t - \frac{T}{2}; t + \frac{T}{2})} \frac{1}{|\mathbf{v}_I \cdot \mathbf{n}_I|} \psi_k(t_I^k) \mathbf{v}_I \cdot \mathbf{n}_I \quad (3.224)
\end{aligned}$$

where  $\mathbf{n}_k$  is the outward unit normal of the element of area  $A_k$  of phase  $k$ , and  $\mathbf{v}_I$  is the velocity of the local interface.  $\psi_k(t_I^k)$  denotes the value of  $\psi$  on the phase  $k$  side of the interface. It is also noted that  $\mathbf{v}_I \cdot \mathbf{n}_I$  is positive when the interface is approaching the point under consideration and negative when the interface is leaving it [51, 118].

For the particular case when  $\psi_k = 1$  it is recognized that (3.217), (3.218) and (3.224) can be manipulated and expressed as:

$$\langle 1 \rangle_T = \frac{1}{T} \int_{t-T/2}^{t+T/2} X_k dt' = \frac{T_k}{T} = \beta_k \quad (3.225)$$

and

$$0 = \frac{\partial \beta_k}{\partial t} - \sum_{t_I^k \in (t-T/2; t+T/2)} \frac{\mathbf{v}_I \cdot \mathbf{n}_I}{|\mathbf{v}_I \cdot \mathbf{n}_I|} \quad (3.226)$$

in accordance with the work of [26, 47, 51, 118].

The second theorem we utilize relates the average of a spatial derivative to the spatial derivative of the average, and is termed the *Gauss rule* for time averaging:

$$\frac{1}{T} \int_{t-T/2}^{t+T/2} (X_k \nabla \psi_k) dt' = \nabla \left[ \frac{1}{T} \int_{t-T/2}^{t+T/2} X_k \psi_k dt' \right] + \frac{1}{T} \sum_{t_I^k \in (t - \frac{T}{2}; t + \frac{T}{2})} \frac{1}{|\mathbf{v}_I \cdot \mathbf{n}_I|} \mathbf{n}_I \psi_k(t_I^k) \quad (3.227)$$

In the compact notation, we get:

$$\begin{aligned}
\langle \nabla \psi_k \rangle_T &= \nabla \langle \psi_k \rangle_T + \frac{1}{T} \sum_{t_I^k \in (t - \frac{T}{2}; t + \frac{T}{2})} \frac{1}{|\mathbf{v}_I \cdot \mathbf{n}_I|} \mathbf{n}_I \psi_k(t_I^k) \\
&= \nabla (\beta_k \langle \psi_k \rangle_{T_k}) + \frac{1}{T} \sum_{t_I^k \in (t - \frac{T}{2}; t + \frac{T}{2})} \frac{1}{|\mathbf{v}_I \cdot \mathbf{n}_I|} \mathbf{n}_I \psi_k(t_I^k) \quad (3.228)
\end{aligned}$$

A special case of (3.228) is the theorem for the time average of a divergence:

$$\langle \nabla \cdot \psi_k \rangle_T = \nabla \cdot \langle \psi_k \rangle_T + \frac{1}{T} \sum_{t_I^k \in (t - \frac{T}{2}; t + \frac{T}{2})} \frac{1}{|\mathbf{v}_I \cdot \mathbf{n}_I|} \mathbf{n}_I \cdot \psi_k(t_I^k)$$

$$= \nabla \cdot (\beta_k \langle \psi_k \rangle_{T_k}) + \frac{1}{T} \sum_{t_I^k \in (t - \frac{T}{2}; t + \frac{T}{2})} \frac{1}{|\mathbf{v}_I \cdot \mathbf{n}_I|} \mathbf{n}_I \cdot \psi_k(t_I^k) \quad (3.229)$$

where  $\psi_k$  is interpreted as a vector or a second order tensor field.

For the particular case when  $\psi_k = 1$  it is recognized that (3.228) reduces to:

$$0 = \nabla \beta_k + \frac{1}{T} \sum_{t_I^k \in (t - \frac{T}{2}; t + \frac{T}{2})} \frac{1}{|\mathbf{v}_I \cdot \mathbf{n}_I|} \mathbf{n}_I \quad (3.230)$$

which is an important relationship frequently utilized manipulating the averaged terms [51]. The same relationship is obtained from (3.229) if  $\psi_k$  is replaced with the unit tensor  $\mathbf{e}$ .

By taking into account the particular forms of the Leibnitz's and Gauss' theorems valid for time averaging (3.224), (3.228) and (3.229), the averaged generic Eq. (3.222) becomes:

$$\begin{aligned} & \frac{\partial(\beta_k \langle \rho_k \psi_k \rangle_{T_k})}{\partial t} + \nabla \cdot (\beta_k \langle \rho_k \mathbf{v}_k \psi_k \rangle_{T_k}) + \nabla \cdot (\beta_k \langle \mathbf{J}_k \rangle_{T_k}) \\ &= -\frac{1}{T} \sum_{t_I^k \in (t - \frac{T}{2}; t + \frac{T}{2})} \frac{1}{|\mathbf{v}_I \cdot \mathbf{n}_I|} (\dot{m}_k \psi_k + \mathbf{J}_k \cdot \mathbf{n}_k) + \beta_k \langle \sum_c \rho_{k,c} \phi_{k,c} \rangle_{T_k} \end{aligned} \quad (3.231)$$

where  $\dot{m}_k$  is the interface mass transfer rate as defined by (3.145).

The interfacial transfer terms occurring on the RHS of (3.231) can be rewritten as: [118]:

$$-\frac{1}{T} \sum_{t_I^k \in (t - \frac{T}{2}; t + \frac{T}{2})} \frac{1}{|\mathbf{v}_I \cdot \mathbf{n}_I|} (\dot{m}_k \psi_k + \mathbf{J}_k \cdot \mathbf{n}_k) = - \sum_j l_j^{-1} (\dot{m}_k \psi_k + \mathbf{J}_k \cdot \mathbf{n}_k)_j \quad (3.232)$$

where  $j$  denotes the  $j$ -th interface passing through  $\mathbf{r}$  during the time interval  $T$  and where  $l_j = T |\mathbf{v}_I \cdot \mathbf{n}_I|_j$  is the interfacial transport length for interface  $j$ .

The local jump conditions are time averaged in a similar manner. To derive the averaged form of the generic condition we multiply (3.113) with  $\frac{1}{|\mathbf{v}_I \cdot \mathbf{n}_I|}$ , take the sum over all the interface occurrences obtained within the entire averaging time interval  $t_I^k \in [t - T/2; t + T/2]$ , and thereafter multiply the resulting relation with the fixed reciprocal averaging time period  $T$ . The averaged jump condition becomes:

$$\begin{aligned} & -\frac{1}{T} \sum_{t_I^k \in (t - \frac{T}{2}; t + \frac{T}{2})} \frac{1}{|\mathbf{v}_I \cdot \mathbf{n}_I|} \left( \sum_k [\dot{m}_k \psi_k + \mathbf{J}_k \cdot \mathbf{n}_k] + M_I \right) \\ &= - \sum_j l_j^{-1} \left( \sum_k [\dot{m}_k \psi_k + \mathbf{J}_k \cdot \mathbf{n}_k] + M_I \right)_j = 0 \end{aligned} \quad (3.233)$$

The averaged equations governing each phase and the corresponding jump conditions are then achieved defining the specific values of the generic variables in (3.231) and (3.233) in accordance with Table 3.1.

*Mass:*

The time averaged continuity equation appears by substituting  $\psi_k = 1$ ,  $\mathbf{J}_k = 0$  and  $\phi_{c,k} = 0$  into (3.231):

$$\frac{\partial(\beta_k \langle \rho_k \rangle_{T_k})}{\partial t} + \nabla \cdot (\beta_k \langle \rho_k \mathbf{v}_k \rangle_{T_k}) = - \sum_j l_j^{-1} \dot{m}_{kj} = \Gamma_{Tk} \quad (3.234)$$

Introducing the values for the interface properties  $M_I = 0$  into (3.233), yields:

$$\sum_k \Gamma_{Tk} = 0 \quad (3.235)$$

The interfacial mass transfer terms due to phase change is defined by

$$\Gamma_{Tk} = - \sum_j l_j^{-1} \dot{m}_{kj} = a_{T_I} \langle \dot{m}_k \rangle_{T_I} \quad (3.236)$$

in which  $\langle \dot{m}_k \rangle_{T_I} = - \sum_j \frac{\dot{m}_{kj}}{l_j} / a_{T_I}$  denotes the interfacial area averaged mass transfer rate [118]. The interfacial area density is defined in accordance with (3.237). The surface area concentration per volume is given by [118]:

$$a_{T_I} = \sum_j l_j^{-1} \quad (3.237)$$

*Momentum:*

The time averaged momentum equation appears by substituting  $\psi_k = \mathbf{v}_k$ ,  $\mathbf{J}_k = \mathbf{T}_k$  and  $\phi_{c,k} = \mathbf{g}_{c,k}$  into (3.231):

$$\begin{aligned} \frac{\partial(\beta_k \langle \rho_k \mathbf{v}_k \rangle_{T_k})}{\partial t} + \nabla \cdot (\beta_k \langle \rho_k \mathbf{v}_k \mathbf{v}_k \rangle_{T_k}) + \nabla \cdot (\beta_k \langle \mathbf{T}_k \rangle_{T_k}) \\ = - \sum_j l_j^{-1} (\dot{m}_k \mathbf{v}_k + \mathbf{T}_k \cdot \mathbf{n}_k)_j + \beta_k \langle \sum_c \rho_c \mathbf{g}_c \rangle_{T_k} \end{aligned} \quad (3.238)$$

Introducing the values for the interface properties  $\mathbf{M}_I = 2\sigma_I H_I \mathbf{n}_I + \nabla_I \sigma_I$  into (3.233), yields:

$$\sum_k (\mathbf{M}_{Tk}^\Gamma + \mathbf{M}_{Tk}^T) = \sum_j l_j^{-1} \mathbf{M}_{Ij} \quad (3.239)$$

The interfacial momentum transfer due to phase change is defined by:

$$\mathbf{M}_k^\Gamma = - \sum_j l_j^{-1} \dot{m}_{kj} \mathbf{v}_{kj} = \Gamma_{Tk} \langle \mathbf{v}_k \rangle_{T_I}^{\Gamma_k} \quad (3.240)$$

in which the mass transfer weighted interfacial area averaged velocity  $\langle \mathbf{v}_k \rangle_{T_I}^{\Gamma_k}$  is defined in analogy to the mass-weighted averaged variables known from turbulence theory [118] (p. 133).

The interfacial momentum stresses yield:

$$\mathbf{M}_k^T = - \sum_j l_j^{-1} \mathbf{T}_{kj} \cdot \mathbf{n}_{kj} = - \sum_j l_j^{-1} (p_k \mathbf{e} + \boldsymbol{\sigma}_k)_j \cdot \mathbf{n}_{kj} \quad (3.241)$$

where the total stress tensor of both phases has been modeled using the Newtonian strain-stress formulation.

In a similar manner as for the volume averaging method in Sect. 3.5.1, the stress terms are normally rewritten introducing interfacial mean quantities weighted by the interfacial mass transfer rate (i.e., in the volume averaging method the interfacial area averaged stresses are not weighted by the mass transfer rate). The interfacial mean pressure weighted by the interfacial mass transfer rate per unit surface area becomes:

$$\langle p_k \rangle_{T_I} = \frac{\sum_j \frac{p_{kj} \dot{m}_{kj}}{l_j}}{\sum_j \frac{\dot{m}_{kj}}{l_j}} \quad (3.242)$$

Naturally, the interfacial mean viscous stress weighted by the mass transfer rate per unit surface area is then defined by:

$$\langle \boldsymbol{\sigma}_k \rangle_{T_I} = \frac{\sum_j \frac{\boldsymbol{\sigma}_{kj} \dot{m}_{kj}}{l_j}}{\sum_j \frac{\dot{m}_{kj}}{l_j}} \quad (3.243)$$

The corresponding fluctuating interfacial quantities are defined by:

$$p'_{k,I} = p_k - \langle p_k \rangle_{T_I} \quad (3.244)$$

$$\boldsymbol{\sigma}'_{k,I} = \boldsymbol{\sigma}_k - \langle \boldsymbol{\sigma}_k \rangle_{T_I} \quad (3.245)$$

Proceeding in the same way as explained presenting the volume averaging procedure, we obtain the following result

$$\mathbf{M}_k^T = \langle p_k \rangle_{T_I} \nabla \beta_k + \langle \boldsymbol{\sigma}_k \rangle_{T_I} \cdot \nabla \beta_k + \mathbf{F}_k \quad (3.246)$$

The interfacial pressure difference effect and the combined interfacial shear and time fraction gradient effect are treated in the same manner as suggested discussing the

analogous terms in (3.161). The modified definition of the generalized drag force follows naturally from an analogy to (3.163).

Utilizing (3.230) and the mean value theorem for integrals, the term on the RHS of (3.239) can be expressed as:

$$\begin{aligned}
 \sum_j l_j^{-1} \mathbf{M}_{Ij} &= \sum_j l_j^{-1} (2\sigma_I H_I \mathbf{n}_I + \nabla_I \sigma_I)_j \\
 &\approx 2\langle \sigma_I H_I \rangle_{T_I} \sum_j \frac{\mathbf{n}_{I,kj}}{T |\mathbf{v}_{I,kj} \cdot \mathbf{n}_{kj}|} + \sum_j l_j^{-1} \nabla_{Ij} \sigma_I \\
 &\approx 2\langle \sigma_I \rangle_{T_I} \langle H_I \rangle_{T_I} \nabla \beta_2 + a_{T_I} \langle \nabla_I \sigma_I \rangle_{T_I}
 \end{aligned} \tag{3.247}$$

where  $\langle H_I \rangle_{T_I}$  is the interfacial area averaged curvature [118]. The mean curvature is defined in accordance with (3.80). In this equation the sign convention is given by the definition  $\mathbf{n}_I = \mathbf{n}_1$ .

*Energy:*

The time averaged energy equation appears by substituting  $\psi_k = e_k + \frac{1}{2}v_k^2$ ,  $\mathbf{J}_k = \mathbf{T}_k \cdot \mathbf{v}_k + \mathbf{q}_k$  and  $\phi_{c,k} = \mathbf{v}_k \cdot \mathbf{g}_{c,k}$  into (3.231):

$$\begin{aligned}
 &\frac{\partial}{\partial t} \left( \beta_k \langle \rho_k (e_k + \frac{1}{2}v_k^2) \rangle_{T_k} \right) + \nabla \cdot \left( \beta_k \langle \rho_k \mathbf{v}_k (e_k + \frac{1}{2}v_k^2) \rangle_{T_k} \right) \\
 &\quad + \nabla \cdot \left( \beta_k \langle \mathbf{T}_k \cdot \mathbf{v}_k \rangle_{T_k} \right) + \nabla \cdot \left( \beta_k \langle \mathbf{q}_k \rangle_{T_k} \right) \\
 &= - \sum_j l_j^{-1} \left( \dot{m}_k (e_k + \frac{1}{2}v_k^2) + (\mathbf{T}_k \cdot \mathbf{v}_k + \mathbf{q}_k) \cdot \mathbf{n}_k \right)_j \\
 &\quad + \beta_k \left( \sum_c \rho_{k,c} \mathbf{v}_{k,c} \cdot \mathbf{g}_{k,c} \right)_{T_k}
 \end{aligned} \tag{3.248}$$

Introducing the values for the interface properties

$M_I = \nabla_I \cdot \mathbf{q}_I - \nabla_I \cdot (\sigma_I \mathbf{v}_I)$  into (3.233), yields:

$$\sum_k (E_k^E + E_k^W + E_k^\Gamma) = \sum_j l_j^{-1} M_{I,j} \tag{3.249}$$

The interfacial energy transfer due to phase change is defined by:

$$\begin{aligned}
 E_k^\Gamma &= \sum_j l_j^{-1} \rho_{kj} (e_k + \frac{1}{2}v_k^2)_j (\mathbf{v}_I - \mathbf{v}_k)_j \cdot \mathbf{n}_{kj} = - \sum_j l_j^{-1} \dot{m}_{kj} (e_k + \frac{1}{2}v_k^2)_j \\
 &= \Gamma_{Tk} \langle (e_k + \frac{1}{2}v_k^2) \rangle_{T_I}^{\Gamma_{Tk}}
 \end{aligned} \tag{3.250}$$

in which  $\langle (e_k + \frac{1}{2}v_k^2) \rangle_{T_I}^{\Gamma_k}$  denotes the mass transfer weighted interfacial (internal and mechanical) energy [118] (p. 137).

The interfacial heat transfer is given by:

$$E_k^E = - \sum_j l_j^{-1} \mathbf{q}_{kj} \cdot \mathbf{n}_{kj} = a_{T_I} \langle \mathbf{q}_k \cdot \mathbf{n}_k \rangle_{T_I}, \quad (3.251)$$

in which  $\langle \mathbf{q}_k \cdot \mathbf{n}_k \rangle_{T_I}$  denotes the interfacial area averaged heat transfer flux. The interfacial work by viscous and pressure forces yield:

$$E_k^W = - \sum_j l_j^{-1} (\mathbf{T}_k \cdot \mathbf{v}_k)_j \cdot \mathbf{n}_{kj} \quad (3.252)$$

The surface energy sources are expressed as the product of the interfacial area concentration and the averaged interfacial fluxes:

$$\begin{aligned} \sum_j l_j^{-1} M_{Ij} &= - \sum_j l_j^{-1} (-\nabla_I \cdot (\sigma_I \mathbf{v}_I) + \nabla_I \cdot \mathbf{q}_I)_j \\ &= \langle \nabla_I \cdot (\sigma_I \mathbf{v}_I) \rangle_{T_I} a_{T_I} - \langle \nabla_I \cdot \mathbf{q}_I \rangle_{T_I} a_{T_I} \end{aligned} \quad (3.253)$$

where  $-\langle \nabla_I \cdot \mathbf{q}_I \rangle_{T_I}$  and  $\langle \nabla_I \cdot (\sigma_I \mathbf{v}_I) \rangle_{T_I}$  are the interfacial accumulated residence time averaged interfacial energy fluxes.

*Chemical species:*

The time averaged species mass balance appears by substituting  $\psi_k = \omega_{k,s}$ ,  $\mathbf{J}_k = \mathbf{j}_{k,s}$  and  $\phi_{c,k} = R_{k,s}/\rho_{k,c}$  into (3.231):

$$\begin{aligned} \frac{\partial(\beta_k \langle \rho_{k,s} \rangle_{T_k})}{\partial t} + \nabla \cdot (\beta_k \langle \rho_{k,s} \mathbf{v}_k \rangle_{T_k}) + \nabla \cdot (\beta_k \langle \mathbf{j}_{k,s} \rangle_{T_k}) \\ = - \sum_j l_j^{-1} (\dot{m}_k \omega_{k,s} + \mathbf{j}_{k,s} \cdot \mathbf{n}_k)_j + \beta_k \langle R_{k,s} \rangle_{T_k} \end{aligned} \quad (3.254)$$

Introducing the values for the interface properties  $M_I = R_{I,s}$  into (3.233), yields:

$$\sum_k (\mathbf{J}_{k,s}^{\Gamma} + \mathbf{J}_{k,s}^j) = \sum_j l_j^{-1} M_{Ij} \quad (3.255)$$

The interfacial species mass transfer due to phase change is defined by:

$$\begin{aligned} \mathbf{J}_{k,s}^{\Gamma} &= \sum_j l_j^{-1} \rho_{kj} \omega_{kj,s} (\mathbf{v}_I - \mathbf{v}_k)_j \cdot \mathbf{n}_{kj} = - \sum_j l_j^{-1} \dot{m}_{kj} \omega_{kj,s} \\ &= \Gamma_{T_I} \langle \omega_{k,s} \rangle_{T_I}, \end{aligned} \quad (3.256)$$

in which the  $\langle \omega_{k,s} \rangle_{T_I}$  denotes the mass transfer weighted interfacial species  $s$  mass fraction [118] (p. 133).

The other interfacial mass transfer fluxes are given by:

$$\mathbf{J}_k^j = - \sum_j l_j^{-1} \mathbf{j}_{kj} \cdot \mathbf{n}_{kj} = a_{T_I} \langle \mathbf{j}_k \cdot \mathbf{n}_k \rangle_{T_I} \quad (3.257)$$

in which  $\langle \mathbf{J}_k \cdot \mathbf{n}_k \rangle_{T_I}$  denotes the interfacial area averaged mass transfer flux.

The interfacial production term due to heterogeneous reactions is normally rewritten as:

$$\sum_j l_j^{-1} M_{Ij} = \sum_j l_j^{-1} R_{Ij,s} = \langle R_{I,s} \rangle_{T_I} a_I = \rho_{\text{Bulk}} \langle R_{I,s} \rangle_{T_I}^m \quad (3.258)$$

in which the interfacial reaction rate per unit interface area is commonly substituted by the more practical reaction rate per unit mass  $\langle R_{I,s} \rangle_{T_I}^m = \langle R_{I,s} \rangle_{T_I} a_I / \rho_{\text{Bulk}}$  ( $kg/kg, cat \times s$ ) in which  $\rho_{\text{Bulk}}$  denotes the bulk density of the catalyst ( $kg, cat/m^3$ ).

In order to carry out computations with the time averaged equations on the form (3.231), we need to relate the average of products to products of averages and derive constitutive equations for the interfacial coupling terms. Proceeding in a similar manner as suggested deriving the volume averaged equations, the first problem is generally solved introducing mass- and phase weighted time averaged variables and the concept of *temporal decomposition* that is analogous to the temporal decomposition conventionally used in the study of turbulent transport phenomena [95, 118].

The mass-weighted time average of the quantity  $\psi_k$  is defined by:

$$\langle \psi_k \rangle_T^{X_k \rho_k} = \frac{\frac{1}{T} \int_{t-T/2}^{t+T/2} (X_k \rho_k \psi_k) dt'}{\frac{1}{T} \int_{t-T/2}^{t+T/2} (X_k \rho_k) dt'} = \frac{\langle \rho_k \psi_k \rangle_T}{\langle \rho_k \rangle_T} = \frac{\langle \rho_k \psi_k \rangle_{T_k}}{\langle \rho_k \rangle_{T_k}} \quad (3.259)$$

In analogy to the conventional Favre decomposition and time averaging procedure we let  $\psi_k''$  denote the temporal fluctuation of the instantaneous variable  $\psi_k$  about the mass-weighted time average value  $\langle \psi_k \rangle_T^{X_k \rho_k}$ , as defined by:

$$\psi_k'' = \psi_k - \langle \psi_k \rangle_T^{X_k \rho_k} \quad (3.260)$$

Introducing (3.260) into (3.259) we obtain an important relationship:

$$\begin{aligned} \langle \rho_k \rangle_T \langle \psi_k \rangle_T^{X_k \rho_k} &= \langle \rho_k \psi_k \rangle_T \\ &= \langle \rho_k (\langle \psi_k \rangle_T^{X_k \rho_k} + \psi_k'') \rangle_T \\ &= \langle \rho_k \langle \psi_k \rangle_T^{X_k \rho_k} \rangle_T + \langle \rho_k \psi_k'' \rangle_T \\ &= \langle \rho_k \rangle_T \langle \psi_k \rangle_T^{X_k \rho_k} \end{aligned} \quad (3.261)$$

in which we have shown that  $\langle \rho_k \psi_k'' \rangle_T = \beta_k \langle \rho_k \psi_k'' \rangle_{T_k} = \langle \psi_k'' \rangle_T^{X_k \rho_k} = 0$  because  $\langle \psi_k \rangle_T^{X_k \rho_k}$  is constant within  $T$ .

Using (3.261) the convective term in the averaged Eq. (3.231) can be written as:

$$\begin{aligned} \langle \rho_k \mathbf{v}_k \psi_k \rangle_{T_k} &= \langle \rho_k \mathbf{v}_k \psi_k \rangle_T^{X_k} \\ &= \langle \rho_k (\langle \mathbf{v}_k \rangle_k^{X_k \rho_k} + \mathbf{v}_k'') (\langle \psi_k \rangle_k^{X_k \rho_k} + \psi_k'') \rangle_T^{X_k} \\ &= \langle \rho_k \rangle_T \langle \mathbf{v}_k \rangle_T^{X_k \rho_k} \langle \psi_k \rangle_T^{X_k \rho_k} + \langle \rho_k \mathbf{v}_k'' \psi_k'' \rangle_T \end{aligned} \quad (3.262)$$

Introducing the mass weighted variables (3.260) and manipulating the convective terms by use of the concept of temporal decomposition (3.259), the averaged Eq. (3.231) becomes:

$$\begin{aligned} \frac{\partial (\beta_k \langle \rho_k \rangle_{T_k} \langle \psi_k \rangle_T^{X_k \rho_k})}{\partial t} &+ \nabla \cdot (\beta_k \langle \rho_k \rangle_{T_k} \langle \mathbf{v}_k \rangle_T^{X_k \rho_k} \langle \psi_k \rangle_T^{X_k \rho_k}) + \nabla \cdot (\beta_k \langle \mathbf{J}_k \rangle_{T_k}) \\ &= - \sum_j l_j^{-1} (\dot{m}_k \psi_k + \mathbf{J}_k)_j \cdot \mathbf{n}_{kj} + \beta_k \sum_c \langle \rho_{k,c} \phi_c \rangle_{T_k} \\ &\quad - \nabla \cdot (\beta_k \langle \rho_k \mathbf{v}_k'' \psi_k'' \rangle_{T_k}) \end{aligned} \quad (3.263)$$

As in the volume averaged equations discussed in Sect. 3.5.1, three undetermined terms can be identified in the time averaged equations (3.263). The first term,  $-\nabla \cdot (\beta_k \langle \rho_k \mathbf{v}_k'' \psi_k'' \rangle_{T_k})$  denotes the covariance or correlation terms. The second term,  $-\sum_j l_j^{-1} \mathbf{J}_{kj} \cdot \mathbf{n}_{kj}$ , accounts for the effects of interfacial stress, heat and species mass transfer, whereas the third term,  $-\sum_j l_j^{-1} \dot{m}_{kj} \psi_{kj}$ , account for the interfacial transfer due to phase change.

To save space the governing time averaged equations for each of the primary variables are *not* listed here as their mathematical form coincides with the volume averaged model formulation given in Sect. 3.5.1. Nevertheless, it is important to note that the physical interpretations of the mean quantities and the temporal covariance terms differ from their spatial counterparts. Furthermore, the conventional constitutive equations for the unknown terms are discussed in Chap. 5, and the same modeling closures are normally adopted for any model formulation even though their physical interpretation differ.

### 3.5.3 The Ensemble Averaging Procedure

In this section we examine the ensemble averaging method in the framework of the generic single averaging procedure proposed by Drew [58] and further elaborated in [59, 60, 62, 146]. The paper by Enwald et al. [71] summarizes this approach nicely in the setting of fluidized bed reactor simulations. Other statistical averaging methods exist as well, some of them have been assessed by [3, 29, 30, 110, 134, 151,

182, 262–264]. These reports might be recommended for complementary studies. As distinct from the time and volume averaging procedures, the application of the ensemble averaging operator is not restricted by any space- and time scales. The ensemble averaging is thus considered the fundamental method [62, 63].

Generally, an ensemble average is defined in terms of an infinite number of realizations of the flow, consisting of variations of position, configuration, and velocities of the discrete units and the fluid between them. This means that we imagine that one can measure a local instantaneous quantity for each of an infinity of experiments which are alike except for presumably unimportant details of their behavior, and obtain the averaged values by averaging the quantity over the ensemble. For this reason the ensemble average can be interpreted as a measure related to the repeatability of experiments. On the other hand, for chaotic multiphase systems an exact experiment or realization is hardly repeatable since physical characteristics like the detailed boundary and initial conditions cannot be controlled with sufficient accuracy [60]. An inaccurate repetition of the experiment will thus rather lead to another member of the ensemble. Besides, it goes without saying that in physical analysis an infinite number of experiments cannot be realized, so the measured data is not averaged over an infinity of realizations. The best that one can do is to compute ensemble averages over a sufficiently large but finite number of realizations to ensure that the average measures become stable and do not fluctuate significantly. For such systems a correct detailed prediction cannot be made either because the physical characteristics like the boundary and initial conditions cannot be specified [63].

Consider a local instantaneous scalar, vector or tensor valued function defined by  $\psi \equiv \psi(\mathbf{r}, t)$ , and let  $\langle \psi \rangle_e(\mathbf{r}, t)$  denote the corresponding averaged field. The ensemble averaging operator can be defined in terms of a continuous probability density function [58, 62, 146]. For this purpose a few mathematical prerequisites are needed. Let  $\mathcal{R}$  denote an appropriate space domain,  $\tau$  a time domain and  $\varepsilon$  an event space of a process  $\mathcal{P}$ . In this method a statistical process refers to the set of possible flows that could occur using appropriate initial and boundary conditions.<sup>15</sup> In this notation a generic local instantaneous variable  $\psi$ , defined in  $\mathcal{P}$ , is written as  $\psi \equiv \psi(\mathbf{r}, t; \mu)$ . It follows that  $\mathbf{r} \in \mathcal{R}$  is the position vector,  $t \in \tau$  is the time and  $\mu \in \varepsilon$  is a particular realization of the process  $\mathcal{P}$ . A realization of the flow designates a possible motion that could have happened. In order to avoid mathematical difficulties when applying the averaging operators to the generic equation we introduce the phase indicator function  $X_k(\mathbf{r}, t; \mu)$  in any realization. This Heaviside function picks the phase  $k$  while ignoring the other phases and the interface. The characteristic function

---

<sup>15</sup> For some turbulent flows, the boundary conditions and initial conditions cannot be controlled sufficiently to allow repeatable experiments. In this case, although turbulent flows are not really deterministic, a useful conceptualization of the ensemble average assumes that the flow is deterministic but that randomness may arise through the uncertainty in the initial and boundary conditions [62].

Another possible conceptualization of the ensemble average imagines that the process is affected by small random forces through the motion. Particulate flows can then be described by distributions of positions, velocities and sizes adopting the basic principles of kinetic theory [91, 182, 262–264]. This alternative ensemble averaging approach is examined in relation to granular flows in Chap. 4.

is defined by:

$$X_k(\mathbf{r}, t; \mu) = \begin{cases} 1 & \text{if phase } k \text{ is present at location } \mathbf{r} \text{ in the realization } \mu, \\ 0 & \text{otherwise.} \end{cases} \quad (3.264)$$

The  $X_k$  is considered a generalized function which is especially useful in connection with differentiation of discontinuous functions within an integral. The ensemble average of  $\psi$  is then defined by:

$$\langle \psi_k \rangle_e = \int_{\varepsilon} \psi_k(\mathbf{r}, t; \mu) p(\mu) d\mu = \int_{\varepsilon} \psi_k(\mathbf{r}, t; \mu) dm(\mu) \quad (3.265)$$

where  $p(\mu)d\mu = dm(\mu)$  is the probability density for observing a realization  $\mu$  in the interval  $d\mu$  on the set of all possible events  $\varepsilon$ . In this method one refers to  $\varepsilon$  as the ensemble.

From the definition of a probability density function we note:

$$\int_{\varepsilon} p(\mu) d\mu = 1 \quad (3.266)$$

Before the averaging operator can be applied to the generic transport equation we need to take into account that multiphase mixtures are characterized by the presence of discontinuities in the fields. It is generally assumed that the fields of interest are smooth within each separate phase  $k$ , but that they can change discontinuously across the interfaces dividing the phases. Thereby the property functions are well behaved within each of the continuous phases, but in order to average the exact local instantaneous equation taking the discontinuous interfaces into account we need extended expressions for  $\langle \partial \psi_k / \partial t \rangle_e$  and  $\langle \nabla \psi_k \rangle_e$ . That is, for a well behaved function  $\psi_k$  connected to the bulk phases conventional axioms similar to (1.385) can still be applied, while to deal with the discontinuous fields related to the interfaces we introduce the phase indicator function so that  $\langle X_k \partial \psi_k / \partial t \rangle_e$  and  $\langle X_k \nabla \psi_k \rangle_e$  are considered generalized functions which can be manipulated in terms of test functions as outlined by [58, 59, 62]. Compared to the previous averaging procedures (e.g., [47, 51]), the use of generalized functions eliminates certain difficulties encountered when applying the averaging operators to discontinuous fields.<sup>16</sup> The trade-off for the simple derivation of the averaged equations and jump conditions is that all the mathematical manipulations involve generalized functions [58].

---

<sup>16</sup> It is noted that the original Reynolds axioms are not applicable to discontinuous functions as normally occur across the interfaces in multiphase flow. As a remedy, Drew [58] extended these functions making them continuous by use of the generalized function concept connecting the functions of the continuous phases on each side of the interface across the interface. Hence the discontinuous functions are modified to be continuous but locally very steep functions across the interface. Formally the averaging axioms can then be extended to include the interfaces, giving rise to the modified formulations of the axioms.

The particular forms of the Leibnitz's and Gauss' rules used for ensemble averaging are given by:

$$\begin{aligned}\langle X_k \frac{\partial \psi_k}{\partial t} \rangle_e &= \langle \frac{\partial X_k \psi_k}{\partial t} \rangle_e - \langle \psi_k \frac{\partial X_k}{\partial t} \rangle_e \\ &= \frac{\partial \langle X_k \psi_k \rangle_e}{\partial t} - \langle \psi_k \frac{\partial X_k}{\partial t} \rangle_e\end{aligned}\quad (3.267)$$

and

$$\begin{aligned}\langle X_k \nabla \psi_k \rangle_e &= \langle \nabla X_k \psi_k \rangle_e - \langle \psi_k \nabla X_k \rangle_e \\ &= \nabla \langle X_k \psi_k \rangle_e - \langle \psi_k \nabla X_k \rangle_e\end{aligned}\quad (3.268)$$

The last term on the RHS in both of these equations are related to the surface average of  $\psi_k$  over the interface and evaluated on the phase  $k$  side of the face [62]. The other terms on the RHS in both equations are related to the bulk phase average of  $\psi_k$  and are treated applying the conventional averaging axioms on the form (1.385).

The ensemble average of the phase indicator function is equivalent to the average occurrence of phase  $k$ :

$$\gamma_k = \langle X_k \rangle_e \quad (3.269)$$

where

$$\sum_{k=1}^2 \gamma_k = 1 \quad (3.270)$$

It is noted that both the time fraction  $\beta_k$  and the average occurrence or number fraction  $\gamma_k$  are often treated as equivalent to the local volume fraction  $\alpha_k$  of phase  $k$ . However, this assumption is strictly correct for stationary and homogeneous flows only. This equivalence of averages is not obvious so some kind of justification might be needed. Drew [58] pointed out that mathematically the local averaging operators for the volume, time and ensemble averages are formally similar. Besides, both the time and volume averages can be viewed as approximations to the ensemble average provided that the ergodic hypothesis holds on the local scale. Under these restrictions, with the ensemble averaging notation as basis, all the single averaging operators can be written in a generic manner. In this notation the time average of  $\psi_k$  is defined by taking one realization  $\mu^*$ , integrating over the time interval from  $t - T/2$  to  $t + T/2$ , and normalizing:

$$\langle \psi_k(\mathbf{r}, t; \mu^*) \rangle_T = \frac{1}{T} \int_{t-T/2}^{t+T/2} \psi_k(\mathbf{r}, \tau; \mu^*) d\tau \quad (3.271)$$

which has the practical advantage that we need not sample the ensemble repeatedly but rather perform a large number of samples in time within one realization.

In a similar manner the volume average can be seen as an ensemble average in which  $\psi_k$  is integrated over a sub-ensemble represented by  $\mu_\eta$  for  $\eta \in V$ . The volume average is then defined by:

$$\langle \psi_k \rangle_V = \frac{1}{V} \int_V \psi_k(\mathbf{r}, t; \mu_\eta^*) dv = \frac{1}{V} \int_V \psi_k(\mathbf{r} + , t; \mu^*) dv_\eta \quad (3.272)$$

It is emphasized that these time and volume averaging operators are appropriate only for statistically steady and homogeneous flows in which the ergodic hypothesis holds.

The averaged balance equations are obtained by multiplying the exact local instantaneous Eqs. (3.86) and (3.113) by  $X_k$  and then applying the single generic averaging operator.  $X_k$  is a generalized function satisfying the topological equation on the form [58, 60]:

$$\frac{D_I X_k}{Dt} = \frac{\partial X_k}{\partial t} + \mathbf{v}_I \cdot \nabla X_k = 0 \quad (3.273)$$

This relation is imagined as the material derivative of  $X_k$  following the interface [60]. For a point in space that is located on the interface  $X_k$  takes the value  $X_k = 0$ , otherwise  $X_k = 1$ . In either case the partial derivatives are both zero, so all the terms in (3.273) are zero. On the other hand, considering a point located on the surface that move with the interface velocity, Drew [58, 60, 62] imagines that the function  $X_k$  is expressing a constant jump determined by the generalized functions. Thus its material derivative is zero.

Using the  $X_k$  function we can average the generic transport equation. Preliminarily, we put up the resulting equation in the compact notation:

$$\begin{aligned} \langle X_k \frac{\partial(\rho_k \psi_k)}{\partial t} \rangle_e + \langle X_k \nabla \cdot (\rho_k \mathbf{v}_k \psi_k) \rangle_e + \langle X_k \nabla \cdot \mathbf{J}_k \rangle_e \\ = \langle X_k \sum_c \rho_{k,c} \phi_{k,c} \rangle_e \end{aligned} \quad (3.274)$$

The first, second and third terms in (3.274) have to be reformulated using the extended forms of the conventional averaging theorems.

The extended form of the Leibnitz's rule can be derived by use of the phase indicator function (3.264), the topological Eq. (3.273), the Reynolds averaging rules (1.385) and the chain rule [58]:

$$\begin{aligned} \langle X_k \frac{\partial \psi_k}{\partial t} \rangle_e &= \langle \frac{\partial(X_k \psi_k)}{\partial t} - \psi_k \frac{\partial X_k}{\partial t} \rangle_e \\ &= \langle \frac{\partial(X_k \psi_k)}{\partial t} + (\psi_k \mathbf{v}_I) \cdot \nabla X_k \rangle_e \\ &= \langle \frac{\partial(X_k \psi_k)}{\partial t} \rangle_e + \langle (\psi_k \mathbf{v}_I) \cdot \nabla X_k \rangle_e \end{aligned} \quad (3.275)$$

$$= \frac{\partial \langle X_k \psi_k \rangle_e}{\partial t} + \langle (\psi_k \mathbf{v}_I) \cdot \nabla X_k \rangle_e$$

In a similar manner the extended form of Gauss' rule can be derived by use of the phase indicator function (3.264), the topological Eq. (3.273), the Reynolds averaging rules (1.385) and the chain rule [58]:

$$\begin{aligned} \langle X_k \nabla \psi_k \rangle_e &= \langle \nabla (X_k \psi_k) - \psi_k \nabla X_k \rangle_e \\ &= \langle \nabla (X_k \psi_k) \rangle_e - \langle \psi_k \nabla X_k \rangle_e \\ &= \nabla \langle X_k \psi_k \rangle_e - \langle \psi_k \nabla X_k \rangle_e \end{aligned} \quad (3.276)$$

Applying the generic form of Leibnitz's theorem (3.275) to the first term in (3.274), we get:

$$\langle X_k \frac{\partial (\rho_k \psi_k)}{\partial t} \rangle_e = \frac{\partial \langle X_k \rho_k \psi_k \rangle_e}{\partial t} + \langle (\rho_k \psi_k \mathbf{v}_I) \cdot \nabla X_k \rangle_e \quad (3.277)$$

Similarly, by applying the generic form of Gauss' rule (3.276) to the second and the third terms in (3.274) we obtain the following results:

$$\langle X_k \nabla \cdot (\rho_k \mathbf{v}_k \psi_k) \rangle_e = \nabla \cdot \langle X_k \rho_k \mathbf{v}_k \psi_k \rangle_e - \langle (\rho_k \mathbf{v}_k \psi_k) \cdot \nabla X_k \rangle_e \quad (3.278)$$

and

$$\langle X_k \nabla \cdot \mathbf{J}_k \rangle_e = \nabla \cdot \langle X_k \mathbf{J}_k \rangle_e - \langle \mathbf{J}_k \cdot \nabla X_k \rangle_e \quad (3.279)$$

Introducing these modified formulations (3.277), (3.278) and (3.279), the averaged generic Eq. (3.274) can be written as:

$$\begin{aligned} &\frac{\partial \langle X_k \rho_k \psi_k \rangle_e}{\partial t} + \nabla \cdot \langle X_k \rho_k \mathbf{v}_k \psi_k \rangle_e + \nabla \cdot \langle X_k \mathbf{J}_k \rangle_e - \langle X_k \sum_c \rho_{k,c} \phi_{k,c} \rangle_e \\ &= \langle (\rho_k \mathbf{v}_k \psi_k) \cdot \nabla X_k \rangle_e + \langle \mathbf{J}_k \cdot \nabla X_k \rangle_e - \langle \rho_k \psi_k \mathbf{v}_I \cdot \nabla X_k \rangle_e \\ &= \langle [\rho_k \psi_k (\mathbf{v}_k - \mathbf{v}_I) + \mathbf{J}_k] \cdot \nabla X_k \rangle_e \end{aligned} \quad (3.280)$$

The RHS of (3.280) denotes the interfacial transport terms.

The averaged equations of the form (3.280) cannot be solved directly, as they contain averages of products of the dependent variables. To obtain a solvable set of equations, we need to relate the average of products to products of average variables. For this purpose the phase- and mass weighted quantities are introduced.

The weighted mean quantities are defined in agreement with the standard single phase Favre averaging procedure [52, 71, 118]. That is, we define:

*Phase-weighted averaging:*

$$\langle \psi_k \rangle_e^{X_k} = \frac{\langle X_k \psi_k \rangle_e}{\langle X_k \rangle_e} = \frac{\langle X_k \psi_k \rangle_e}{\langle \gamma_k \rangle_e} \quad (3.281)$$

*Mass-weighted averaging:*

$$\langle \psi_k \rangle_e^{X_k \rho_k} = \frac{\langle X_k \rho_k \psi_k \rangle_e}{\langle X_k \rho_k \rangle_e} \quad (3.282)$$

The generalized instantaneous quantity  $\psi_k$  is decomposed into a weighted mean component and a fluctuation component in analogy to the Favre averaging procedure for compressible flows [79, 140]:

$$\psi_k = \langle \psi_k \rangle_e^{X_k \rho_k} + \psi_k'' \quad (3.283)$$

where  $\psi_k''$  is the superimposed fluctuation component of the instantaneous quantity  $\psi_k$  around its mean weighted component  $\langle \psi_k \rangle_e^{X_k \rho_k}$ .

The average of a mass weighted fluctuating quantity like  $\langle \psi_k'' \rangle_e^{X_k \rho_k}$  is equal to zero by definition,  $\langle \psi_k'' \rangle_e^{X_k \rho_k} = 0$ . This result can be verified decomposing  $\psi_k$  on the RHS of the weighted variable definition (3.282) using (3.283):

$$\begin{aligned} \langle X_k \rho_k \rangle_e \langle \psi_k \rangle_e^{X_k \rho_k} &= \langle X_k \rho_k \psi_k \rangle_e \\ &= \langle X_k \rho_k (\langle \psi_k \rangle_e^{X_k \rho_k} + \psi_k'') \rangle_e \\ &= \langle X_k \rho_k \langle \psi_k \rangle_e^{X_k \rho_k} \rangle_e + \langle X_k \rho_k \psi_k'' \rangle_e \end{aligned} \quad (3.284)$$

Comparing this result with the definition of the weighted component of  $\psi_k$  given by (3.282), it follows that  $\langle X_k \rho_k \psi_k'' \rangle_e = 0$ . From the latter relation we can deduce, the important result:

$$\begin{aligned} \langle X_k \rho_k \psi_k'' \rangle_e &= \langle X_k \rho_k \rangle_e \langle \psi_k'' \rangle_e^{X_k \rho_k} = \langle X_k \rangle_e \langle \rho_k \rangle_e^{X_k} \langle \psi_k'' \rangle_e^{X_k \rho_k} \\ &= \gamma_k \langle \rho_k \rangle_e^{X_k} \langle \psi_k'' \rangle_e^{X_k \rho_k} \\ &= 0 \end{aligned} \quad (3.285)$$

By definition the phase indicator function  $X_k$  cannot be decomposed into a mean component and a fluctuation component, thus the only way this relation can be fulfilled is by defining  $\langle \psi_k'' \rangle_e^{X_k \rho_k} = 0$ .

If we adopt (3.285), all the terms in the generic Eq. (3.280) can be reformulated and expressed in terms of weighted quantities and a large number of unknown covariances. The different terms in the equation are rewritten as:

*The transient term:*

$$\begin{aligned}
 \langle X_k \rho_k \psi_k \rangle_e &= \langle X_k \rho_k \rangle_e \langle \psi_k \rangle_e^{X_k \rho_k} \\
 &= \langle X_k \rangle_e \langle \rho_k \rangle_e^{X_k} \langle \psi_k \rangle_e^{X_k \rho_k} \\
 &= \gamma_k \langle \rho_k \rangle_e^{X_k} \langle \psi_k \rangle_e^{X_k \rho_k}
 \end{aligned} \tag{3.286}$$

*The convective term:*

$$\begin{aligned}
 \langle X_k \rho_k \mathbf{v}_k \psi_k \rangle_e &= \langle X_k \rho_k (\langle \mathbf{v}_k \rangle_e^{X_k \rho_k} + \mathbf{v}''_k) (\langle \psi_k \rangle_e^{X_k \rho_k} + \psi''_k) \rangle_e \\
 &= \langle X_k \rho_k (\langle \mathbf{v}_k \rangle_e^{X_k \rho_k} \langle \psi_k \rangle_e^{X_k \rho_k} + \langle \mathbf{v}_k \rangle_e^{X_k \rho_k} \psi''_k \\
 &\quad + \mathbf{v}''_k \langle \psi_k \rangle_e^{X_k \rho_k} + \mathbf{v}''_k \psi''_k) \rangle_e \\
 &= \langle X_k \rho_k \rangle_e \langle \mathbf{v}_k \rangle_e^{X_k \rho_k} \langle \psi_k \rangle_e^{X_k \rho_k} \\
 &\quad + \langle X_k \rho_k \psi''_k \rangle_e \langle \mathbf{v}_k \rangle_e^{X_k \rho_k} \\
 &\quad + \langle X_k \rho_k \mathbf{v}''_k \rangle_e \langle \psi_k \rangle_e^{X_k \rho_k} + \langle X_k \rho_k \mathbf{v}''_k \psi''_k \rangle_e \\
 &= \langle X_k \rangle_e \langle \rho_k \rangle_e^{X_k} \langle \mathbf{v}_k \rangle_e^{X_k \rho_k} \langle \psi_k \rangle_e^{X_k \rho_k} \\
 &\quad + \langle X_k \rangle_e \langle \rho_k \mathbf{v}''_k \psi''_k \rangle_e^{X_k} \\
 &= \gamma_k \langle \rho_k \rangle_e^{X_k} \langle \mathbf{v}_k \rangle_e^{X_k \rho_k} \langle \psi_k \rangle_e^{X_k \rho_k} + \gamma_k \langle \rho_k \mathbf{v}''_k \psi''_k \rangle_e^{X_k}
 \end{aligned} \tag{3.287}$$

The covariances of phase  $k$  are normally defined by the phasic average of the product of the fluctuating arbitrary variable and the velocity components:

$$\mathbf{J}_k^{Re, X_k} = \frac{\langle X_k \rho_k \mathbf{v}''_k \psi''_k \rangle_e}{\langle X_k \rangle_e} = \frac{\langle X_k \rho_k \mathbf{v}''_k \psi''_k \rangle_e}{\gamma_k} \tag{3.288}$$

*The diffusive term:*

$$\langle X_k \mathbf{J}_k \rangle_e = \langle X_k \rangle_e \langle \mathbf{J}_k \rangle_e^{X_k} = \gamma_k \langle \mathbf{J}_k \rangle_e^{X_k} \tag{3.289}$$

*The volume production term:*

$$\begin{aligned}
 \langle X_k \sum_c \rho_{k,c} \phi_{k,c} \rangle_e &= \sum_c \langle X_k \rho_{k,c} \rangle_e \langle \phi_{k,c} \rangle_e^{X_k \rho_k} \\
 &= \langle X_k \rangle_e \sum_c \langle \rho_{k,c} \rangle_e^{X_k} \langle \phi_{k,c} \rangle_e^{X_k \rho_k} \\
 &= \gamma_k \sum_c \langle \rho_{k,c} \rangle_e^{X_k} \langle \phi_{k,c} \rangle_e^{X_k \rho_k}
 \end{aligned} \tag{3.290}$$

Introducing the reformulated forms of the terms examined above, the exact macroscopic transport Eq. (3.280) (i.e., without including any constitutive equations for the unknown terms) can be expressed as:

$$\begin{aligned}
& \frac{\partial(\gamma_k \langle \rho_k \rangle_e^{X_k} \langle \psi_k \rangle_e^{X_k \rho_k})}{\partial t} + \nabla \cdot (\gamma_k \langle \rho_k \rangle_e^{X_k} \langle \mathbf{v}_k \rangle_e^{X_k \rho_k} \langle \psi_k \rangle_e^{X_k \rho_k}) \\
& + \nabla \cdot (\gamma_k (\mathbf{J}_k^{X_k} + \mathbf{J}_k^{Re, X_k})) - \gamma_k \sum_c \langle \rho_{k,c} \rangle_e^{X_k} \langle \phi_{k,c} \rangle_e^{X_k \rho_k} \\
& = \langle [\rho_k \psi_k (\mathbf{v}_k - \mathbf{v}_I) + \mathbf{J}_k] \cdot \nabla X_k \rangle_e = \langle (\dot{m}_k \psi_k + \mathbf{J}_k \cdot \mathbf{n}_k) \frac{\partial X_k}{\partial n} \rangle_e
\end{aligned} \tag{3.291}$$

The gradient of the phase indicator function, being a generalized scalar function [58], can be expressed as:

$$\nabla X_k = \left( \frac{\partial X_k}{\partial n} \right) \mathbf{n}_k = -\delta(\mathbf{r} - \mathbf{r}_I) \mathbf{n}_k \tag{3.292}$$

in which  $\delta(\mathbf{r} - \mathbf{r}_I)$  denotes the Dirac's delta function for the interface and  $\mathbf{n}_k$  is the unit normal to the interface between the phases in the direction out of phase  $k$ . It is noted that two different sign conventions are in common use considering the definitions of the interfacial terms. We follow the sign convention by [58, 71], but a different set of consistent definitions are proposed in the latest reports [59–62, 145]. The reason for switching the sign convention becomes clear shortly, as all the interfacial fluxes in our derivation apparently have opposite sign compared to the conventional formulations presented in this chapter.

The Dirac delta function or the gradient in the phase indicator function serves to pick out the mass and molecular fluxes at the interface. The Dirac delta function has the property:

$$\int_{-\infty}^{+\infty} f(\xi) \delta(\xi - a) d\xi = f(a) \tag{3.293}$$

Averaging the product of the absolute value of the gradient and the fluxes gives as the result the average contributory effect of mass and molecular fluxes at the interfaces over the whole domain of integration [71]. Drew [58] defined the averaged interfacial area per unit volume by:

$$a_{eI} = \left\langle \frac{\partial X}{\partial n} \right\rangle_e \tag{3.294}$$

The averaged jump conditions are derived by multiplying the exact jump condition (3.113) by  $\frac{\partial X_k}{\partial n}$  (for a specific value of  $k$  [60, 71]) and averaging, recognizing that  $\mathbf{n}_1 = -\mathbf{n}_2$  and  $\frac{\partial X_1}{\partial n} = \frac{\partial X_2}{\partial n}$ :

$$\sum_k \langle (\dot{m}_k \psi_k + \mathbf{J}_k \cdot \mathbf{n}_k) \frac{\partial X_k}{\partial n} \rangle_e = -\langle M_I \frac{\partial X_I}{\partial n} \rangle_e \tag{3.295}$$

or

$$\sum_k \langle [\rho_k (\mathbf{v}_k - \mathbf{v}_I) \psi_k + \mathbf{J}_k] \cdot \nabla X_k \rangle_e = -\langle M_I \frac{\partial X_I}{\partial n} \rangle_e \tag{3.296}$$

in which it is understood that on the RHS no summation should be made (henceforth we drop the index  $l$  inferring that we have chosen either  $l = 1$  or  $l = 2$ ) and the factor  $\frac{\partial X_l}{\partial n} = \mathbf{n}_l \cdot \nabla X_l$  is to be expressed in accordance with the prevailing sign convention for the interface terms (3.292).

The averaged equations governing each phase and the corresponding jump conditions are then achieved defining the specific values of the generic variables in (3.291) and (3.295) in accordance with Table 3.1:

*Mass:*

The volume averaged continuity equation appears by substituting  $\psi_k = 1$ ,  $\mathbf{J}_k = 0$  and  $\phi_{c,k} = 0$  into (3.291):

$$\frac{\partial(\gamma_k \langle \rho_k \rangle_e^{X_k})}{\partial t} + \nabla \cdot (\gamma_k \langle \rho_k \rangle_e^{X_k} \langle \mathbf{v}_k \rangle_e^{X_k \rho_k}) = \langle \dot{m}_k \frac{\partial X_k}{\partial n} \rangle_e = \Gamma_k \quad (3.297)$$

Introducing the values for the interface properties  $M_I = 0$  into (3.295), yields:

$$\sum_k \Gamma_k = 0 \quad (3.298)$$

The interfacial mass transfer terms due to phase change is defined by:

$$\Gamma_k = \langle \dot{m}_k \frac{\partial X_k}{\partial n} \rangle_e = a_{eI} \langle \dot{m}_k \rangle_{eI} \quad (3.299)$$

in which  $\langle \dot{m}_k \rangle_{eI} = \langle \dot{m}_k \frac{\partial X_k}{\partial n_k} \rangle_e / a_{eI}$  denotes the interfacial area averaged mass transfer rate [62]. The interfacial area density is defined in accordance with (3.294).

*Momentum:*

The averaged momentum equation appears by substituting  $\psi_k = \mathbf{v}_k$ ,  $\mathbf{J}_k = \mathbf{T}_k$  and  $\phi_{c,k} = \mathbf{g}_{c,k}$  into (3.291):

$$\begin{aligned} & \frac{\partial(\gamma_k \langle \rho_k \rangle_e^{X_k} \langle \mathbf{v}_k \rangle_e^{X_k \rho_k})}{\partial t} + \nabla \cdot (\gamma_k \langle \rho_k \rangle_e^{X_k} \langle \mathbf{v}_k \rangle_e^{X_k \rho_k} \langle \mathbf{v}_k \rangle_e^{X_k \rho_k}) \\ & + \nabla \cdot (\gamma_k (\langle \mathbf{T}_k \rangle_e^{X_k} + \langle \mathbf{T}_k \rangle_e^{Re, X_k})) = \langle (\dot{m}_k \mathbf{v}_k + \mathbf{T}_k \cdot \mathbf{n}_k) \frac{\partial X_k}{\partial n} \rangle_e \\ & + \gamma_k \langle \rho_k \rangle_e^{X_k} \sum_c \langle \omega_{k,c} \rangle_e^{X_k \rho_k} \langle \mathbf{g}_{k,c} \rangle_e^{X_k \rho_k} \end{aligned} \quad (3.300)$$

Introducing the values for the interface properties  $\mathbf{M}_I = 2\sigma_I H_I \mathbf{n}_I + \nabla_I \sigma_I$  into (3.295), yields:

$$\sum_k (\mathbf{M}_k^I + \mathbf{M}_k^T) = -\langle \mathbf{M}_I \frac{\partial X}{\partial n} \rangle_e \quad (3.301)$$

The interfacial momentum transfer due to phase change is defined by:

$$\mathbf{M}_k^\Gamma = \langle \dot{m}_k \mathbf{v}_k \frac{\partial X_k}{\partial n} \rangle_e = \Gamma_k \langle \mathbf{v}_k \rangle_{e_I}^{\Gamma_k} \quad (3.302)$$

in which the mass transfer weighted interfacial area averaged velocity  $\langle \mathbf{v}_k \rangle_{e_I}^{\Gamma_k}$  is defined in analogy to the mass-weighted averaged variables known from turbulence theory [118] (p. 133).

The interfacial momentum stresses yield:

$$\mathbf{M}_k^T = \langle \mathbf{T}_k \cdot \mathbf{n}_k \frac{\partial X_k}{\partial n} \rangle_e = \langle (p_k \mathbf{e} + \boldsymbol{\sigma}_k) \cdot \mathbf{n}_k \frac{\partial X_k}{\partial n} \rangle_e \quad (3.303)$$

where the total stress tensor of both phases has been modeled using the Newtonian strain-stress formulation.

In a similar manner as for the single averaging methods in Sects. 3.5.1, 3.5.2 and 3.5.3, the stress terms are normally rewritten introducing an interfacial averaged pressure  $\langle p_k \rangle_{e_I}$  and an interfacial averaged viscous stress  $\langle \boldsymbol{\sigma}_k \rangle_{e_I}$ . In this method the interfacial pressure is normally defined by:

$$\langle p_k \rangle_{e_I} = \frac{\langle p_k \frac{\partial X_k}{\partial n} \rangle_e}{\langle \frac{\partial X_k}{\partial n} \rangle_e} = \frac{\langle p_k \frac{\partial X}{\partial n_I} \rangle_e}{a_{e_I}} \quad (3.304)$$

Naturally, the interfacial viscous stress is defined by:

$$\langle \boldsymbol{\sigma}_k \rangle_{e_I} = \frac{\langle \boldsymbol{\sigma}_k \frac{\partial X_k}{\partial n} \rangle_e}{\langle \frac{\partial X_k}{\partial n} \rangle_e} = \frac{\langle \boldsymbol{\sigma}_k \frac{\partial X}{\partial n_I} \rangle_e}{a_{e_I}} \quad (3.305)$$

The corresponding fluctuating interfacial quantities are defined by:

$$p_{k,I}'' = p_k - \langle p_k \rangle_{e_I} \quad (3.306)$$

$$\boldsymbol{\sigma}_{k,I}'' = \boldsymbol{\sigma}_k - \langle \boldsymbol{\sigma}_k \rangle_{e_I} \quad (3.307)$$

Proceeding in the same way as explained presenting the volume averaging procedure, we obtain the following result:

$$\begin{aligned} \mathbf{M}_k^T &= \langle \mathbf{T}_k \cdot \nabla X_k \rangle_e = \langle p_k \nabla X_k \rangle_e + \langle \boldsymbol{\sigma}_k \cdot \nabla X_k \rangle_e \\ &= \langle p_k \rangle_{e_I} \langle \nabla X_k \rangle_e + \langle \boldsymbol{\sigma}_k \rangle_{e_I} \cdot \langle \nabla X_k \rangle_e + \langle \mathbf{T}_{k,I}'' \cdot \nabla X_k \rangle_e \\ &= \langle p_k \rangle_{e_I} \nabla \gamma_k + \langle \boldsymbol{\sigma}_k \rangle_{e_I} \cdot \nabla \gamma_k + \mathbf{F}_k \end{aligned} \quad (3.308)$$

The interfacial pressure difference effect and the combined interfacial shear and time fraction gradient effect are treated in the same manner as suggested discussing the analogous terms in (3.161). The modified definition of the generalized drag force follows naturally from an analogy to (3.163).

Utilizing (3.292), (3.276) with  $\psi_k = 1$  and the mean value theorem for integrals, the term on the RHS of (3.301) can be defined by the index  $l = 1$  and expressed as:

$$\begin{aligned}
 -\langle \mathbf{M}_I \frac{\partial X}{\partial n} \rangle_e &= -\langle (2\sigma_I H_I \mathbf{n}_1 + \nabla_I \sigma_I) \frac{\partial X_1}{\partial n_1} \rangle_e \\
 &\approx -2\langle \sigma_I H_I \rangle_{e_I} \langle \mathbf{n}_1 \frac{\partial X_1}{\partial n_1} \rangle_e - \langle \nabla_I \sigma_I \frac{\partial X_1}{\partial n_1} \rangle_e \\
 &\approx -2\langle \sigma_I \rangle_{e_I} \langle H_I \rangle_{e_I} \nabla \gamma_2 - a_I \langle \nabla_I \sigma_I \rangle_{e_I}
 \end{aligned} \tag{3.309}$$

where  $\langle H_I \rangle_{e_I}$  is the interfacial area averaged curvature [118]. The mean curvature is defined by (3.80). Again, we have used the sign convention that occurs by  $\mathbf{n}_I = \mathbf{n}_1$ .

*Energy:*

The averaged energy equation appears by substituting  $\psi_k = e_k + \frac{1}{2}v_k^2$ ,  $\mathbf{J}_k = \mathbf{T}_k \cdot \mathbf{v}_k + \mathbf{q}_k$  and  $\phi_{c,k} = \mathbf{v}_k \cdot \mathbf{g}_{c,k}$  into (3.291):

$$\begin{aligned}
 &\frac{\partial}{\partial t} \left( \gamma_k \langle \rho_k \rangle_e^{X_k} (\langle e_k \rangle_e^{X_k \rho_k} + \frac{1}{2} (\langle v_k \rangle_e^{X_k \rho_k})^2 + \frac{1}{2} \langle \mathbf{v}_k'' \cdot \mathbf{v}_k'' \rangle_e^{X_k \rho_k}) \right) \\
 &+ \nabla \cdot \left( \gamma_k \langle \rho_k \rangle_e^{X_k} \langle \mathbf{v}_k \rangle_e^{X_k \rho_k} \langle e_k \rangle_e^{X_k \rho_k} + \langle \rho_k \mathbf{v}_k'' e_k'' \rangle_e^{X_k} \right) \\
 &+ \frac{1}{2} \nabla \cdot \left( \gamma_k \langle \rho_k \rangle_e^{X_k} \langle \mathbf{v}_k \rangle_e^{X_k \rho_k} ((\langle v_k \rangle_e^{X_k \rho_k})^2 + \langle \mathbf{v}_k'' \cdot \mathbf{v}_k'' \rangle_e^{X_k \rho_k}) \right) \\
 &+ \nabla \cdot \left( \langle \mathbf{v}_k \rangle_e^{X_k \rho_k} \cdot (\gamma_k \langle \rho_k \mathbf{v}_k'' \mathbf{v}_k'' \rangle_e^{X_k}) \right) \\
 &+ \frac{1}{2} \nabla \cdot \left( \gamma_k \langle \rho_k \rangle_e^{X_k} \langle \mathbf{v}_k'' (\mathbf{v}_k'' \cdot \mathbf{v}_k'') \rangle_e^{X_k \rho_k} \right) + \nabla \cdot \left( \gamma_k \langle \mathbf{q}_k \rangle_e^{X_k} \right) \\
 &+ \nabla \cdot \left( \gamma_k (\langle \mathbf{T}_k \rangle_e^{X_k} \cdot \langle \mathbf{v}_k \rangle_e^{X_k \rho_k} + \langle \mathbf{T}_k \cdot \mathbf{v}_k'' \rangle_e^{X_k}) \right) \\
 &= \Gamma_k \left( \langle e_k \rangle_{e_I}^{\Gamma_k} + \frac{1}{2} (\langle v_k \rangle_{e_I}^{\Gamma_k})^2 \right) + E_k^W + E_k^E \\
 &+ \gamma_k \left\langle \sum_c \rho_{k,c} \mathbf{v}_{k,c} \cdot \mathbf{g}_{k,c} \right\rangle_e^{X_k}
 \end{aligned} \tag{3.310}$$

Introducing the values for the interface properties

$M_I = \nabla_I \cdot \mathbf{q}_I - \nabla_I \cdot (\sigma_I \mathbf{v}_I)$  into (3.295), yields:

$$\sum_k (E_k^E + E_k^W + E_k^\Gamma) = -\langle M_I \frac{\partial X}{\partial n} \rangle_e \tag{3.311}$$

The interfacial energy transfer due to phase change is defined by:

$$E_k^\Gamma = -\left\langle \frac{\partial X_k}{\partial n} \rho_k \left( e_k + \frac{1}{2} v_k^2 \right) (\mathbf{v}_I - \mathbf{v}_k) \cdot \mathbf{n}_k \right\rangle_e$$

$$= \left\langle \frac{\partial X_k}{\partial n} \dot{m}_k \left( e_k + \frac{1}{2} v_k^2 \right) \right\rangle_e = \Gamma_k \left\langle \left( e_k + \frac{1}{2} v_k^2 \right) \right\rangle_{e_I}^{\Gamma_k}, \quad (3.312)$$

in which  $\left\langle \left( e_k + \frac{1}{2} v_k^2 \right) \right\rangle_{e_I}^{\Gamma_k}$  denotes the mass transfer weighted interfacial (internal and mechanical) energy [118](p. 137).

The interfacial heat transfer is given by:

$$E_k^E = \left\langle \mathbf{q}_k \cdot \mathbf{n}_k \frac{\partial X_k}{\partial n} \right\rangle_e = a_{e_I} \left\langle \mathbf{q}_k \cdot \mathbf{n}_k \right\rangle_{e_I}, \quad (3.313)$$

in which  $\left\langle \mathbf{q}_k \cdot \mathbf{n}_k \right\rangle_{e_I}$  denotes the interfacial area averaged heat transfer flux.

The interfacial work by viscous and pressure forces yields:

$$E_k^W = \left\langle (\mathbf{T}_k \cdot \mathbf{v}_k) \cdot \mathbf{n}_k \frac{\partial X_k}{\partial n} \right\rangle_e \quad (3.314)$$

The surface energy sources are expressed as the product of the interfacial area concentration and the averaged interfacial fluxes:

$$\begin{aligned} -\left\langle M_I \frac{\partial X}{\partial n} \right\rangle_e &= \left\langle (-\nabla_I \cdot (\sigma_I \mathbf{v}_I) + \nabla_I \cdot \mathbf{q}_I) \frac{\partial X_I}{\partial n_I} \right\rangle_e \\ &= -\left\langle \nabla_I \cdot (\sigma_I \mathbf{v}_I) \right\rangle_{e_I} a_{e_I} + \left\langle \nabla_I \cdot \mathbf{q}_I \right\rangle_{e_I} a_{e_I} \end{aligned} \quad (3.315)$$

where  $\left\langle \nabla_I \cdot \mathbf{q}_I \right\rangle_{e_I}$  and  $-\left\langle \nabla_I \cdot (\sigma_I \mathbf{v}_I) \right\rangle_{e_I}$  are the interfacial averaged interfacial energy fluxes.

*Chemical Species:*

The averaged species mass balance appears by substituting  $\psi_k = \omega_{k,s}$ ,  $\mathbf{J}_k = \mathbf{j}_{k,s}$  and  $\phi_{c,k} = R_{k,s}/\rho_{k,c}$  into (3.291):

$$\begin{aligned} \frac{\partial (\gamma_k \langle \rho_k \rangle_e^{X_k} \langle \omega_{k,s} \rangle_e^{X_k \rho_k})}{\partial t} + \nabla \cdot (\gamma_k \langle \rho_k \rangle_e^{X_k} \langle \omega_{k,s} \rangle_e^{X_k \rho_k} \langle \mathbf{v}_k \rangle_e^{X_k \rho_k}) + \nabla \cdot (\gamma_k \langle \mathbf{j}_{k,s} \rangle_e^{X_k}) \\ = \left\langle \dot{m}_k \omega_{k,s} + \mathbf{j}_{k,s} \cdot \mathbf{n}_k \right\rangle_e \frac{\partial X_k}{\partial n} + \gamma_k \langle R_{k,s} \rangle_e^{X_k} \end{aligned} \quad (3.316)$$

Introducing the values for the interface properties  $M_I = R_{I,s}$  into (3.295), yields:

$$\sum_k (\mathbf{J}_{k,s}^\Gamma + \mathbf{J}_{k,s}^j) = -\left\langle M_I \frac{\partial X}{\partial n} \right\rangle_e \quad (3.317)$$

The interfacial species mass transfer due to phase change is defined by:

$$\begin{aligned} \mathbf{J}_{k,s}^\Gamma &= -\left\langle \rho_k \omega_{k,s} (\mathbf{v}_I - \mathbf{v}_k) \cdot \mathbf{n}_k \frac{\partial X_k}{\partial n} \right\rangle_e = \left\langle \dot{m}_k \omega_{k,s} \frac{\partial X_k}{\partial n} \right\rangle_e \\ &= \Gamma_k \langle \omega_{k,s} \rangle_{e_I}^{\Gamma_k}, \end{aligned} \quad (3.318)$$

in which the  $\langle \omega_{k,s} \rangle_{e_I}^{\Gamma_k}$ , denotes the mass transfer weighted interfacial species  $s$  mass fraction [118] (p. 133).

The other interfacial mass transfer fluxes are given by:

$$\mathbf{J}_{k,s}^j = \langle \mathbf{j}_{k,s} \cdot \mathbf{n}_k \frac{\partial X_k}{\partial n} \rangle_e = a_{e_I} \langle \mathbf{j}_{k,s} \cdot \mathbf{n}_k \rangle_{e_I} \quad (3.319)$$

in which  $\langle \mathbf{j}_{k,s} \cdot \mathbf{n}_k \rangle_{e_I}$  denotes the interfacial area averaged mass transfer flux.

The interfacial production term due to heterogeneous reactions is normally rewritten as:

$$- \langle R_{I,s} \frac{\partial X}{\partial n} \rangle_e = \langle R_{I,s} \rangle_{e_I} a_{e_I} = \rho_{\text{Bulk}} \langle R_{I,s} \rangle_{e_I}^m \quad (3.320)$$

in which the interfacial reaction rate per unit interface area is commonly substituted by the more practical reaction rate per unit mass  $\langle R_{I,s} \rangle_{e_I}^m = \langle R_{I,s} \rangle_{e_I} a_{e_I} / \rho_{\text{Bulk}}$  ( $kg/kg, cat \times s$ ) in which  $\rho_{\text{Bulk}}$  denotes the bulk density of the catalyst ( $kg, cat/m_r^3$ ).

As expected, three groups of undetermined terms appear in the averaged Eq. (3.291). The first term,  $\nabla \cdot (\gamma_k \langle \rho_k \mathbf{v}'' \psi'' \rangle_e^{X_k})$  denotes the covariance or correlation terms. The second term,  $\langle \mathbf{J}_k \cdot \mathbf{n}_k \frac{\partial X_k}{\partial n} \rangle_e$ , accounts for the effects of interfacial stress, heat and species mass transfer, whereas the third term,  $\langle \dot{m}_k \psi_k \frac{\partial X_k}{\partial n} \rangle_e$ , account for the interfacial transfer due to phase change. The conventional constitutive equations are discussed in Chap. 5.

### 3.5.4 The Time After Volume Averaging Procedure

In this section we examine the *multiple averaging* operators with emphasis on the time after volume averaging technique. The literature cited concerning the multiple averaging operators like the space followed by time or ensemble averaging are [12, 26, 47, 50, 51, 69, 78, 144, 187, 202–205, 219, 220, 244, 258]. These reports might be considered for complementary studies.

The time after volume averaging procedure can be applied under a unified set of conditions denoting the sum of the two sub-sets of requirements formulated in Sects. 3.5.1 and 3.5.2 for the pure volume and time averaging procedures to handle the scale disparity in a proper manner.

It has been shown that the time-volume and volume-time averaging operators are mathematically commutative [47, 51]. Nevertheless, Sha and Slattery [202] argued that in experimental analysis the instrumentation often records space average followed by a time average data. For this reason it might be convenient to formulate a consistent model formulation for the theoretical analysis. Later, Soo and co-workers [203, 204, 219, 220] on the other hand state that the order of performing volume averaging and time averaging cannot be arbitrarily chosen due to the different physical interpretations of the different averages. Hence, volume averaging was preferred

for constructing a continuum for each phase while time averaging was performed after volume averaging to account for the high-frequency fluctuations.

To close the rigorous time after volume averaged equations several modeling strategies have emerged over the years relating the average of products to products of averages. We may roughly divide these methods into two groups, one class of concepts dealing with separated flows and a second group of approaches considering dispersed flows. In this context it is worth mentioning that when formulating the early stratified flow models the time after area averaging method was preferred describing one-dimensional two-phase pipe flows [18, 26, 47, 51, 246] and thermo-fluid dynamics in boiling water nuclear reactors [12, 203, 204, 244, 258]. Moreover, a three-dimensional generalization of the area averaging method intended for stratified flows was derived by [144]. It is pointed out that no decomposition of the field variables was performed in any of the early time and spatially averaged stratified flow models [12, 55, 244, 258]. Instead, correlation or distribution coefficients are introduced and defined as the ratio between the average of the product of macroscopic variables and the product of the averaged macroscopic field variables

$$C_k = \frac{\overline{\alpha_k \langle \rho_k \rangle_{V_k}^{\alpha_k} \langle \psi_k \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}}}{\overline{\alpha_k} \overline{\langle \rho_k \rangle_{V_k}^{\alpha_k}} \overline{\langle \psi_k \rangle_V^{\alpha_k \rho_k}} \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}}} \quad (3.321)$$

In this theory the covariance coefficients are affected by the size of the averaging scales in time and space [55]. However, in engineering practice these coefficients are commonly set to unity because very little data on the distribution coefficients are available [12, 244, 258].

In this work the application of the time after volume averaging method to dispersed flows is of particular interest. In this specific application the variables are usually decomposed both in time and space. However, the spatial covariances are generally neglected merely due to a general lack of understanding of the physical processes considered by these terms. It is generally assumed that for dispersed mixtures the effect of non-locality and thus the spatial covariances can be neglected [55, 219, 220]. The temporal decomposition of the spatially averaged variables gives rise to terms of mean and fluctuating quantities where the temporal covariances are interpreted as the turbulent contributions. Therefore, in this double averaging procedure the first part of the model formulation coincides with the standard volume averaging method as outlined in Sect. 3.5.1. The time averaging theorems used are similar to the conventional Reynolds or Favre averaging procedures, and deviate from the time averaging operator described in Sect. 3.5.2 in that the operator is applied to the continuous variable fields achieved after the smoothing volume averaging.

Let the time averaging operator, when applied to any volume averaged scalar, vector, or tensor valued function  $\langle \psi_k \rangle_V$  associated with phase  $k$ , be defined by:

$$\overline{\langle \psi_k \rangle_V} = \frac{1}{T} \int_{t-T/2}^{t+T/2} \langle \psi_k \rangle_V dt \quad (3.322)$$

where  $\langle \psi_k \rangle_V$  is continuous and has no jump discontinuities. That is,  $\langle \psi_k \rangle_V$  has no jump discontinuities in space because this function is already spatially smoothed.

In accordance with the conventional Reynolds axioms (1.385), the Leibnitz's rule is given by:

$$\overline{\frac{\partial \langle \psi_k \rangle_V}{\partial t}} = \frac{\partial \overline{\langle \psi_k \rangle_V}}{\partial t} \quad (3.323)$$

Likewise, the Gauss' rule for a scalar field yields:

$$\overline{\nabla \langle \psi_k \rangle_V} = \nabla \overline{\langle \psi_k \rangle_V} \quad (3.324)$$

The particular form of Gauss' rule used for vectors and tensors is written:

$$\overline{\nabla \cdot \langle \psi_k \rangle_V} = \nabla \cdot \overline{\langle \psi_k \rangle_V} \quad (3.325)$$

An instantaneous volume-averaged quantity can be decomposed into two parts, the mean and the fluctuation<sup>17</sup>:

$$\langle \psi_k \rangle_V = \overline{\langle \psi_k \rangle_V} + \langle \psi_k \rangle'_V \quad (3.327)$$

where  $\langle \psi_k \rangle'_V$  denotes the superimposed fluctuation component of the instantaneous variable  $\langle \psi_k \rangle_V$  around it's mean component  $\overline{\langle \psi_k \rangle_V}$ .

Defining a Favre averaging procedure the generalized instantaneous quantity,  $\psi_k$  is *decomposed* into a weighted mean component and a fluctuation component [79, 140]:

$$\langle \psi_k \rangle_V = \widetilde{\langle \psi_k \rangle_V^{\alpha_k \rho_k}} + \langle \psi_k \rangle''_V \quad (3.328)$$

where  $\langle \psi_k \rangle''_V$  denotes the deviation between the instantaneous variable  $\langle \psi_k \rangle_V$  and it's mean mass-weighted component  $\widetilde{\langle \psi_k \rangle_V^{\alpha_k \rho_k}}$ .

The mean mass-weighted variable is defined as:

$$\widetilde{\langle \psi_k \rangle_V^{\alpha_k \rho_k}} = \frac{\overline{\langle \rho_k \rangle_V \langle \psi_k \rangle_V}}{\overline{\langle \rho_k \rangle_V}} \quad (3.329)$$

Alternatively, starting out from the mass-weighted volume averaged variables  $\langle \psi_k \rangle_V^{\alpha_k \rho_k}$ , a decomposition analogous to (3.328) can be defined as:

---

<sup>17</sup> For comparison we note that if we reverse the order in which we apply the averaging operators to the generalized quantity  $\psi$ , the deviation  $\widehat{\psi}_k$  between the un-smoothed local time averaged  $\overline{\psi}_k$  and the time- and volume averaged property value  $\langle \psi_k \rangle_V$  is defined by:

$$\widehat{\psi}_k = \overline{\psi}_k - \langle \psi_k \rangle_V \quad (3.326)$$

$$\langle \psi_k \rangle_V^{\alpha_k \rho_k} = \overline{\overline{\langle \psi_k \rangle_V^{\alpha_k \rho_k}}},^{\alpha_k \rho_k} + \langle \psi_k \rangle_V^{\alpha_k \rho_k, ''} \quad (3.330)$$

where  $\langle \psi_k \rangle_V^{\alpha_k \rho_k, ''}$  denotes the deviation between the instantaneous mass-weighted volume average variable  $\langle \psi_k \rangle_V^{\alpha_k \rho_k}$  and it's mass-weighted mean and mass-weighted volume average variable  $\overline{\overline{\langle \psi_k \rangle_V^{\alpha_k \rho_k}}},^{\alpha_k \rho_k}$ .

The mass-weighted mean and mass-weighted volume average variable is defined as:

$$\overline{\overline{\langle \psi_k \rangle_V^{\alpha_k \rho_k}}},^{\alpha_k \rho_k} = \frac{\overline{\langle \rho_k \rangle_V \langle \psi_k \rangle_V^{\alpha_k \rho_k}}}{\overline{\langle \rho_k \rangle_V}} \quad (3.331)$$

Multiplying relation (3.330) by  $\langle \rho_k \rangle_V$  and time average, the result is:

$$\overline{\langle \rho_k \rangle_V \langle \psi_k \rangle_V^{\alpha_k \rho_k}} = \overline{\langle \rho_k \rangle_V} \overline{\overline{\langle \psi_k \rangle_V^{\alpha_k \rho_k}}},^{\alpha_k \rho_k} + \overline{\langle \rho_k \rangle_V \langle \psi_k \rangle_V^{\alpha_k \rho_k, ''}} \quad (3.332)$$

A comparison with (3.331) reveals that the latter term in (3.332) equals zero:

$$\overline{\langle \rho_k \rangle_V \langle \psi_k \rangle_V^{\alpha_k \rho_k, ''}} = 0 \quad (3.333)$$

Moreover, the time average of the fluctuating components in (3.327) equals zero, whereas the time average of the fluctuating component in (3.328) is not equal to zero:

$$\overline{\langle \psi_k \rangle_V''} \neq \overline{\langle \psi_k \rangle_V'} = 0 \quad (3.334)$$

Furthermore, the time average of an instantaneous volume averaged quantity equals the volume average of a time averaged quantity:

$$\begin{aligned} \overline{\langle \psi_k \rangle_V} &= \frac{1}{T} \int_{t-T/2}^{t+T/2} \left[ \frac{1}{V} \int_V (\overline{\psi_k} + \psi_k') dv \right] dt = \frac{1}{V} \int_V \left[ \frac{1}{T} \int_{t-T/2}^{t+T/2} (\overline{\psi_k} + \psi_k') dt \right] dv \\ &= \overline{\langle \psi_k \rangle_V} \end{aligned} \quad (3.335)$$

It is noted that the particular forms of the Leibnitz's and Gauss' rules which are valid for time averaging of discontinuous functions and used in Sect. 3.5.2 are not applicable for the time after volume averaging process considered in this section, because the interfacial discontinuities are smoothed out after volume averaging has been performed [219]. Instead, the conventional single phase Favre and Reynolds temporal decomposition and time averaging concepts are valid and can be applied without modifications [79, 140, 190]. Besides, related to the single averaging operators like the volume averaging procedure described in Sect. 3.5.1, the main purpose of the Reynolds and Favre decomposition and averaging rules is to separate the averages of product into products of average. On the other hand, applying a time averaging operator to the instantaneous volume averaged variables the main purpose

is to separate the high frequency fluctuating components from the time-averaged variables in analogy to single phase turbulence modeling.

Taking (3.143) and (3.146) as starting point for the time averaging, we can write:

$$\begin{aligned} \frac{\partial \langle \rho_k \psi_k \rangle_V}{\partial t} + \nabla \cdot \langle \rho_k \mathbf{v}_k \psi_k \rangle_V + \nabla \cdot \langle \mathbf{J}_k \rangle_V \\ = -\frac{1}{V} \int_{A_I} \overline{(\dot{m}_k \psi_k)} da + \frac{1}{V} \int_{A_I} \overline{(\mathbf{J}_k \cdot \mathbf{n}_k)} da + \overline{\langle \sum_c \rho_{k,c} \phi_{k,c} \rangle_V} \end{aligned} \quad (3.336)$$

and

$$\frac{1}{V} \int_{A_I} \overline{(\sum_k [\dot{m}_k \psi_k + \mathbf{J}_k \cdot \mathbf{n}_k] + M_I)} da = 0 \quad (3.337)$$

So far in the derivation of the averaged equations the basic concepts used are considered fairly rigorous, but in order to put (3.336) and (3.337) into directly usable forms several modeling approaches have emerged proposing quite different manipulations and approximations of the undetermined terms.

The rigorous form of the averaged equations for the particular quantities governing phase  $k$  and the corresponding jump conditions can be achieved defining the specific values of the generic variables in (3.336) and (3.337) in accordance with Table 3.1.

*Mass:*

The time after volume averaged continuity equation appears by substituting  $\psi_k = 1$ ,  $\mathbf{J}_k = 0$  and  $\phi_{c,k} = 0$  into (3.336). The result is:

$$\frac{\partial \langle \rho_k \rangle_V}{\partial t} + \nabla \cdot \langle \rho_k \mathbf{v}_k \rangle_V = -\frac{1}{V} \int_{A_I} \overline{\dot{m}_k} da \quad (3.338)$$

Introducing the values for the interface properties  $M_I = 0$  into (3.337), we get:

$$\sum_k \overline{\Gamma_{Vk}} = 0 \quad (3.339)$$

The interfacial mass transfer terms due to phase change is defined by:

$$\overline{\Gamma_{Vk}} = -\frac{1}{V} \int_{A_I} \overline{\dot{m}_k} da = \overline{a_I \langle \dot{m}_k \rangle_{A_I}} \approx \overline{a_I} \overline{\langle \dot{m}_k \rangle_{A_I}} \quad (3.340)$$

in which the turbulent contributions are commonly lumped into the empirical model parameters or simply neglected.

*Momentum:*

The time after volume averaged momentum equation appears by substituting  $\psi_k = \mathbf{v}_k$ ,  $\mathbf{J}_k = \mathbf{T}_k$  and  $\phi_{c,k} = \mathbf{g}_{c,k}$  into (3.336). The result is:

$$\begin{aligned} & \frac{\partial(\overline{\langle \rho_k \mathbf{v}_k \rangle_V})}{\partial t} + \nabla \cdot (\overline{\langle \rho_k \mathbf{v}_k \mathbf{v}_k \rangle_V}) + \nabla \cdot (\overline{\langle \mathbf{T}_k \rangle_V}) \\ &= -\frac{1}{V} \int_{A_I} (\dot{m}_k \mathbf{v}_k + \mathbf{T}_k \cdot \mathbf{n}_k) da + \overline{\langle \sum_c \rho_c \mathbf{g}_c \rangle_V} \end{aligned} \quad (3.341)$$

Introducing the values for the interface properties  $\mathbf{M}_I = 2\sigma_I H_I \mathbf{n}_I + \nabla_I \sigma_I$  into (3.337), yields:

$$\sum_k (\overline{\mathbf{M}_k^I} + \overline{\mathbf{M}_k^T}) = -\frac{1}{V} \int_{A_I} \mathbf{M}_I da \quad (3.342)$$

The interfacial momentum transfer due to phase change is defined by time averaging (3.153):

$$\overline{\mathbf{M}_k^I} = -\frac{1}{V} \int_{A_I} \dot{m}_k \mathbf{v}_k da = \overline{\Gamma_{Vk} \langle \mathbf{v}_k \rangle_{A_I}^{\Gamma_{Vk}}} \approx \overline{\Gamma_{Vk} \langle \mathbf{v}_k \rangle_{A_I}^{\Gamma_{Vk}}} \quad (3.343)$$

in which the turbulent contributions are usually lumped into the empirical model parameters or simply neglected.

The interfacial momentum stresses (3.154) yield:

$$\overline{\mathbf{M}_k^T} = -\frac{1}{V} \int_{A_I} \mathbf{T}_k \cdot \mathbf{n}_k da = -\frac{1}{V} \int_{A_I} (p_k \mathbf{e} + \boldsymbol{\sigma}_k) \cdot \mathbf{n}_k da \quad (3.344)$$

in which the turbulent contributions are taken into account through the empirical drag coefficients. Sha et al. [204] also indicate that several additional covariance momentum transfer terms may occur due to high frequency fluctuations. For example, there may be interfacial stresses akin to Reynolds stresses, interfacial momentum transfer associated with the high frequency fluctuating mass generation which may not vanish locally, and interfacial momentum transfer due to eddy mass diffusion. However, experimentally its hard to distinguish between the different contributions, and the contributions of the high frequency correlation terms on the net interfacial momentum transfer flux are usually assumed to be of the same order of magnitude as the uncertainty reflected by the empirical drag coefficients.

By time averaging the term on the RHS of (3.152) can be expressed as

$$\frac{1}{V} \int_{A_I} \mathbf{M}_I da \approx 2 \overline{\langle \sigma_I \rangle_{A_I} \langle H_I \rangle_{A_I} \nabla \alpha_2} + \overline{a_I \langle \nabla_I \sigma_I \rangle_{A_I}}$$

$$\approx 2\overline{\langle\sigma_I\rangle_{A_I}}\overline{\langle H_I\rangle_{A_I}}\nabla\overline{\alpha_2} + \overline{a_I}\overline{\langle\nabla_I\sigma_I\rangle_{A_I}} \quad (3.345)$$

In these terms the turbulent contributions are usually neglected due to limited knowledge of the turbulent interfacial processes.

*Energy:*

The time after volume averaged energy equation appears by substituting  $\psi_k = e_k + \frac{1}{2}v_k^2$ ,  $\mathbf{J}_k = \mathbf{T}_k \cdot \mathbf{v}_k + \mathbf{q}_k$  and  $\phi_{c,k} = \mathbf{v}_k \cdot \mathbf{g}_{c,k}$  into (3.336). The averaged energy equation takes the form:

$$\begin{aligned} & \frac{\partial}{\partial t} \left( \overline{\langle \rho_k (e_k + \frac{1}{2}v_k^2) \rangle_V} \right) + \nabla \cdot \left( \overline{\langle \rho_k \mathbf{v}_k (e_k + \frac{1}{2}v_k^2) \rangle_V} \right) \\ & + \nabla \cdot \left( \overline{\langle \mathbf{T}_k \cdot \mathbf{v}_k \rangle_V} \right) + \nabla \cdot \left( \overline{\langle \mathbf{q}_k \rangle_V} \right) \\ & = -\frac{1}{V} \int_{A_I} \left( \dot{m}_k (e_k + \frac{1}{2}v_k^2) + (\mathbf{T}_k \cdot \mathbf{v}_k + \mathbf{q}_k) \cdot \mathbf{n}_k \right) da \\ & + \overline{\left\langle \sum_c \rho_{k,c} \mathbf{v}_{k,c} \cdot \mathbf{g}_{k,c} \right\rangle_V} \end{aligned} \quad (3.346)$$

Introducing the values for the interface properties

$M_I = \nabla_I \cdot \mathbf{q}_I - \nabla_I \cdot (\sigma_I \mathbf{v}_I)$  into (3.337), yields:

$$\sum_k \overline{(E_k^E + E_k^W + E_k^F)} = \frac{1}{V} \int_{A_I} M_I da \quad (3.347)$$

The time after volume averaged interfacial energy transfer due to phase change is defined by:

$$\begin{aligned} \overline{E_k^F} &= -\frac{1}{V} \int_{A_I} \dot{m}_k (e_k + \frac{1}{2}v_k^2) da = \overline{\Gamma_{Vk} \langle (e_k + \frac{1}{2}v_k^2) \rangle_{A_I}^{\Gamma_{Vk}}} \\ &\approx \overline{\Gamma_{Vk} \langle (e_k + \frac{1}{2}v_k^2) \rangle_{A_I}^{\Gamma_{Vk}}} \end{aligned} \quad (3.348)$$

in which the turbulent contribution is commonly lumped into the empirical model parameters.

The time after volume averaged interfacial heat transfer is given by:

$$\overline{E_k^E} = -\frac{1}{V} \int_{A_I} \mathbf{q}_k \cdot \mathbf{n}_k da = \overline{a_I \langle \mathbf{q}_k \cdot \mathbf{n}_k \rangle_{A_I}} \approx \overline{a_I \langle \mathbf{q}_k \cdot \mathbf{n}_k \rangle_{A_I}} \quad (3.349)$$

in which the turbulent contributions are usually lumped into the empirical model parameters. Nevertheless, in a few approaches the effective flux is split into a laminar and a turbulent contribution. It can be shown that the concepts of the averaging indicates that there may be contributions to the interfacial energy flux due to the high frequency fluctuations [203].

The interfacial work by viscous and pressure forces yields:

$$\overline{E_k^W} = -\frac{1}{V} \overline{\int_{A_I} (\boldsymbol{\tau}_k \cdot \mathbf{v}_k) \cdot \mathbf{n}_k da} \quad (3.350)$$

The surface energy sources are expressed as the product of the interfacial area concentration and the averaged interfacial fluxes:

$$\begin{aligned} \frac{1}{V} \overline{\int_{A_I} M_I da} &= -\frac{1}{V} \overline{\int_{A_I} (-\nabla_I \cdot (\sigma_I \mathbf{v}_I) + \nabla_I \cdot \mathbf{q}_I) da} \\ &= \overline{\langle \nabla_I \cdot (\sigma_I \mathbf{v}_I) \rangle_{A_I} a_I} - \overline{\langle \nabla_I \cdot \mathbf{q}_I \rangle_{A_I} a_I} \end{aligned} \quad (3.351)$$

The turbulent contributions are usually neglected due to limited understanding of the phenomena involved.

*Chemical species:*

The time after volume averaged species mass balance appears by substituting  $\psi_k = \omega_{k,s}$ ,  $\mathbf{J}_k = \mathbf{j}_{k,s}$  and  $\phi_{c,k} = R_{k,s}/\rho_{k,c}$  into (3.336). The averaged species mass balance becomes:

$$\begin{aligned} \frac{\partial(\overline{\langle \rho_{k,s} \rangle_V})}{\partial t} + \nabla \cdot (\overline{\langle \rho_{k,s} \mathbf{v}_k \rangle_V}) + \nabla \cdot (\overline{\langle \mathbf{j}_{k,s} \rangle_V}) \\ = -\frac{1}{V} \overline{\int_{A_I} (\dot{m}_k \omega_{k,s} + \mathbf{j}_{k,s} \cdot \mathbf{n}_k) da} + \overline{\langle R_{k,s} \rangle_V} \end{aligned} \quad (3.352)$$

Introducing the values for the interface properties  $M_I = R_{I,s}$  into (3.337), yields:

$$\sum_k \overline{(\mathbf{J}_{k,s}^F + \mathbf{J}_{k,s}^j)} = \frac{1}{V} \overline{\int_{A_I} M_I da} \quad (3.353)$$

The interfacial species mass transfer due to phase change is defined by:

$$\overline{\mathbf{J}_{k,s}^F} = -\frac{1}{V} \overline{\int_{A_I} \dot{m}_k \omega_{k,s} da} = \overline{\Gamma_{Vk} \langle \omega_{k,s} \rangle_{A_I}^{\Gamma_{Vk}}} \approx \overline{\Gamma_{Vk}} \overline{\langle \omega_{k,s} \rangle_{A_I}^{\Gamma_{Vk}}} \quad (3.354)$$

In the interfacial coupling terms the turbulent contributions are commonly taken into account through the empirical model parameters.

The other interfacial mass transfer fluxes are given by:

$$\overline{\mathbf{J}_k^j} = -\frac{1}{V} \int_{A_I} \mathbf{j}_k \cdot \mathbf{n}_k da = \overline{a_I \langle \mathbf{j}_k \cdot \mathbf{n}_k \rangle_{A_I}} \approx \overline{a_I} \overline{\langle \mathbf{j}_k \cdot \mathbf{n}_k \rangle_{A_I}} \quad (3.355)$$

The turbulent contributions are usually taken into account through the empirical model parameters or simply neglected due to the lack of understanding of these processes.

The interfacial production term due to heterogeneous reactions is normally rewritten as:

$$\frac{1}{V} \int_{A_I} M_I da = \frac{1}{V} \int_{A_I} R_{I,s} da = \overline{\langle R_{I,s} \rangle_{A_I} a_I} \approx \overline{\rho_{\text{Bulk}}} \overline{\langle R_{I,s} \rangle^m} \quad (3.356)$$

The turbulent contributions to the interfacial terms are normally neglected since our knowledge concerning these phenomena are limited.

In order to carry out computations with the time after volume averaged transport equations on the form (3.336) and (3.337), we need to relate the average of products to products of averages and derive constitutive equations for the interfacial coupling terms.

### 3.5.4.1 The Favre Decomposition Method

One way to solve the first problem is to introduce mass- and phase weighted volume averaged variables and the concepts of spatial and temporal decomposition of the volume averaged variables. The mass-weighted volume average of the quantity  $\psi_k$  is defined by (3.187) and the phase-weighted volume average is defined by (3.123). However, for dispersed flows all the spatial covariances are neglected in this averaging method [78, 219, 220]. The turbulence effects are thereafter considered by temporal decomposition of the weighted quantities followed by time averaging in a way resembling the analysis of variable density single phase flows [79, 140]. In particular, mass-weighted averaging akin to Favre averaging in compressible flows is employed in accordance with the work of [93, 124, 148]. This approach has the merit of reducing the number of covariance terms emerging after the averaging operation as compared to conventional Reynolds averaging. The phase velocities and the scalar variables representing the balanced quantities are normally mass-weighted before they are temporally decomposed into phase mean and fluctuating components, while the remaining scalar variables are decomposed into phase mean and fluctuating components without any prior mass-weighting.

From (3.189) the volume averaged mass flux of phase  $k$  in (3.143) is reformulated using a spatial decomposition (3.188) of the velocity variable. Thus, we can write:

$$\langle \rho_k \mathbf{v}_k \rangle_V = \langle \rho_k (\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} + \widehat{\mathbf{v}}_k) \rangle_V = \langle \rho_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \quad (3.357)$$

The subsequent temporal decomposition of the scalar variables is as a main rule performed in accordance with (3.327), while the velocity and  $\psi_k$  variables are decomposed using the approach for mass-weighted variables (3.330). After time averaging the mass flux (3.357) of phase  $k$ , we obtain:

$$\begin{aligned} \overline{\langle \rho_k \mathbf{v}_k \rangle_V} &= \overline{\langle \rho_k \rangle_V (\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} + \widehat{\mathbf{v}}_k)}^{\alpha_k \rho_k} = \overline{\langle \rho_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''}} + \overline{\langle \rho_k \rangle_V \widehat{\mathbf{v}}_k}^{\alpha_k \rho_k} \\ &= \overline{\langle \rho_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}}^{\alpha_k \rho_k} + \overline{\langle \rho_k \rangle_V \widehat{\mathbf{v}}_k}^{\alpha_k \rho_k, ''} \\ &= \overline{\langle \rho_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}}^{\alpha_k \rho_k} \end{aligned} \quad (3.358)$$

Besides, the term  $\overline{\langle \rho_k \rangle_V} = \overline{\alpha_k \langle \rho_k \rangle_{V_k}}$  is treated as one field variable for compressible flows, whereas for incompressible flows the mass-weighted average variable reduces to a phase-weighted average.

In accordance with (3.190) the convective term in the generic volume averaged equation (3.143) is manipulated introducing mass-weighted variables (3.187) and the concept of spatial decomposition (3.188). Hence, the volume averaged convection term is given by:

$$\begin{aligned} \langle \rho_k \mathbf{v}_k \psi_k \rangle_V &= \langle \rho_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \langle \psi_k \rangle_V^{\alpha_k \rho_k} + \langle \rho_k \widehat{\psi}_k \widehat{\mathbf{v}}_k \rangle_V \\ &\approx \langle \rho_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \langle \psi_k \rangle_V^{\alpha_k \rho_k} \end{aligned} \quad (3.359)$$

in which the volume average of products is approximated by the product of averages. That is, the covariance of the spatial deviation variables are normally neglected.

With a temporal decomposition of the volume averaged variables (3.327) and (3.330), we get:

$$\begin{aligned} \overline{\langle \rho_k \mathbf{v}_k \psi_k \rangle_V} &\approx \overline{\langle \rho_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \langle \psi_k \rangle_V^{\alpha_k \rho_k}} \\ &= \overline{\langle \rho_k \rangle_V (\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} + \widehat{\mathbf{v}}_k) (\langle \psi_k \rangle_V^{\alpha_k \rho_k} + \widehat{\psi}_k)}^{\alpha_k \rho_k} \\ &= \overline{\langle \rho_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \langle \psi_k \rangle_V^{\alpha_k \rho_k}}^{\alpha_k \rho_k} + \overline{\langle \rho_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \widehat{\psi}_k}^{\alpha_k \rho_k} \\ &\quad + \overline{\langle \rho_k \rangle_V \widehat{\mathbf{v}}_k \langle \psi_k \rangle_V^{\alpha_k \rho_k}}^{\alpha_k \rho_k} + \overline{\langle \rho_k \rangle_V \widehat{\mathbf{v}}_k \widehat{\psi}_k}^{\alpha_k \rho_k} \\ &= \overline{\langle \rho_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \langle \psi_k \rangle_V^{\alpha_k \rho_k}}^{\alpha_k \rho_k} + \overline{\langle \rho_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''} \langle \psi_k \rangle_V^{\alpha_k \rho_k, ''}}^{\alpha_k \rho_k} \end{aligned} \quad (3.360)$$

Using (3.358) and (3.360) the averaged equations governing phase  $k$  can be modeled as:

*Mass:*

The reformulated time after volume averaged continuity equation appears by substituting (3.358) into (3.338). The result is:

$$\frac{\partial(\overline{\langle \rho_k \rangle_V})}{\partial t} + \nabla \cdot (\overline{\langle \rho_k \rangle_V} \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}},^{\alpha_k \rho_k}) = \overline{\Gamma_k} \quad (3.361)$$

in which the source term  $\overline{\Gamma_k}$  may be a complex function of low and high frequency contributions. However, in most reactor simulations only the low-frequency contributions are taken into account.

*Momentum:*

The reformulated time after volume averaged momentum equation appears by substituting (3.187) and (3.360) into (3.341). The result is:

$$\begin{aligned} & \frac{\partial}{\partial t} \left( \overline{\langle \rho_k \rangle_V} \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}},^{\alpha_k \rho_k} \right) + \nabla \cdot \left( \overline{\langle \rho_k \rangle_V} \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}},^{\alpha_k \rho_k} \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}},^{\alpha_k \rho_k} \right) \\ &= - \nabla \cdot \left( \overline{\langle \rho_k \rangle_V} \overline{\langle p_k \rangle_V} \right) - \nabla \cdot \left( \overline{\langle \rho_k \rangle_V} \overline{\langle \boldsymbol{\sigma}_k \rangle_V^{Re}},^{\alpha_k} + \overline{\langle \boldsymbol{\sigma}_k \rangle_V^{Re}},^{\alpha_k} \right) \\ & \quad - \frac{1}{V} \int_{A_I} (\dot{m}_k \mathbf{v}_k + \mathbf{T}_k \cdot \mathbf{n}_k) da + \overline{\langle \rho_k \rangle_V} \sum_c \overline{\langle \omega_{k,c} \rangle_V^{\alpha_k \rho_k}} \mathbf{g}_{k,c} \end{aligned} \quad (3.362)$$

The time after volume averaged momentum flux is given in accordance with (3.360) as:

$$\begin{aligned} \overline{\langle \rho_k \mathbf{v}_k \mathbf{v}_k \rangle_V} &= \overline{\langle \rho_k \rangle_V} \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}},^{\alpha_k \rho_k} \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}},^{\alpha_k \rho_k} \\ & \quad + \overline{\langle \rho_k \rangle_V} \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''}},^{\alpha_k \rho_k, ''} \end{aligned} \quad (3.363)$$

The second term on the RHS of (3.363) represents the Reynolds stress of phase  $k$ , defined by:

$$\overline{\langle \boldsymbol{\sigma}_k \rangle_V^{Re}} = \overline{\langle \rho_k \rangle_V} \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''}},^{\alpha_k \rho_k, ''} \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''}},^{\alpha_k \rho_k, ''} \quad (3.364)$$

We may introduce a phase weighted Reynolds stress in analogy to the quantities used in the multiphase single averaging operators [148]. The phase-weighted Reynolds stress term can be defined by:

$$\overline{\langle \boldsymbol{\sigma}_k \rangle_V^{Re}}^{\alpha_k} = \frac{\overline{\langle \boldsymbol{\sigma}_k \rangle_V^{Re}}}{\overline{\alpha_k}} = \frac{\overline{\langle \rho_k \rangle_V} \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''}},^{\alpha_k \rho_k, ''} \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''}},^{\alpha_k \rho_k, ''}}{\overline{\alpha_k}} \quad (3.365)$$

which needs to be modeled by a suitable turbulence model for phase  $k$ .

A consistent phase-weighted definition of the time after volume averaged viscous stress term yields:

$$\overline{\langle \sigma_k \rangle_V}^{\alpha_k} = \frac{\overline{\langle \sigma_k \rangle_V}}{\overline{\alpha_k}} \quad (3.366)$$

The pressure term is normally rewritten using the conventional Reynolds decomposition concept, thus:

$$\begin{aligned} \nabla \cdot \overline{\langle p_k \mathbf{e} \rangle_V} &= \nabla \cdot \overline{\langle p_k \rangle_V} = \nabla \cdot \left( \overline{\alpha_k \langle p_k \rangle_{V_k}} + \overline{\alpha'_k \langle p_k \rangle'_{V_k}} \right) \\ &\approx \nabla \cdot (\overline{\alpha_k} \overline{\langle p_k \rangle_{V_k}}) \end{aligned} \quad (3.367)$$

The temporal covariance term is normally neglected due to the lack of knowledge on the physical processes taking place (i.e.,  $\overline{\alpha'_k \langle p_k \rangle'_{V_k}} \approx 0$ ). Preliminary analysis based on a hypothesis that these terms are of diffusive nature has been performed by [127]. The source term is derived in the following way:

$$\begin{aligned} \sum_c \overline{\langle \rho_{k,c} \rangle_V} \mathbf{g}_{k,c} &= \sum_c \overline{\langle \rho_k \omega_{k,c} \rangle_V} \mathbf{g}_{k,c} \\ &= \overline{\langle \rho_k \rangle_V} \sum_c \overline{\overline{\langle \omega_{k,c} \rangle_V}^{\alpha_k \rho_k}} \mathbf{g}_{k,c} \end{aligned} \quad (3.368)$$

in which the particular scalar  $\omega_{k,c}$  denoting the balanced species mass fraction is represented by a mass-weighted quantity.

*Energy:*

The reformulated time after volume averaged energy equation appears by substituting (3.187) and (3.360) into (3.346). The energy equation takes the form:

$$\begin{aligned} &\frac{\partial}{\partial t} (\overline{\langle \rho_k \rangle_V} \overline{\overline{\langle E_k \rangle_V}^{\alpha_k \rho_k}})^{\alpha_k \rho_k} + \nabla \cdot (\overline{\langle \rho_k \rangle_V} \overline{\overline{\langle \mathbf{v} \rangle_V}^{\alpha_k \rho_k}})^{\alpha_k \rho_k} \overline{\overline{\langle E_k \rangle_V}^{\alpha_k \rho_k}})^{\alpha_k \rho_k} \\ &= - \nabla \cdot (\overline{\langle p_k \rangle_V} \overline{\overline{\langle \mathbf{v}_k \rangle_V}^{\alpha_k \rho_k}})^{\alpha_k \rho_k} - \nabla \cdot (\overline{\langle \mathbf{q}_k \rangle_V}) \\ &\quad - \nabla \cdot (\overline{\langle \mathbf{v}_k \rangle_V}^{\alpha_k \rho_k})^{\alpha_k \rho_k} \cdot (\overline{\langle \sigma_k \rangle_V} + \overline{\langle \sigma \rangle_V}^{Re}) \\ &\quad + \nabla \cdot (\overline{\langle \rho_k \rangle_V} D_{k,t}^{e_k} \nabla \overline{\overline{\langle e_k \rangle_V}^{\alpha_k \rho_k}})^{\alpha_k \rho_k} \\ &\quad - \frac{1}{V} \int_{A_I} \left( \dot{m}_k (e_k + \frac{1}{2} v_k^2) + (\mathbf{T}_k \cdot \mathbf{v}_k + \mathbf{q}_k) \cdot \mathbf{n}_k \right) da + \overline{\langle \rho_k \rangle_V} \\ &\quad \times \sum_c \left( \overline{\overline{\langle \omega_{k,c} \rangle_V}^{\alpha_k \rho_k}})^{\alpha_k \rho_k} \overline{\overline{\langle \mathbf{v}_{k,c} \rangle_V}^{\alpha_k \rho_k}})^{\alpha_k \rho_k} - D_{k,t}^{\omega_{k,s}} \nabla \overline{\overline{\langle \omega_{k,c} \rangle_V}^{\alpha_k \rho_k}})^{\alpha_k \rho_k} \cdot \mathbf{g}_{k,c} \right) \end{aligned} \quad (3.369)$$

where  $\overline{\overline{\langle E_k \rangle_V}^{\alpha_k \rho_k}})^{\alpha_k \rho_k} = \overline{\overline{\langle e_k \rangle_V}^{\alpha_k \rho_k}})^{\alpha_k \rho_k} + \frac{1}{2} (\overline{\overline{\langle \mathbf{v}_k \rangle_V}^{\alpha_k \rho_k}})^{\alpha_k \rho_k} \cdot \overline{\overline{\langle \mathbf{v}_k \rangle_V}^{\alpha_k \rho_k}})^{\alpha_k \rho_k}$ .

The transient terms in (3.346) are reformulated in the following way:

$$\begin{aligned}
\overline{\langle \rho_k (e_k + \frac{1}{2} v_k^2) \rangle_V} &= \overline{\langle \rho_k e_k \rangle_V} + \frac{1}{2} \overline{\langle \rho_k v_k^2 \rangle_V} \\
&= \overline{\langle \rho_k e_k \rangle_V} + \frac{1}{2} \overline{\langle \rho_k (\mathbf{v}_k \cdot \mathbf{v}_k) \rangle_V}
\end{aligned} \tag{3.370}$$

in which we adopt (3.187) for the *internal energy*-density covariance:

$$\overline{\langle \rho_k e_k \rangle_V} = \overline{\langle \rho_k \rangle_V} \overline{\langle e_k \rangle_V}^{\alpha_k \rho_k} \tag{3.371}$$

where the particular scalar  $e_k$  denoting the internal energy is represented by a mass-weighted quantity.

The *kinetic energy term* in (3.346) is more cumbersome to deal with. The volume average kinetic energy term yields:

$$\begin{aligned}
\langle \rho_k (\mathbf{v}_k \cdot \mathbf{v}_k) \rangle_V &= \langle \rho_k ((\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} + \widehat{\mathbf{v}}_k) \cdot (\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} + \widehat{\mathbf{v}}_k)) \rangle_V \\
&= \langle \rho_k (\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \cdot \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} + 2 \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \cdot \widehat{\mathbf{v}}_k + \widehat{\mathbf{v}}_k \cdot \widehat{\mathbf{v}}_k) \rangle_V \\
&= \langle \rho_k \rangle_V (\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \cdot \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}) + \langle \rho_k \rangle_V (\widehat{\mathbf{v}}_k \cdot \widehat{\mathbf{v}}_k) \\
&\approx \langle \rho_k \rangle_V (\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \cdot \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k})
\end{aligned} \tag{3.372}$$

After time averaging the volume averaged kinetic energy term, we get:

$$\begin{aligned}
\overline{\langle \rho_k (\mathbf{v}_k \cdot \mathbf{v}_k) \rangle_V} &\approx \overline{\langle \rho_k \rangle_V (\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \cdot \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k})} \\
&= \overline{\langle \rho_k \rangle_V ((\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} + \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''}) \cdot (\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} + \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''}))} \\
&= \overline{\langle \rho_k \rangle_V (\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \cdot \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k})} + \overline{\langle \rho_k \rangle_V (\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''} \cdot \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''})} \\
&\approx \overline{\langle \rho_k \rangle_V (\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \cdot \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k})}
\end{aligned} \tag{3.373}$$

The *convective energy flux* in (3.346) is also split into two separate contributions:

$$\begin{aligned}
\overline{\langle \rho_k \mathbf{v}_k (e_k + \frac{1}{2} v_k^2) \rangle_V} &= \overline{\langle \rho_k \mathbf{v}_k e_k \rangle_V} + \frac{1}{2} \overline{\langle \rho_k \mathbf{v}_k v_k^2 \rangle_V} \\
&= \overline{\langle \rho_k \mathbf{v}_k e_k \rangle_V} + \frac{1}{2} \overline{\langle \rho_k \mathbf{v}_k (\mathbf{v}_k \cdot \mathbf{v}_k) \rangle_V}
\end{aligned} \tag{3.374}$$

The time after volume averaged internal energy flux, i.e., the first term on the RHS of (3.374), is reformulated in accordance with (3.360) and given by:

$$\begin{aligned}
\overline{\langle \rho_k \mathbf{v}_k e_k \rangle_V} &= \overline{\langle \rho_k \rangle_V} \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}} \overline{\langle e_k \rangle_V^{\alpha_k \rho_k}} \\
&\quad + \overline{\langle \rho_k \rangle_V} \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''}} \overline{\langle e_k \rangle_V^{\alpha_k \rho_k, ''}}
\end{aligned} \tag{3.375}$$

The second term on the RHS of (3.375) represents the thermal transport due to the fluctuations in velocity and internal energy. This term can be modeled in accordance with the gradient hypothesis and the Boussinesq transport coefficient concept. That is, we approximate the covariance by:

$$\overline{\langle \rho_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''} \langle e_k \rangle_V^{\alpha_k \rho_k, ''}} = -\overline{\langle \rho_k \rangle_V} D_{k,t}^{e_k} \nabla \overline{\langle e_k \rangle_V^{\alpha_k \rho_k, ''}}, \alpha_k \rho_k \quad (3.376)$$

and  $D_{k,t}^{e_k}$  is the eddy thermal diffusivity.

The volume averaged *kinetic energy flux* in (3.374) is given by:

$$\begin{aligned} & \langle \rho_k \mathbf{v}_k (\mathbf{v}_k \cdot \mathbf{v}_k) \rangle_V \\ &= \langle \rho_k (\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} + \widehat{\mathbf{v}}_k) ((\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} + \widehat{\mathbf{v}}_k) \cdot (\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} + \widehat{\mathbf{v}}_k)) \rangle_V \\ &= \langle \rho_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} (\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \cdot \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}) \\ &\quad + \langle \rho_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} (2 \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \cdot \widehat{\mathbf{v}}_k + \widehat{\mathbf{v}}_k \cdot \widehat{\mathbf{v}}_k) \rangle_V \\ &\quad + \langle \rho_k \widehat{\mathbf{v}}_k (\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \cdot \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} + 2 \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \cdot \widehat{\mathbf{v}}_k + \widehat{\mathbf{v}}_k \cdot \widehat{\mathbf{v}}_k) \rangle_V \\ &= \langle \rho_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} (\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \cdot \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} + \widehat{\mathbf{v}}_k \cdot \widehat{\mathbf{v}}_k) \rangle_V \\ &\quad + 2 \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \cdot \langle \rho_k \widehat{\mathbf{v}}_k \widehat{\mathbf{v}}_k \rangle_V + \langle \rho_k \widehat{\mathbf{v}}_k (\widehat{\mathbf{v}}_k \cdot \widehat{\mathbf{v}}_k) \rangle_V \\ &\approx \langle \rho_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} (\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \cdot \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}) \end{aligned} \quad (3.377)$$

After introducing a temporal decomposition of the mass-weighted velocity variable and time averaging the volume averaged term in (3.377), we get:

$$\begin{aligned} \overline{\langle \rho_k \mathbf{v}_k (\mathbf{v}_k \cdot \mathbf{v}_k) \rangle_V} &\approx \overline{\langle \rho_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} (\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \cdot \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k})} \\ &= \overline{\langle \rho_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}} \cdot \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \cdot \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}} \\ &\quad + \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}} \cdot \overline{\langle \rho_k \rangle_V (\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''} \cdot \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''})} \\ &\quad + \overline{2 \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \cdot \langle \rho_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''} \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''}} \\ &\quad + \overline{\langle \rho_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''} (\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''} \cdot \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''})} \\ &\approx \overline{\langle \rho_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}} \cdot \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \cdot \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}} \\ &\quad + \overline{2 \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \cdot \langle \rho_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''} \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''}} \end{aligned} \quad (3.378)$$

The second term on the RHS of (3.378) represents the energy transport due to the fluctuations in velocity. This term can be expressed in terms of the Reynolds stresses as:

$$\overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}} \cdot \overline{\langle \rho_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''} \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''}} = \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}} \cdot \overline{\langle \boldsymbol{\sigma}_k \rangle_V^{Re}} \quad (3.379)$$

In addition, the volume averaged expansion work in (3.346) is estimated by:

$$\begin{aligned}
\nabla \cdot (\langle p_k \mathbf{e} \cdot \mathbf{v}_k \rangle_V) &= \nabla \cdot (\langle p_k \mathbf{v}_k \rangle_V) \\
&= \nabla \cdot (\langle (p_k)_V + \widehat{p}_k \rangle (\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} + \widehat{\mathbf{v}}_k))_V \\
&= \nabla \cdot (\langle p_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} + \langle p_k \rangle_V \langle \widehat{\mathbf{v}}_k \rangle_V \\
&\quad + \langle \widehat{p}_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} + \langle \widehat{p}_k \widehat{\mathbf{v}}_k \rangle_V) \\
&\approx \nabla \cdot (\langle p_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k})
\end{aligned} \tag{3.380}$$

After time averaging the volume averaged expansion work term, the result is:

$$\begin{aligned}
\nabla \cdot \overline{\langle p_k \mathbf{e} \cdot \mathbf{v}_k \rangle_V} &= \nabla \cdot \overline{\langle p_k \mathbf{v}_k \rangle_V} \\
&\approx \nabla \cdot \overline{\langle p_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}} \\
&= \nabla \cdot (\overline{\langle p_k \rangle_V} + \langle p_k \rangle'_V) \cdot \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}} + \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''}} \\
&= \nabla \cdot (\overline{\langle p_k \rangle_V} \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}} + \overline{\langle p_k \rangle_V} \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''}} \\
&\quad + \langle p_k \rangle'_V \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''}}) \\
&\approx \nabla \cdot (\overline{\langle p_k \rangle_V} \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}})
\end{aligned} \tag{3.381}$$

The work performed by the viscous forces in (3.346) is treated in a similar manner. The volume averaged term is approximated as:

$$\begin{aligned}
\nabla \cdot (\langle \boldsymbol{\sigma}_k \cdot \mathbf{v}_k \rangle_V) &= \nabla \cdot (\langle (\boldsymbol{\sigma}_k)_V + \widehat{\boldsymbol{\sigma}}_k \rangle \cdot (\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} + \widehat{\mathbf{v}}_k))_V \\
&= \nabla \cdot (\langle \boldsymbol{\sigma}_k \rangle_V \cdot \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} + \langle \boldsymbol{\sigma}_k \rangle_V \cdot \langle \widehat{\mathbf{v}}_k \rangle_V \\
&\quad + \langle \widehat{\boldsymbol{\sigma}}_k \rangle_V \cdot \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} + \langle \widehat{\boldsymbol{\sigma}}_k \cdot \widehat{\mathbf{v}}_k \rangle_V) \\
&\approx \nabla \cdot (\langle \boldsymbol{\sigma}_k \rangle_V \cdot \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k})
\end{aligned} \tag{3.382}$$

By time averaging the result is:

$$\begin{aligned}
\nabla \cdot \overline{\langle \boldsymbol{\sigma}_k \cdot \mathbf{v}_k \rangle_V} &\approx \nabla \cdot \overline{\langle \boldsymbol{\sigma}_k \rangle_V \cdot \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}} \\
&= \nabla \cdot (\overline{\langle \boldsymbol{\sigma}_k \rangle_V} + \langle \boldsymbol{\sigma}_k \rangle'_V) \cdot \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}} + \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''}} \\
&= \nabla \cdot (\overline{\langle \boldsymbol{\sigma}_k \rangle_V} \cdot \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}} + \overline{\langle \boldsymbol{\sigma}_k \rangle_V} \cdot \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''}} \\
&\quad + \langle \boldsymbol{\sigma}_k \rangle'_V \cdot \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''}}) \\
&\approx \nabla \cdot (\overline{\langle \boldsymbol{\sigma}_k \rangle_V} \cdot \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}})
\end{aligned} \tag{3.383}$$

The variables in the body force (3.346) are spatially decomposed and volume averaged, the result can be expressed as:

$$\begin{aligned}
\langle \sum_c \rho_{k,c} \mathbf{v}_{k,c} \cdot \mathbf{g}_{k,c} \rangle_V &= \sum_c \langle \rho_k \omega_{k,c} \mathbf{v}_{k,c} \rangle_V \cdot \mathbf{g}_{k,c} \\
&= \sum_c (\langle \rho_k \rangle_V \langle \omega_{k,c} \rangle_V^{\alpha_k \rho_k} \langle \mathbf{v}_{k,c} \rangle_V^{\alpha_k \rho_k} + \langle \rho_k \widehat{\omega}_{k,c} \widehat{\mathbf{v}}_{k,c} \rangle_V) \cdot \mathbf{g}_{k,c} \\
&\approx \langle \rho_k \rangle_V \sum_c \langle \omega_{k,c} \rangle_V^{\alpha_k \rho_k} (\langle \mathbf{v}_{k,c} \rangle_V^{\alpha_k \rho_k} \cdot \mathbf{g}_{k,c})
\end{aligned} \tag{3.384}$$

By subsequent time averaging, yields:

$$\begin{aligned}
\overline{\langle \sum_c \rho_{k,c} \mathbf{v}_{k,c} \cdot \mathbf{g}_{k,c} \rangle_V} &= \sum_c \overline{\langle \rho_k \omega_{k,c} \mathbf{v}_{k,c} \rangle_V \cdot \mathbf{g}_{k,c}} \\
&\approx \sum_c \overline{\langle \rho_k \rangle_V \langle \omega_{k,c} \rangle_V^{\alpha_k \rho_k} \langle \mathbf{v}_{k,c} \rangle_V^{\alpha_k \rho_k} \cdot \mathbf{g}_{k,c}} \\
&= \sum_c (\overline{\langle \rho_k \rangle_V} \overline{\langle \omega_{k,c} \rangle_V^{\alpha_k \rho_k}} \overline{\langle \mathbf{v}_{k,c} \rangle_V^{\alpha_k \rho_k}}) \cdot \mathbf{g}_{k,c} \\
&\quad + \sum_c (\overline{\langle \rho_k \rangle_V \langle \omega_{k,c} \rangle_V^{\alpha_k \rho_k, ''} \langle \mathbf{v}_{k,c} \rangle_V^{\alpha_k \rho_k, ''}}) \cdot \mathbf{g}_{k,c} \\
&\approx \overline{\langle \rho_k \rangle_V} \sum_c (\overline{\langle \omega_{k,c} \rangle_V^{\alpha_k \rho_k}} \overline{\langle \mathbf{v}_{k,c} \rangle_V^{\alpha_k \rho_k}} - D_{k,t} \nabla \overline{\langle \omega_{k,c} \rangle_V^{\alpha_k \rho_k}}) \cdot \mathbf{g}_{k,c}
\end{aligned} \tag{3.385}$$

The second term on the RHS represents the species mass transport due to the fluctuations in velocity and species mass fractions. This term is modeled as:

$$\overline{\langle \rho_k \rangle_V \langle \mathbf{v}_{k,c} \rangle_V^{\alpha_k \rho_k, ''} \langle \omega_{k,s} \rangle_V^{\alpha_k \rho_k, ''}} \approx -\overline{\langle \rho_k \rangle_V} D_{k,t}^{\omega_{k,s}} \nabla \overline{\langle \omega_k \rangle_V^{\alpha_k \rho_k}} \tag{3.386}$$

in which  $D_{k,t}^{\omega_{k,s}}$  is the eddy mass diffusivity.

*Chemical species:*

The reformulated time after volume averaged species mass balance appears by substituting (3.187) and (3.360) into (3.352). The averaged species mass balance becomes:

$$\begin{aligned}
\frac{\partial}{\partial t} (\overline{\langle \rho_k \rangle_V} \overline{\langle \omega_{k,s} \rangle_V^{\alpha_k \rho_k}}) &+ \nabla \cdot (\overline{\langle \rho_k \rangle_V} \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k}} \overline{\langle \omega_{k,s} \rangle_V^{\alpha_k \rho_k}}) \\
&= -\nabla \cdot (\overline{\langle \mathbf{j}_{k,s} \rangle_V}) + \nabla \cdot (\overline{\langle \rho_k \rangle_V} D_{k,t}^{\omega_{k,s}} \nabla \overline{\langle \omega_k \rangle_V^{\alpha_k \rho_k}}) \\
&\quad - \frac{1}{V} \int_{A_I} (\dot{m}_k \omega_{k,s} + \mathbf{j}_{k,s} \cdot \mathbf{n}_k) da + \overline{\langle R_{k,s} \rangle_V}
\end{aligned} \tag{3.387}$$

The transient term in (3.387) is modeled as:

$$\overline{\langle \rho_{k,s} \rangle_V} = \overline{\langle \rho_k \omega_{k,s} \rangle_V} = \overline{\langle \rho_k \rangle_V \langle \omega_{k,s} \rangle_V^{\alpha_k \rho_k}}$$

$$\begin{aligned}
&= \overline{\overline{\langle \rho_k \rangle_V \langle \omega_{k,s} \rangle_V^{\alpha_k \rho_k}}},^{\alpha_k \rho_k} + \overline{\langle \omega_{k,s} \rangle_V^{\alpha_k \rho_k, ''}} \quad (3.388) \\
&= \overline{\langle \rho_k \rangle_V \langle \omega_{k,s} \rangle_V^{\alpha_k \rho_k}},^{\alpha_k \rho_k} + \overline{\langle \rho_k \rangle_V \langle \omega_{k,s} \rangle_V^{\alpha_k \rho_k, ''}} \\
&= \overline{\langle \rho_k \rangle_V \langle \omega_{k,s} \rangle_V^{\alpha_k \rho_k}},^{\alpha_k \rho_k}
\end{aligned}$$

The time after volume averaged convective mass flux of species  $s$  in (3.387) is approximated in accordance with (3.360) and given by:

$$\begin{aligned}
\overline{\langle \rho_k \mathbf{v}_k \omega_{k,s} \rangle_V} &= \overline{\langle \rho_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \langle \omega_{k,s} \rangle_V^{\alpha_k \rho_k}},^{\alpha_k \rho_k} \\
&\quad + \overline{\langle \rho_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k, ''} \langle \omega_{k,s} \rangle_V^{\alpha_k \rho_k, ''}} \quad (3.389) \\
&\approx \overline{\langle \rho_k \rangle_V \langle \mathbf{v}_k \rangle_V^{\alpha_k \rho_k} \langle \omega_{k,s} \rangle_V^{\alpha_k \rho_k}},^{\alpha_k \rho_k} \\
&\quad - \overline{\langle \rho_k \rangle_V D_{k,t}^{\omega_{k,s}} \nabla \langle \omega_k \rangle_V^{\alpha_k \rho_k}},^{\alpha_k \rho_k}
\end{aligned}$$

*Time after volume averaged equations for incompressible fluid.*

We end this section by summarizing the governing equations valid for *incompressible fluids*, since this model formulation is often used in engineering research. For incompressible fluids the fluid properties (e.g.,  $\rho_k$ ,  $\mu_k$ ) are constants so the density variable is conveniently denoted by  $\rho_k$  and simply moved outside the averaging overlined bracket. For these particular flows the mass-weighted and the phase-weighted averaged quantities are equal, thus:

$$\overline{\langle \psi_k \rangle_V^{\rho_k \alpha_k}},^{\alpha_k \rho_k} = \frac{\overline{\rho_k \alpha_k \langle \psi_k \rangle_V}}{\rho_k \alpha_k} = \overline{\langle \psi_k \rangle_V^{\alpha_k}},^{\alpha_k} = \frac{\overline{\alpha_k \langle \psi_k \rangle_V}}{\alpha_k} \quad (3.390)$$

The relationship between the conventional Reynolds time average in (3.327) and the weighted Favre time average variables in (3.330) follows directly from their definitions [140]:

$$\begin{aligned}
\langle \psi_k \rangle_V &= \overline{\langle \psi_k \rangle_V} + \langle \psi_k \rangle_V' = \overline{\langle \psi_k \rangle_V^{\alpha_k \rho_k}},^{\alpha_k \rho_k} + \langle \psi_k \rangle_V^{\alpha_k \rho_k, ''} \\
&= \overline{\langle \psi_k \rangle_V^{\alpha_k}},^{\alpha_k} + \langle \psi_k \rangle_V^{\alpha_k, ''} \quad (3.391)
\end{aligned}$$

Decomposing the phase-weighted volume averaged quantity in (3.390) using the Favre procedure, we get:

$$\begin{aligned}
\overline{\alpha_k \langle \psi_k \rangle_V} &= \overline{\alpha_k \langle \psi_k \rangle_V^{\alpha_k}},^{\alpha_k} = \overline{\alpha_k (\langle \psi_k \rangle_V^{\alpha_k} + \langle \psi_k \rangle_V^{\alpha_k, ''})} \\
&= \overline{\alpha_k \langle \psi_k \rangle_V^{\alpha_k}},^{\alpha_k} + \overline{\alpha_k \langle \psi_k \rangle_V^{\alpha_k, ''}} \\
&= \overline{\alpha_k \langle \psi_k \rangle_V^{\alpha_k}} \quad (3.392)
\end{aligned}$$

Comparing (3.392) with the definition of the weighted component of  $\psi_k$  given by (3.390), it follows that:

$$\overline{\alpha_k \langle \psi_k \rangle_V^{\alpha_k, ''}} = 0 \quad (3.393)$$

An important consequence of (3.393) is that:

$$\overline{\alpha_k \langle \psi_k \rangle_V^{\alpha_k, ''}} = \overline{(\overline{\alpha_k} + \alpha'_k) \langle \psi_k \rangle_V^{\alpha_k, ''}} = \overline{\alpha_k} \overline{\langle \psi_k \rangle_V^{\alpha_k, ''}} + \overline{\alpha'_k \langle \psi_k \rangle_V^{\alpha_k, ''}} = 0 \quad (3.394)$$

After rearranging, the resulting relation yields:

$$\overline{\langle \psi_k \rangle_V^{\alpha_k, ''}} = - \frac{\overline{\alpha'_k \langle \psi_k \rangle_V^{\alpha_k, ''}}}{\overline{\alpha_k}} \neq 0 \quad (3.395)$$

This means that the time average of the fluctuation component, related to the phase weighted averaged variables, is not zero by definition.

Besides, multiplying both sides of the expression (3.391) by  $\alpha_k$  and thereafter time averaging the resulting equation, we get a relation between the Favre and Reynolds averaged variables:

$$\overline{\alpha_k \langle \psi_k \rangle_V} = \overline{\alpha_k} \overline{\langle \psi_k \rangle_V} + \overline{\alpha'_k \langle \psi_k \rangle_V} = \overline{\alpha_k \langle \psi_k \rangle_V^{\alpha_k \rho_k}},^{\alpha_k} + \overline{\alpha_k \langle \psi_k \rangle_V^{\alpha_k, ''}} \quad (3.396)$$

Then, since  $\overline{\alpha_k \langle \psi_k \rangle_V^{\alpha_k, ''}} = 0$  by (3.393), we observe that:

$$\overline{\langle \psi_k \rangle_V^{\alpha_k \rho_k}},^{\alpha_k} - \overline{\langle \psi_k \rangle_V} = \frac{\overline{\alpha'_k \langle \psi_k \rangle'_V}}{\overline{\alpha_k}} \quad (3.397)$$

Furthermore, taking the time average of (3.330), we get:

$$\overline{\langle \psi_k \rangle_V} = \overline{\langle \psi_k \rangle_V^{\alpha_k \rho_k}},^{\alpha_k} + \overline{\langle \psi_k \rangle_V^{\alpha_k, ''}} \quad (3.398)$$

and it follows that:

$$\overline{\langle \psi_k \rangle_V^{\alpha_k}},^{\alpha_k} - \overline{\langle \psi_k \rangle_V} = -\overline{\langle \psi_k \rangle_V^{\alpha_k, ''}} = \frac{\overline{\alpha'_k \langle \psi_k \rangle_V^{\alpha_k, ''}}}{\overline{\alpha_k}} = \frac{\overline{\alpha'_k \langle \psi_k \rangle'_V}}{\overline{\alpha_k}} \quad (3.399)$$

From this result it is seen that  $\overline{\langle \psi_k \rangle_V^{\alpha_k}},^{\alpha_k}$  equals the difference between the two average values of the variable  $\psi_k$ , and can be expressed in terms of either forms of the volume fraction covariances.

The governing equations for incompressible flows can thus be expressed by:

*Mass:*

The incompressible form of the time after volume averaged continuity Eq. (3.361) becomes:

$$\frac{\partial(\overline{\alpha_k} \rho_k)}{\partial t} + \nabla \cdot (\overline{\alpha_k} \rho_k \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k}}) = \overline{\Gamma_k} \quad (3.400)$$

*Momentum:*

The incompressible form of the time after volume averaged momentum equation (3.362) is given by:

$$\begin{aligned} & \frac{\partial}{\partial t} (\overline{\alpha_k} \rho_k \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k}}) + \nabla \cdot (\overline{\alpha_k} \rho_k \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k}} \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k}}) \\ &= -\nabla \cdot (\overline{\alpha_k} \overline{\langle p_k \rangle_{V_k}}) - \nabla \cdot \left( \overline{\alpha_k} \overline{\langle \boldsymbol{\sigma}_k \rangle_V^{\alpha_k}} + \overline{\langle \boldsymbol{\sigma}_k \rangle_V^{Re}} \right) \\ & \quad - \overline{\frac{1}{V} \int_{A_I} (\dot{m}_k \mathbf{v}_k + \mathbf{T}_k \cdot \mathbf{n}_k) da} + \overline{\alpha_k} \rho_k \sum_c \overline{\langle \omega_k \rangle_V^{\alpha_k}} \mathbf{g}_{k,c} \end{aligned} \quad (3.401)$$

*Energy:*

The incompressible form of the time after volume averaged energy equation (3.369) can be expressed as:

$$\begin{aligned} & \frac{\partial}{\partial t} (\overline{\alpha_k} \rho_k \overline{\langle E_k \rangle_V^{\alpha_k}}) + \nabla \cdot (\overline{\alpha_k} \rho_k \overline{\langle \mathbf{v} \rangle_V^{\alpha_k}} \overline{\langle E_k \rangle_V^{\alpha_k}}) \\ &= -\nabla \cdot (\overline{\langle p_k \rangle_V} \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k}}) - \nabla \cdot (\overline{\alpha_k} \overline{\langle \mathbf{q}_k \rangle_{V_k}}) \\ & \quad - \nabla \cdot (\overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k}} \cdot (\overline{\langle \boldsymbol{\sigma}_k \rangle_V} + \overline{\langle \boldsymbol{\sigma} \rangle_V^{Re}})) \\ & \quad + \nabla \cdot (\overline{\alpha_k} \rho_k D_{k,t}^{e_k} \nabla \overline{\langle e_k \rangle_V^{\alpha_k}}) \\ & \quad - \overline{\frac{1}{V} \int_{A_I} \left( \dot{m}_k (e_k + \frac{1}{2} v_k^2) + (\mathbf{T}_k \cdot \mathbf{v}_k + \mathbf{q}_k) \cdot \mathbf{n}_k \right) da} \\ & \quad + \overline{\alpha_k} \rho_k \sum_c (\overline{\langle \omega_{k,c} \rangle_V^{\alpha_k}} \overline{\langle \mathbf{v}_{k,c} \rangle_V^{\alpha_k}} - D_{k,t}^{\omega_{k,c}} \nabla \overline{\langle \omega_{k,c} \rangle_V^{\alpha_k}}) \cdot \mathbf{g}_{k,c} \end{aligned} \quad (3.402)$$

*Chemical Species:*

The incompressible form of the time after volume averaged species mass balance equation (3.387) can be expressed as:

$$\begin{aligned} & \frac{\partial}{\partial t} (\overline{\alpha_k} \rho_k \overline{\langle \omega_{k,s} \rangle_V^{\alpha_k}}) + \nabla \cdot (\overline{\alpha_k} \rho_k \overline{\langle \mathbf{v}_k \rangle_V^{\alpha_k}} \overline{\langle \omega_{k,s} \rangle_V^{\alpha_k}}) \\ &= -\nabla \cdot (\overline{\langle \mathbf{j}_{k,s} \rangle_V}) + \nabla \cdot (\rho_k D_{k,t}^{\omega_{k,s}} \nabla \overline{\langle \omega_k \rangle_V^{\alpha_k}}) \end{aligned}$$

$$- \frac{1}{V} \int_{A_I} (\dot{m}_k \omega_{k,s} + \mathbf{j}_{k,s} \cdot \mathbf{n}_k) da + \overline{\langle R_{k,s} \rangle_V} \quad (3.403)$$

### 3.5.4.2 The Conventional Reynolds Decomposition Method

The alternative Reynolds averaged equations are derived without introducing any weighted-average variables. Instead we adopt the conventional Reynolds averaging method [69, 127, 133, 219]. In the past, almost all the practical problems of multiphase flow and reactor modeling were dealt with using these equations. By applying the Reynolds averaging rules (1.385) to the volume averaged equations (3.143), the terms in the averaged generic equation (3.336) can be expressed as follows:

*The transient term:*

$$\begin{aligned} \overline{\alpha_k \langle \rho_k \rangle_{V_k} \langle \psi_k \rangle_V} &= \overline{\alpha'_k \langle \rho_k \rangle'_{V_k} \langle \psi_k \rangle'_V} + \overline{\alpha_k \langle \rho_k \rangle'_{V_k} \langle \psi_k \rangle'_V} \\ &\quad + \overline{\alpha'_k \langle \psi_k \rangle'_V \langle \rho_k \rangle_{V_k}} + \overline{\alpha'_k \langle \rho_k \rangle'_{V_k} \langle \psi_k \rangle_V} \\ &\quad + \overline{\alpha_k \langle \rho_k \rangle_{V_k} \langle \psi_k \rangle_V} \end{aligned} \quad (3.404)$$

*The convective term:*

$$\begin{aligned} &\overline{\alpha_k \langle \rho_k \rangle_{V_k} \langle \mathbf{v}_k \rangle_V \langle \psi_k \rangle_V} \\ &= \overline{\alpha'_k \langle \rho_k \rangle'_{V_k} \langle \mathbf{v}_k \rangle'_V \langle \psi_k \rangle'_V} + \overline{\alpha_k \langle \rho_k \rangle'_{V_k} \langle \mathbf{v}_k \rangle'_V \langle \psi_k \rangle'_V} \\ &\quad + \overline{\langle \rho_k \rangle_{V_k} \alpha'_k \langle \mathbf{v}_k \rangle'_V \langle \psi_k \rangle'_V} + \overline{\alpha_k \langle \rho_k \rangle_{V_k} \langle \mathbf{v}_k \rangle'_V \langle \psi_k \rangle'_V} \\ &\quad + \overline{\alpha'_k \langle \rho_k \rangle'_{V_k} \langle \psi_k \rangle'_V \langle \mathbf{v}_k \rangle_V} + \overline{\langle \rho_k \rangle_{V_k} \langle \mathbf{v}_k \rangle_V \alpha'_k \langle \psi_k \rangle'_V} \\ &\quad + \overline{\alpha_k \langle \mathbf{v}_k \rangle_V \langle \rho_k \rangle'_{V_k} \langle \psi_k \rangle'_V} + \overline{\alpha'_k \langle \rho_k \rangle'_{V_k} \langle \mathbf{v}_k \rangle'_V \langle \psi_k \rangle_V} \\ &\quad + \overline{\alpha_k \langle \rho_k \rangle'_{V_k} \langle \mathbf{v}_k \rangle'_V \langle \psi_k \rangle_V} + \overline{\langle \rho_k \rangle_{V_k} \alpha'_k \langle \mathbf{v}_k \rangle'_V \langle \psi_k \rangle_V} \\ &\quad + \overline{\alpha'_k \langle \rho_k \rangle'_{V_k} \langle \mathbf{v}_k \rangle_V \langle \psi_k \rangle_V} + \overline{\alpha_k \langle \rho_k \rangle_{V_k} \langle \mathbf{v}_k \rangle_V \langle \psi_k \rangle_V} \end{aligned} \quad (3.405)$$

*The diffusive term:*

$$\overline{\alpha_k \langle \mathbf{J}_k \rangle_{V_k}} = \overline{\alpha'_k \langle \mathbf{J}_k \rangle'_{V_k}} + \overline{\alpha_k \langle \mathbf{J}_k \rangle'_{V_k}} \quad (3.406)$$

*The volume production term:*

$$\begin{aligned} &\overline{\alpha_k \langle \rho_k \rangle_{V_k} \sum_c \langle \omega_{k,c} \rangle_V \langle \phi_{k,c} \rangle_V} \\ &= \sum_c \left( \overline{\alpha_k \langle \rho_k \rangle_{V_k} \langle \omega_{k,c} \rangle_V \langle \phi_{k,c} \rangle_V} + \overline{\alpha_k \langle \rho_k \rangle_{V_k} \langle \omega_{k,c} \rangle'_V \langle \phi_{k,c} \rangle'_V} \right) \end{aligned}$$

$$\begin{aligned}
& + \overline{\alpha_k} \overline{\langle \omega_{k,c} \rangle_V} \overline{\langle \rho_k \rangle'_{V_k} \langle \phi_{k,c} \rangle'_V} + \overline{\alpha_k} \overline{\langle \phi_{k,c} \rangle_V} \overline{\langle \rho_k \rangle'_{V_k} \langle \omega_{k,c} \rangle'_V} \\
& + \overline{\alpha_k} \overline{\langle \phi_{k,c} \rangle_V} \overline{\langle \rho_k \rangle'_{V_k} \langle \omega_{k,c} \rangle'_V} + \overline{\alpha_k} \overline{\langle \rho_k \rangle'_{V_k} \langle \omega_{k,c} \rangle'_V} \overline{\langle \phi_{k,c} \rangle'_V} \\
& + \overline{\langle \rho_k \rangle_{V_k}} \overline{\langle \omega_{k,c} \rangle_V} \overline{\alpha'_k \langle \phi_{k,c} \rangle'_V} + \overline{\langle \rho_k \rangle_{V_k}} \overline{\langle \phi_{k,c} \rangle_V} \overline{\alpha'_k \langle \omega_{k,c} \rangle'_V} \\
& + \overline{\langle \rho_k \rangle_{V_k}} \overline{\alpha'_k \langle \omega_{k,c} \rangle'_V} \overline{\langle \phi_{k,c} \rangle'_V} + \overline{\langle \omega_{k,c} \rangle_V} \overline{\langle \phi_{k,c} \rangle_V} \overline{\alpha'_k \langle \rho_k \rangle'_{V_k}} \\
& + \overline{\langle \omega_{k,c} \rangle_V} \overline{\alpha'_k \langle \rho_k \rangle'_{V_k}} \overline{\langle \phi_{k,c} \rangle'_V} + \overline{\langle \phi_{k,c} \rangle_V} \overline{\alpha'_k \langle \rho_k \rangle'_{V_k}} \overline{\langle \omega_{k,c} \rangle'_V} \\
& + \overline{\alpha'_k \langle \rho_{k,c} \rangle'_{V_k}} \overline{\langle \omega_{k,c} \rangle'_V} \overline{\langle \phi_{k,c} \rangle'_V} \Big) \quad (3.407)
\end{aligned}$$

Substituting the given expressions (3.404) to (3.407) for the terms in the governing equation, (3.336) is expressed as:

$$\begin{aligned}
& \frac{\partial}{\partial t} (\overline{\alpha_k} \overline{\langle \rho_k \rangle_{V_k}} \overline{\langle \psi_k \rangle_V}) + \nabla \cdot (\overline{\alpha_k} \overline{\langle \rho_k \rangle_{V_k}} \overline{\langle \mathbf{v}_k \rangle_V} \overline{\langle \psi_k \rangle_V}) \\
& = -\nabla \cdot \left( \overline{\alpha_k} \overline{\langle \mathbf{J}_k \rangle_{V_k}} + \overline{\alpha'_k \langle \mathbf{J}_k \rangle'_{V_k}} \right) \\
& + \sum_c \overline{\alpha_k} \overline{\langle \rho_k \rangle_{V_k}} \overline{\langle \omega_{k,c} \rangle_V} \overline{\langle \phi_{k,c} \rangle'_V} \\
& - \frac{1}{V} \int_{A_I} (\dot{m}_k \psi_k) da - \frac{1}{V} \int_{A_I} (\mathbf{J}_k \cdot \mathbf{n}_k) da \\
& - \left[ \frac{\partial}{\partial t} \left( \overline{\alpha'_k \langle \rho_k \rangle'_{V_k} \langle \psi_k \rangle'_V} + \overline{\alpha_k \langle \rho_k \rangle'_{V_k} \langle \psi_k \rangle'_V} \right. \right. \\
& \quad \left. \left. + \overline{\alpha'_k \langle \psi_k \rangle'_V \langle \rho_k \rangle_{V_k}} + \overline{\alpha'_k \langle \rho_k \rangle'_{V_k} \langle \psi_k \rangle_V} \right) \right] \\
& - \left[ \nabla \cdot \left( \overline{\alpha'_k \langle \rho_k \rangle'_{V_k} \langle \mathbf{v}_k \rangle'_V \langle \psi_k \rangle'_V} + \overline{\alpha_k \langle \rho_k \rangle'_{V_k} \langle \mathbf{v}_k \rangle'_V \langle \psi_k \rangle'_V} \right. \right. \\
& \quad + \overline{\langle \rho_k \rangle_{V_k} \alpha'_k \langle \mathbf{v}_k \rangle'_V \langle \psi_k \rangle'_V} + \overline{\alpha_k \langle \rho_k \rangle_{V_k} \langle \mathbf{v}_k \rangle'_V \langle \psi_k \rangle'_V} \\
& \quad + \overline{\alpha'_k \langle \rho_k \rangle'_V \langle \psi_k \rangle'_V \langle \mathbf{v}_k \rangle_V} + \overline{\langle \rho_k \rangle_{V_k} \langle \mathbf{v}_k \rangle_V \alpha'_k \langle \psi_k \rangle'_V} \\
& \quad + \overline{\alpha_k \langle \mathbf{v}_k \rangle_V \langle \rho_k \rangle'_V \langle \psi_k \rangle'_V} + \overline{\alpha'_k \langle \rho_k \rangle'_{V_k} \langle \mathbf{v}_k \rangle'_V \langle \psi_k \rangle_V} \\
& \quad + \overline{\alpha_k \langle \rho_k \rangle'_{V_k} \langle \mathbf{v}_k \rangle'_V \langle \psi_k \rangle_V} + \overline{\langle \rho_k \rangle_{V_k} \alpha'_k \langle \mathbf{v}_k \rangle'_V \langle \psi_k \rangle_V} \\
& \quad \left. \left. + \overline{\alpha'_k \langle \rho_k \rangle'_{V_k} \langle \mathbf{v}_k \rangle_V \langle \psi_k \rangle_V} \right) \right] \\
& + \sum_c \left( \overline{\alpha_k \langle \rho_k \rangle_{V_k}} \overline{\langle \omega_{k,c} \rangle'_V} \overline{\langle \phi_{k,c} \rangle'_V} \right. \\
& \quad + \overline{\alpha_k} \overline{\langle \omega_{k,c} \rangle_V} \overline{\langle \rho_k \rangle'_{V_k} \langle \phi_{k,c} \rangle'_V} + \overline{\alpha_k} \overline{\langle \phi_{k,c} \rangle_V} \overline{\langle \rho_k \rangle'_{V_k} \langle \omega_{k,c} \rangle'_V} \\
& \quad + \overline{\alpha_k} \overline{\langle \phi_{k,c} \rangle_V} \overline{\langle \rho_k \rangle'_{V_k} \langle \omega_{k,c} \rangle'_V} + \overline{\alpha_k} \overline{\langle \rho_k \rangle'_{V_k} \langle \omega_{k,c} \rangle'_V} \overline{\langle \phi_{k,c} \rangle'_V} \\
& \quad \left. + \overline{\langle \rho_k \rangle_{V_k}} \overline{\langle \omega_{k,c} \rangle_V} \overline{\alpha'_k \langle \phi_{k,c} \rangle'_V} + \overline{\langle \rho_k \rangle_{V_k}} \overline{\langle \phi_{k,c} \rangle_V} \overline{\alpha'_k \langle \omega_{k,c} \rangle'_V} \right)
\end{aligned} \quad (3.408)$$

$$\begin{aligned}
& + \overline{\langle \rho_k \rangle_{V_k}} \overline{\alpha'_k \langle \omega_{k,c} \rangle'_{V_k} \langle \phi_{k,c} \rangle'_V} + \overline{\langle \omega_{k,c} \rangle_V} \overline{\langle \phi_{k,c} \rangle_V} \overline{\alpha'_k \langle \rho_k \rangle'_{V_k}} \\
& + \overline{\langle \omega_{k,c} \rangle_V} \overline{\alpha'_k \langle \rho_k \rangle'_{V_k} \langle \phi_{k,c} \rangle'_V} + \overline{\langle \phi_{k,c} \rangle_V} \overline{\alpha'_k \langle \rho_{k,c} \rangle'_{V_k} \langle \omega_{k,c} \rangle'_V} \\
& + \overline{\alpha'_k \langle \rho_{k,c} \rangle'_{V_k} \langle \omega_{k,c} \rangle'_V \langle \phi_k \rangle'_V} \Big)
\end{aligned}$$

An obvious drawback related to the application of this particular averaging procedure is the extensive need for constitutive relations to achieve a solvable set of equations. The number of covariances are substantially reduced for the cases in which the density fluctuations can be neglected. Nevertheless, the conventional Reynolds averaging procedure gives rise to several covariance terms which lack physical interpretation and are thus generally ignored in spite of limited physical justification.

The incompressible flow form of the volume and time averaged equations which can be derived adopting the conventional Reynolds averaging procedure are more practical. Moreover, the covariance terms of order higher than two are normally neglected in accordance with the conventional single phase turbulence modeling procedure assuming that their relative magnitude is small compared to the lower order covariances. Considering the transient term of the generic transport equation all covariances are usually neglected based on the hypothesis that these terms are smaller than the product of averaged quantities.

The transient term (3.404) is normally approximated by:

$$\overline{\alpha_k \rho_k \langle \psi_k \rangle_V} \approx \overline{\alpha_k} \overline{\rho_k} \overline{\langle \psi_k \rangle_V} \quad (3.409)$$

The convection term (3.405) can be expressed as:

$$\begin{aligned}
& \overline{\alpha_k \langle \rho_k \rangle_{V_k} \langle \mathbf{v}_k \rangle_V \langle \psi_k \rangle_V} \\
& \approx \overline{\alpha_k} \overline{\rho_k} \overline{\langle \mathbf{v}_k \rangle'_V \langle \psi_k \rangle'_V} + \overline{\rho_k} \overline{\langle \mathbf{v}_k \rangle_V} \overline{\alpha'_k \langle \psi_k \rangle'_V} \\
& + \overline{\rho_k} \overline{\alpha'_k \langle \mathbf{v}_k \rangle'_V \langle \psi_k \rangle_V} + \overline{\alpha_k} \overline{\rho_k} \overline{\langle \mathbf{v}_k \rangle_V \langle \psi_k \rangle_V}
\end{aligned} \quad (3.410)$$

The diffusion term (3.406) is normally approximated by:

$$\overline{\alpha_k \langle \mathbf{J}_k \rangle_{V_k}} \approx \overline{\alpha_k} \overline{\langle \mathbf{J}_k \rangle_{V_k}} \quad (3.411)$$

The volume production term (3.407) is approximated by:

$$\overline{\alpha_k \langle \rho_k \rangle_{V_k} \sum_c \langle \omega_{k,c} \rangle_V \langle \phi_{k,c} \rangle_V} \approx \overline{\alpha_k} \overline{\rho_k} \sum_c \overline{\langle \omega_{k,c} \rangle_V \langle \phi_{k,c} \rangle_V} \quad (3.412)$$

The model equations for incompressible flows which are frequently used in engineering research are thus written as:

$$\frac{\partial}{\partial t} (\overline{\alpha_k} \overline{\rho_k} \overline{\langle \psi_k \rangle_V}) + \nabla \cdot (\overline{\alpha_k} \overline{\rho_k} \overline{\langle \mathbf{v}_k \rangle_V} \overline{\langle \psi_k \rangle_V})$$

$$\begin{aligned}
&= -\nabla \cdot \left( \overline{\alpha_k \langle \mathbf{J}_k \rangle_{V_k}} \right) + \overline{\alpha_k} \rho_k \sum_c \overline{\langle \omega_{k,c} \rangle_V \langle \phi_{k,c} \rangle_V} - \frac{1}{V} \overline{\int_{A_I} (\dot{m}_k \psi_k) da} \\
&\quad - \frac{1}{V} \overline{\int_{A_I} (\mathbf{J}_k \cdot \mathbf{n}_k) da} - \left[ \nabla \cdot \left( \overline{\alpha_k} \rho_k \overline{\langle \mathbf{v}_k \rangle'_V \langle \psi_k \rangle'_V} \right. \right. \\
&\quad \left. \left. + \rho_k \overline{\langle \mathbf{v}_k \rangle_V} \overline{\alpha'_k \langle \psi_k \rangle'_V} + \rho_k \overline{\alpha'_k \langle \mathbf{v}_k \rangle'_V \langle \psi_k \rangle_V} \right) \right] \quad (3.413)
\end{aligned}$$

It is easily seen that the incompressible model formulation contains less covariance terms than the model equations for compressible flows (3.408). For this reason the compressible formulation is seldom used, instead the formulation valid for incompressible flows is often used for weakly compressible systems as well.

For convenience, we normally remove the  $\langle \dots \rangle_V$  volume averaging signs from the equations. By introducing the consistent sets of values for the generalized variables we get, as before, the transport equations for the specific balanced quantities:

*Mass:*

$$\frac{\partial(\overline{\alpha_k} \rho_k)}{\partial t} + \nabla(\overline{\alpha_k} \rho_k \overline{\mathbf{v}_k}) = \nabla \cdot (\rho_k D_{k,t}^{\alpha_k} \nabla \overline{\alpha_k}) + \overline{\Gamma_k} \quad (3.414)$$

The covariance is modeled by use of the gradient hypothesis and the Boussinesq turbulent transport coefficient concept:

$$\rho_k \overline{\alpha'_k \mathbf{v}'_k} \approx -\rho_k D_{k,t}^{\alpha_k} \nabla \overline{\alpha_k} \quad (3.415)$$

*Momentum:*

$$\begin{aligned}
&\frac{\partial(\overline{\alpha_k} \rho_k \overline{\mathbf{v}_k})}{\partial t} + \nabla \cdot (\overline{\alpha_k} \rho_k \overline{\mathbf{v}_k} \overline{\mathbf{v}_k}) \\
&= -\nabla(\overline{\alpha_k} \overline{p_k}) - \nabla \cdot (\overline{\alpha_k} \overline{\boldsymbol{\sigma}_k}) + \overline{\alpha_k} \rho_k \mathbf{g} - \nabla \cdot (\overline{\alpha_k} \rho_k \overline{\mathbf{v}'_k \mathbf{v}'_k}) \\
&\quad + 2 \nabla \cdot (\rho_k \overline{\mathbf{v}_k} D_{k,t}^{\alpha_k} \nabla \overline{\alpha_k}) + \overline{\mathbf{M}_k^T} + \overline{\mathbf{M}_k^T} \\
&= -\nabla(\overline{\alpha_k} \overline{p_k}) - \nabla \cdot (\overline{\alpha_k} (\boldsymbol{\sigma}_k + \boldsymbol{\sigma}_k^{Re})) + \overline{\alpha_k} \rho_k \mathbf{g} + 2 \nabla \cdot (\rho_k \overline{\mathbf{v}_k} D_{k,t}^{\alpha_k} \nabla \overline{\alpha_k}) \\
&\quad + \overline{\mathbf{M}_k^T} + \overline{\mathbf{M}_k^T} \quad (3.416)
\end{aligned}$$

The Reynolds stresses are defined by:

$$\boldsymbol{\sigma}_k^{Re} = \rho_k \overline{\mathbf{v}'_k \mathbf{v}'_k} \quad (3.417)$$

Moreover, gravity is often the only body force considered in reactor analysis, and the covariance term is frequently approximated in accordance with (3.415).

*Energy:*

$$\begin{aligned}
& \frac{\partial(\overline{\alpha_k \rho_k E_k})}{\partial t} + \nabla \cdot (\overline{\alpha_k \rho_k \mathbf{v}_k} \overline{E_k}) \\
&= -\nabla \cdot (\overline{\alpha_k} \overline{p_k} \overline{\mathbf{v}_k}) - \nabla \cdot (\overline{\alpha_k} \overline{\boldsymbol{\sigma}_k} \cdot \overline{\mathbf{v}_k}) + \nabla \cdot (\overline{\alpha_k} \overline{\mathbf{q}_k}) + \overline{\alpha_k} \rho_k \overline{\mathbf{v}_k} \cdot \mathbf{g} \\
&+ \nabla \cdot \left( \overline{\alpha_k} \rho_k \overline{\mathbf{v}_k} \cdot \overline{\mathbf{v}'_k \mathbf{v}'_k} + \rho_k \overline{\mathbf{v}_k} \overline{\mathbf{v}_k} \cdot \overline{\alpha'_k \mathbf{v}'_k} \right) + \nabla \cdot (\overline{\alpha_k} \rho_k \overline{\mathbf{v}'_k e'_k}) \\
&+ \nabla \cdot (\overline{e_k} \rho_k \overline{\alpha'_k \mathbf{v}'_k}) \\
&= -\nabla \cdot (\overline{\alpha_k} \overline{p_k} \overline{\mathbf{v}_k}) - \nabla \cdot \left( \overline{\alpha_k} (\overline{\boldsymbol{\sigma}_k} + \overline{\boldsymbol{\sigma}_k^{\text{Re}}}) \cdot \overline{\mathbf{v}_k} \right) + \nabla \cdot (\overline{\alpha_k} \overline{\mathbf{q}_k}) + \overline{\alpha_k} \rho_k \overline{\mathbf{v}_k} \cdot \mathbf{g} \\
&+ \nabla \cdot (\rho_k \overline{\mathbf{v}_k} \overline{\mathbf{v}_k} \cdot (D_{k,t}^{\alpha_k} \nabla \overline{\alpha_k})) + \nabla \cdot (\overline{\alpha_k} \rho_k D_{k,t}^{e_k} \nabla \overline{e_k}) + \nabla \cdot (\overline{e_k} \rho_k D_{k,t}^{\alpha_k} \nabla \overline{\alpha_k})
\end{aligned} \tag{3.418}$$

The additional covariance is modeled as the earlier one by use of the gradient hypothesis and the Boussinesq turbulent transport coefficient concept:

$$\rho_k \overline{\alpha_k} \overline{\mathbf{v}'_k e'_k} \approx -\rho_k \overline{\alpha_k} D_{k,t}^{e_k} \nabla \overline{e_k} \tag{3.419}$$

*Chemical Species:*

$$\begin{aligned}
& \frac{\partial}{\partial t} (\overline{\alpha_k \rho_k \overline{\alpha_k} \omega_{k,s}}) + \nabla \cdot (\overline{\alpha_k \rho_k \overline{\alpha_k} \mathbf{v}_k} \overline{\omega_{k,s}}) \\
&= -\nabla \cdot (\overline{\alpha_k} \overline{\mathbf{j}_{k,s}}) + \nabla \cdot (\overline{\alpha_k} \rho_k D_{k,t}^{\omega_{k,s}} \nabla \overline{\omega_{k,s}}) \\
&- \frac{1}{V} \int_{A_I} (\dot{m}_k \omega_{k,s} + \mathbf{j}_{k,s} \cdot \mathbf{n}_k) da + \overline{\langle R_{k,s} \rangle}_V
\end{aligned} \tag{3.420}$$

where the velocity-mass fraction covariance is modeled by use of the gradient hypothesis and the Boussinesq turbulent transport coefficient concept:

$$\rho_k \overline{\alpha_k} \overline{\mathbf{v}'_k \omega'_{k,s}} \approx -\rho_k \overline{\alpha_k} D_{k,t}^{\omega_{k,s}} \nabla \overline{\omega_{k,s}} \tag{3.421}$$

In one view the time after volume averaging operator gives rise to a set of model equations which is closed introducing numerous simplifying assumptions reducing the accuracy of the simulated results. However, in another viewpoint it is argued that for model validation it is more convenient to use this double averaging method in comparison with the models derived adopting the single averaging operators, since the measured data is in better consistency with the simulated results obtained applying this particular model. More important perhaps, because of the fluctuating volume fraction variable the mathematical form of the resulting time after volume averaged equations differ slightly from those derived using the single averaging operators discussed in Sects. 3.5.1 and 3.5.2. Not only are the physical interpretations

of the various terms different, there are also additional and mathematically deviating terms occurring in this model formulations. It is observed that this fact has induced some confusion in the literature, as inconsistent constitutive equations are sometimes erroneously exchanged between the single- and multiple averaged equations. For this reason caution is needed ensuring that only consistent constitutive equations are used to approximate the unknown covariance terms occurring in the more advanced reactor models.

### 3.5.5 *The Mixture Models*

The basic mixture model concept considers the whole multiphase mixture as a single macroscopic continuum. In the literature the mixture model equations are derived applying various approaches which we conveniently divide into two groups. Basically, the mixture models are either derived applying the balance principle over a macroscopic Eulerian CV or by taking the sum of the averaged equations for the individual phases [17]. The first group of models is known from the work of Wallis [246], Sha and Soo [200] and Bennon and Incropera [19], whereas the second group of formulations emerged from the work of Zuber and Findlay [265], Soo [218] and Ishii [118].

Bedford and Drumheller [17] reviewed the basic principles of the continuum theories that have been developed to model mixtures of immiscible constituents, such as bubbly flows, fluid-particle mixtures, fluid saturated porous media, and composite materials. In the classical continuum theory of mixtures the pseudo-fluid is given effective macroscopic properties which have to be postulated. Balance equations are written for the pseudo-homogeneous mixture mass, momentum and energy in terms of the postulated mixture properties. These three macroscopic mixture conservation equations may be supplemented by postulated phasic balance equations. In these extended versions of the classical theories the mixture properties are given as a volume fraction weighted sum of the phasic properties. To close this model separate continuity equations of the dispersed phases are postulated and incorporated in the formulation to account for the phase distribution phenomena. In particular using the mixture equations together with the continuity equations of the dispersed phases computationally efficient descriptions of the multiphase flow are achieved, since we are considerably reducing the number of transport equations to be solved compared to the full multi-fluid model. It is generally accepted that the extended mixture model concept is appropriate to describe mixture flows in which the dynamics of the phases are closely coupled [118]. In the second group of mixture models the phasic equations are adopted from one of the existing macroscopic multi-fluid model formulations which can be derived from the local instantaneous equations applying different averaging procedures. The mixture model equations are then achieved by taking the sum of the averaged equations for all the individual phases in the system. In the ideal case both approaches provide the same macroscopic equations. To determine the dispersed phase velocities as occurring in the phasic continuity equations

in both formulations, the momentum equation of the dispersed phases are usually approximated by algebraic equations. Depending on the concept used to relate the phase  $k$  velocity to the mixture velocity the extended mixture model formulations are referred to as the algebraic slip-, diffusion- or drift flux models. These mixture models have been applied to investigate chemical engineering problems by [19, 21, 91, 155, 175, 178, 195, 206, 216, 245], among others.

### 3.5.5.1 The Classical Homogeneous Mixture Model

In this section the classical continuum theory of mixtures is reviewed [17]. In this concept the multiphase mixture is treated as a single homogeneous continuum. Thereby the balance principle can be applied to derive conservation laws for the macroscopic pseudo-fluid in analogy to the single phase formulation examined in Chap. 1. Approximate constitutive equations are postulated for the expected macroscopic behavior of the phases.

Consider any quantity  $\psi_m$  associated with a mixture of phases. For an arbitrary material macroscopic control volume<sup>18</sup>  $V_m(t)$  bounded by the surface area  $A_m(t)$ , a generalized integral balance can be postulated stating that the time rate of change is equal to the molecular transport flux plus the volumetric production [200]:

$$\frac{D}{Dt} \int_{V_m(t)} \rho_m \psi_m dv = - \int_{A_m(t)} \mathbf{J}_m \cdot \mathbf{n} da + \int_{V_m(t)} \rho_m \phi_m dv \quad (3.422)$$

In this notation,  $\mathbf{n}$  is the outward directed normal unit vector to the external mixture surface  $A_m(t)$  closing the mixture volume  $V_m(t)$ ,  $D/Dt$  is the substantial time derivative,  $\mathbf{v}_m$  is the velocity associated with the mixture,  $\rho_m$  is the mixture density,  $\psi_m$  is any mixture quantity,  $\mathbf{J}_m$  is the mixture diffusive flux and  $\phi_m$  is the source term. Virtually no mixture theory includes any interfacial properties, so we chose not to include the interface mechanisms in the basic model formulation [121]. It follows from the continuum assumption that the integrands in (3.422) are continuous and differentiable functions, so the integral theorems of Leibnitz and Gauss (see Appendix A) can be applied transforming the system description into an Eulerian control volume formulation. The governing mixture equations are thus derived in the same manner as outlined for single phase flow in Chap. 1. The resulting equation is written:

$$\int_{V_m} \left( \frac{\partial(\rho_m \psi_m)}{\partial t} + \nabla \cdot (\rho_m \mathbf{v}_m \psi_m) + \nabla \cdot \mathbf{J}_m - \rho_m \phi_m \right) dv = 0 \quad (3.423)$$

---

<sup>18</sup> To relate the classical mixture theory to the more familiar volume averaging method we may assume that the mixture CV, which is larger than a phase element but smaller than the characteristic domain dimension, coincides with the averaging volume used in the volume averaging approach.

Since (3.423) must be satisfied for any  $V_m$ , the macroscopic equation can be transformed into its differential form:

$$\frac{\partial(\rho_m \psi_m)}{\partial t} + \nabla \cdot (\rho_m \mathbf{v}_m \psi_m) + \nabla \cdot \mathbf{J}_m - \rho_m \phi_m = 0 \quad (3.424)$$

in which the properties and the constitutive equations required for the mixture mass, momentum, energy, and species transport equations have to be postulated. To deduce the different mixture balance equations the variables in (3.424) are defined in analogy with the single phase variables in Table 3.1. The resulting set of partial differential equations is sometimes called the *macroscopic continuum mixture equations* [206].

The basic mixture model equation (3.424) contains several undetermined quantities which have to be determined. These variables are conventionally postulated as the sum of the volume fraction weighted property values of the phases in the mixture:

The mixture density,  $\rho_m$ , is approximated as:

$$\rho_m = \sum_k \alpha_k \rho_k \quad (3.425)$$

The mixture viscosity,  $\mu_m$ , is approximated as:

$$\mu_m = \sum_k \alpha_k \mu_k \quad (3.426)$$

The mixture diffusive flux,  $\mathbf{J}_m$ , is approximated as:

$$\mathbf{J}_m = \sum_k \alpha_k \mathbf{J}_k \quad (3.427)$$

The mixture mass averaged velocity,  $\mathbf{v}_m$ , is approximated as:

$$\mathbf{v}_m = \frac{\sum_k \alpha_k \rho_k \mathbf{v}_k}{\sum_k \alpha_k \rho_k} = \frac{\sum_k \alpha_k \rho_k \mathbf{v}_k}{\rho_m} \quad (3.428)$$

The generic mass averaged quantity,  $\psi_m$ , is computed as:

$$\psi_m = \frac{\sum_k \alpha_k \rho_k \psi_k}{\sum_k \alpha_k \rho_k} = \frac{\sum_k \alpha_k \rho_k \psi_k}{\rho_m} \quad (3.429)$$

where the actual phase  $k$  volume fraction  $\alpha_k = V_k / V_m$  have been introduced relating the superficial variables and the actual phase variables.

To preserve the system volume the volume fractions  $\alpha_k$  are subject to the natural constraint:

$$\sum_k \alpha_k = 1 \quad (3.430)$$

Since the mixture properties are given as the sum of the volume fraction weighted property values of the different phases in the mixture, the dispersed phase volume fractions were originally calculated from the postulated dispersed phase continuity equations. In the past these macroscopic equations were expressed based on hypothesis and physical intuition rather than basic principles. The modern versions of the classical mixture theories are thus derived starting out from the averaged equations for the individual phases to ensure that the governing equations are correctly formulated.

The main disadvantage reflected by the classical mixture model is that no direct connection is made with the microscopic phenomena. In consequence essential features of the multi-phase systems are easily overlooked, and sometimes unnecessary assumptions are imposed on the macroscopic quantities [108]. For this reason the classical mixture model is seldom used for reactor analysis involving fluid flow calculations, since it is very difficult to postulate reliable parameterizations for the mixture properties and the constitutive equations. However, the mixture model concept determines the basis for the pseudo-homogeneous reactor models which are well known from conventional reactor modeling [84]. In these reactor simulations simplified descriptions of the flow or even predefined velocity profiles are used, nevertheless these empirical models are computationally efficient and thus very useful analyzing the interactions between the reaction kinetics and the different transport processes occurring in such reactive systems. It is emphasized that for many chemical processes idealized flow profiles prevail or the chemical kinetics and the molecular diffusion processes are the rate determining steps so the details of the flow are not essential determining the chemical conversion and heat transport in the reactor [130].

In problems in which the dispersed phase momentum equations can be approximated and reduced to an algebraic relation the mixture model is simpler to solve than the corresponding multi-fluid model, however this model reduction requires several approximate constitutive assumptions so important characteristics of the flow can be lost. Nevertheless the simplicity of this form of the mixture model makes it very useful in many engineering applications. This approximate mixture model formulation is generally expected to provide reasonable predictions for dilute and uniform multiphase flows which are not influenced by any wall effects. In these cases the dispersed phase elements do not significantly affect the momentum and density of the mixture. Such a situation may occur when the dispersed phase elements are very small. There are several concepts available for the purpose of relating the dispersed phase velocity to the mixture velocity, and thereby reducing the dispersed phase momentum equation to a much simpler relation. The algebraic relations frequently mentioned in the multiphase flow literature are outlined in the following sub sections.

### 3.5.5.2 The Algebraic-Slip Mixture Model

In this section we derive the algebraic-slip mixture model equations for cold flow studies starting out from the multi-fluid model equations derived applying the time-after volume averaging operator without mass-weighting [218, 219]. The momentum equations for the dispersed phases are determined in terms of the relative (slip) velocity.

Under isothermal cold flow conditions only the continuity and momentum equations are required as defined by (3.424) choosing appropriate values for the generalized functions analogous to those in Table 3.1. The governing mixture equations are then expressed as:

$$\frac{\partial \rho_m}{\partial t} + \nabla \cdot (\rho_m \mathbf{v}_m) = 0 \quad (3.431)$$

and

$$\frac{\partial(\rho_m \mathbf{v}_m)}{\partial t} + \nabla \cdot (\rho_m \mathbf{v}_m \mathbf{v}_m) = -\nabla p_m - \nabla \cdot (\boldsymbol{\sigma}_m + \boldsymbol{\sigma}_{m,t}) + \rho_m \mathbf{g} \quad (3.432)$$

where  $\mathbf{v}_m$  is the mixture velocity vector which represents the velocity of the mixture mass center,  $\mathbf{g}$  is the acceleration due to gravity,  $p_m$  is the mixture pressure,  $\boldsymbol{\sigma}_m$  is the mixture viscous stress tensor, and  $\boldsymbol{\sigma}_{m,t}$  is the turbulent mixture stress tensor.

For Newtonian fluids the effective stress tensor (i.e., the sum of the viscous and turbulent stresses) is given by:

$$\boldsymbol{\sigma}_{m,\text{eff}} = \boldsymbol{\sigma}_m + \boldsymbol{\sigma}_{m,t} = -\mu_{\text{eff}}(\nabla \mathbf{v}_m + (\nabla \mathbf{v}_m)^T) - \frac{2}{3} \mathbf{e}(\nabla \cdot \mathbf{v}_m) \quad (3.433)$$

In order to approximate the effective viscosity  $\mu_{\text{eff}} = \mu_{m,t} + \mu_m$  for the mixture flows, separate models are needed for the turbulent viscosity  $\mu_{m,t}$  and the mixture viscosity  $\mu_m$ . The standard k- $\epsilon$  model originally developed for single-phase flows has been used to compute the turbulent viscosity  $\mu_{m,t}$  in the majority of publications on numerical simulations of two-phase flows. Nevertheless, it is still an open question whether the approximate turbulence models which were originally developed for single-phase flow are appropriate for two-phase flow simulations [130].

The volume fractions of the dispersed phases can be calculated from the time-after volume averaged phase  $k = d$  continuity equations, as examined in Sect. 3.5.4. A common form of the modeled continuity equations yields:

$$\frac{\partial(\alpha_d \rho_d)}{\partial t} + \nabla \cdot (\alpha_d \rho_d \mathbf{v}_d) = \nabla \cdot (\rho_d D_{\alpha,t}^{\alpha_d} \nabla \alpha_d) \quad (3.434)$$

in which the diffusive terms accounts for dispersive effects of the dispersed phase due to random fluctuations of the fluid-particle motions. This term stems from the modeled volume fraction-velocity covariance in the continuity equation [127, 219].

For turbulent flows the turbulent diffusivity  $D_{\alpha,t}^{\alpha_d}$  is normally determined by the turbulent viscosity as the turbulent Schmidt number is about 1.

In (3.434) the dispersed phase velocity  $\mathbf{v}_d$  occurs as an undetermined variable. The phasic velocities are related to the mixture velocity through the mixture velocity definition (3.428). The dispersed phase velocity is computed from the continuous phase velocity  $\mathbf{v}_c$  and a relative (slip) velocity  $\mathbf{v}_{rk}$ , in accordance with the definitions:

$$\mathbf{v}_{rk} = \mathbf{v}_k - \mathbf{v}_c \quad (3.435)$$

For the relative (slip) velocity  $\mathbf{v}_{rd}$  numerous empirical correlations are available in the literature [38]. Hence it follows that each component of the dispersed phase momentum equation is reduced to an algebraic-slip relation (3.435). This is the reason why this mixture model formulation is referred to as the *algebraic-slip mixture model*. In particular applications alternative relations for the slip velocity (3.435) can be derived introducing suitable simplifying assumptions about the dispersed phase momentum equations comparing the relative importance of the pressure gradient, the drag force, the added mass force, the Basset force, the Magnus force and the Saffman lift force [62, 127, 133]. For gas-liquid flows it is frequently assumed that the last four effects are negligible [21, 215].

The relation for the slip velocity is then written as:

$$\mathbf{v}_{\text{slip},d} = -\frac{\nabla p}{C_{D,d}} \quad (3.436)$$

where  $C_{D,d}$  is a drag force coefficient for which a large number of correlations can be found in literature. It is noted that each of these expressions is only valid under specific operating conditions. The  $C_{D,d}$  depends primarily on the particle Reynolds number  $Re_p$ .

In the past the bubble size dependency was considered negligible for air bubbles in water in the mean diameter size range 1–10 mm. Hence,

$$C_D = 50 \frac{g}{\text{cm}^3 \text{s}} \quad (3.437)$$

was used in this bubble size range, leading to a mean bubble slip velocity of about 20 cm/s, which is in approximate agreement with experimental velocity data of air bubbles in tap water [38, 197].

For dispersed gas-liquid flows it is further assumed that  $p_m = p_c = p$ . The density of the continuous liquid phase is commonly assumed constant  $\rho_l \approx \text{constant}$ , while the density of the gas phases is either given in accordance with the ideal gas law  $\rho_g = \frac{pM_w}{RT}$  or assumed constant. The viscosities of both phases are commonly given constant values. The bubble wake effects are occasionally considered important describing the transversal movement of the bubbles [77, 232]. In these cases it is imagined that small bubbles are accelerated in the wake of larger ones and others are pushed aside. Hence, there is a considerable particle path dispersion on the bubble size

scale which appears as a random motion on the macro scale level considered in the model. The impacts of these random spatially dispersive effect are often assumed embedded in the diffusion-like term occurring in the continuity equation for the gas phase (3.434). The corresponding diffusion coefficient has been related to the turbulent eddy viscosity of the liquid phase [128]. This approach assumes an isotropic dispersion. However, since real bubbles rise relative to the liquid predominantly in the vertical direction, the dispersion will probably not be an isotropic effect [129]. A more general representation might be expressed in terms of a dispersion tensor. However, at present there are neither sufficient knowledge available to model the tensor elements nor enough experimental data to validate such models. This gas-liquid modeling approach has been used performing dynamic simulations of two-phase bubble column reactor flows operating at low gas holdups [21, 215, 216]. A major limitation revealed in these simulations is that there is some difficulties in conserving mass for the dispersed phases, so this concept is not recommended for the purpose of simulating chemically reactive flows.

### 3.5.5.3 The Diffusion Mixture Model

In this section we derive the diffusion mixture model equations starting from the time averaged multi-fluid model expressed in terms of phase- and mass weighted variables [118]. The relative movement of the individual phases is given in terms of diffusion velocities.

The continuity and momentum equations for each phase  $k$  are given by:

$$\frac{\partial}{\partial t}(\alpha_k \langle \rho_k \rangle^{X_k}) + \nabla \cdot (\alpha_k \langle \rho_k \rangle^{X_k} \langle \mathbf{v}_k \rangle^{X_k \rho_k}) = \Gamma_k \quad (3.438)$$

and

$$\begin{aligned} & \frac{\partial}{\partial t}(\alpha_k \langle \rho_k \rangle^{X_k} \langle \mathbf{v}_k \rangle^{X_k \rho_k}) + \nabla \cdot (\alpha_k \langle \rho_k \rangle^{X_k} \langle \mathbf{v}_k \rangle^{X_k \rho_k} \langle \mathbf{v}_k \rangle^{X_k \rho_k}) \\ &= -\alpha_k \nabla \langle p_k \rangle^{X_k} - \nabla \cdot (\alpha_k [\langle \boldsymbol{\sigma}_k \rangle^{X_k} + \langle \boldsymbol{\sigma}_{t,k}^{Re} \rangle^{X_k}]) \\ &+ \alpha_k \langle \rho_k \rangle^{X_k} \langle \mathbf{g} \rangle^{X_k \rho_k} + \mathbf{F}_k \end{aligned} \quad (3.439)$$

The turbulent stress tensor is given by:

$$\langle \boldsymbol{\sigma}_{t,k}^{Re} \rangle^{X_k} = \langle \rho_k \mathbf{v}''_k \mathbf{v}''_k \rangle^{X_k} \quad (3.440)$$

The corresponding time averaged jump conditions yields:

$$\sum_k \Gamma_k = 0 \quad (3.441)$$

$$\sum_k \mathbf{F}_k = \mathbf{F}_I \quad (3.442)$$

where we have neglected the effect of interfacial mass transfer upon the interfacial momentum transfer.

Based on the Favre-averaged continuity equations (3.438), the mixture continuity equation is obtained by taking the sum over all phases:

$$\frac{\partial}{\partial t} \sum_k (\alpha_k \langle \rho_k \rangle^{X_k}) + \nabla \cdot \sum_k \alpha_k \langle \rho_k \rangle^{X_k} \langle \mathbf{v}_k \rangle^{X_k \rho_k} = \sum_k \Gamma_k \quad (3.443)$$

At the interface the total mass is balanced in accordance with the jump mass condition (3.441), thus the RHS of (3.443) must vanish. Hence, by use of the Favre averaged form of (3.425) and (3.428) we obtain the continuity equation for the mixture (3.431).

The mixture momentum equation can be deduced in a similar way from the sum of the momentum balances of the individual phases:

$$\begin{aligned} & \frac{\partial}{\partial t} \sum_k \alpha_k \langle \rho_k \rangle^{X_k} \langle \mathbf{v}_k \rangle^{X_k \rho_k} + \nabla \cdot \sum_k \alpha_k \langle \rho_k \rangle^{X_k} \langle \mathbf{v}_k \rangle^{X_k \rho_k} \langle \mathbf{v}_k \rangle^{X_k \rho_k} \\ &= - \sum_k \alpha_k \nabla \langle p_k \rangle^{X_k} - \nabla \cdot \left( \sum_k \alpha_k [ \langle \boldsymbol{\sigma}_k \rangle^{X_k} + \langle \boldsymbol{\sigma}_{t,k}^{Re} \rangle^{X_k} ] \right) \\ &+ \sum_k \alpha_k \langle \rho_k \rangle^{X_k} \langle \mathbf{g} \rangle^{X_k \rho_k} + \sum_k \mathbf{F}_k \end{aligned} \quad (3.444)$$

Ishii [118] introduced the *diffusion velocity*  $\mathbf{v}_{Mk}$  of phase  $k$  defined as the velocity of phase  $k$  relative to the velocity of the mass center of the mixture:

$$\mathbf{v}_{Mk} = \langle \mathbf{v}_k \rangle^{X_k \rho_k} - \mathbf{v}_m \quad (3.445)$$

Using the given definition of the diffusion velocity (3.445), the Favre form of the mixture density (3.425) and the Favre form of the mixture velocity (3.428), the second term in the mixture momentum balance (3.444) can be reformulated:

$$\begin{aligned} & \nabla \cdot \sum_k \alpha_k \langle \rho_k \rangle^{X_k} \langle \mathbf{v}_k \rangle^{X_k \rho_k} \langle \mathbf{v}_k \rangle^{X_k \rho_k} \\ &= \nabla \cdot (\rho_m \mathbf{v}_m \mathbf{v}_m) + \nabla \cdot \sum_k (\alpha_k \langle \rho_k \rangle^{X_k} \mathbf{v}_{Mk} \mathbf{v}_{Mk}) \end{aligned} \quad (3.446)$$

Introducing the mixture- and diffusion velocity variables (3.428) and (3.445), the momentum Eq. (3.444) takes the form:

$$\frac{\partial}{\partial t} (\rho_m \mathbf{v}_m) + \nabla \cdot (\rho_m \mathbf{v}_m \mathbf{v}_m) = -\nabla p_m - \nabla \cdot (\boldsymbol{\sigma}_m + \boldsymbol{\sigma}_{m,t}^{Re} + \boldsymbol{\sigma}_{Mm}) + \rho_m \mathbf{g} + \mathbf{F}_I \quad (3.447)$$

The last term on the right hand side of the mixture momentum equation (3.447) accounts for the influence of the surface tension force  $\mathbf{F}_I$  on the mixture in accordance with (3.442).

The three stress tensors are defined as:

$$\boldsymbol{\sigma}_m = \sum_k \alpha_k \langle \boldsymbol{\sigma}_k \rangle^{X_k} \quad (3.448)$$

$$\boldsymbol{\sigma}_{m,t}^{Re} = \sum_k \alpha_k \langle \rho_k \mathbf{v}''_k \mathbf{v}''_k \rangle^{X_k} \quad (3.449)$$

$$\boldsymbol{\sigma}_{Mm} = \sum_k \alpha_k \langle \rho_k \rangle^{X_k} \mathbf{v}_{Mk} \mathbf{v}_{Mk} \quad (3.450)$$

These tensors represent the average viscous stress, turbulent stress and diffusion stress due to the phase slip, respectively.

In (3.447) the pressure of the mixture is defined by the relation:

$$\nabla p_m = \sum_k \alpha_k \nabla \langle p_k \rangle^{X_k} \quad (3.451)$$

In practice, the phase pressures are often assumed to be equal, i.e.,  $\langle p_k \rangle^{X_k} = p_m = p$ .

If we now return to consider an individual phase, we may use the definition of the diffusion velocity (3.445) to eliminate the phase velocity in the continuity equation for phase  $k$ :

$$\frac{\partial}{\partial t} (\alpha_k \langle \rho_k \rangle^{X_k}) + \nabla \cdot (\alpha_k \langle \rho_k \rangle^{X_k} \mathbf{v}_m) = \Gamma_k - \nabla \cdot (\alpha_k \langle \rho_k \rangle^{X_k} \mathbf{v}_{Mk}) \quad (3.452)$$

In practice, the diffusion velocity has to be determined through the relative velocity (3.435). Hence, it follows that:

$$\begin{aligned} \mathbf{v}_{Md} &= \langle \mathbf{v}_d \rangle^{X_d \rho_d} - \mathbf{v}_m \\ &= [\mathbf{v}_{rd} + \langle \mathbf{v}_c \rangle^{X_c \rho_c}] - \left[ \frac{1}{\rho_m} \sum_{k=1}^n \alpha_k \langle \rho_k \rangle^{X_k} \langle \mathbf{v}_k \rangle^{X_k \rho_k} \right] \\ &= [\mathbf{v}_{rd} + \langle \mathbf{v}_c \rangle^{X_c \rho_c}] - \left[ \frac{1}{\rho_m} \sum_{k=1}^n \alpha_k \langle \rho_k \rangle^{X_k} (\mathbf{v}_{rk} + \langle \mathbf{v}_c \rangle^{X_c \rho_c}) \right] \\ &= [\mathbf{v}_{rd} + \langle \mathbf{v}_c \rangle^{X_c \rho_c}] \\ &\quad - \left[ \frac{1}{\rho_m} \sum_{d=1}^{n-1} \alpha_d \langle \rho_d \rangle^{X_d} \mathbf{v}_{rd} + \frac{1}{\rho_m} \sum_{k=1}^n \alpha_k \langle \rho_k \rangle^{X_k} \langle \mathbf{v}_c \rangle^{X_c \rho_c} \right] \\ &= \mathbf{v}_{rd} - \frac{1}{\rho_m} \sum_{d=1}^{n-1} \alpha_d \langle \rho_d \rangle^{X_d} \mathbf{v}_{rd} \end{aligned} \quad (3.453)$$

When the diffusion velocity is eliminated, the main difference between the particular diffusion- and algebraic-slip mixture models presented in this section is that the algebraic-slip model is derived using a double time- after volume averaging operator [219], while the diffusion model is derived applying a single time averaging operator combined with the introduction of phase- and mass weighted variables [118]. The given diffusion model formulation has been used simulating the gas-liquid dynamics in cylindrical bubble column reactors [195].

### 3.5.5.4 The Drift-Flux Mixture Model

In this section we derive the drift-flux mixture model starting out from the time averaged multi-fluid model expressed in terms of phase- and mass weighted variables [118]. The relative moment of the phases is given in terms of drift velocities. This approach can be applied for systems where the phase densities are constants and the interface mass transfer can be neglected.

The drift velocity  $\mathbf{v}_{Vk}$  of phase  $k$  is defined as the velocity of phase  $k$  relative to the velocity of the volume center of the mixture [91, 118]:

$$\mathbf{v}_{Vk} = \langle \mathbf{v}_k \rangle^{X_k \rho_k} - \sum_k \alpha_k \langle \mathbf{v}_k \rangle^{X_k \rho_k} = \langle \mathbf{v}_k \rangle^{X_k \rho_k} - \mathbf{j}_m \quad (3.454)$$

where  $\mathbf{j}_m = \sum_k \alpha_k \langle \mathbf{v}_k \rangle^{X_k \rho_k}$  is the volumetric flux of the mixture representing the velocity of the volume center of the mixture. We may then write:

$$\sum_k \alpha_k \mathbf{v}_{Vk} = \sum_k \alpha_k \langle \mathbf{v}_k \rangle^{X_k \rho_k} - \sum_k \alpha_k \mathbf{j}_m = \mathbf{j}_m - \mathbf{j}_m = 0 \quad (3.455)$$

The flux of the dispersed phase relative to the velocity of the volume centre of the mixture is given by [91]:

$$\mathbf{J}_{Vd} = \alpha_d (\langle \mathbf{v}_d \rangle^{X_d \rho_d} - \mathbf{j}_m) = \alpha_d \mathbf{v}_{Vd} \quad (3.456)$$

Introducing the mixture- and drift velocity variables (3.428) and (3.454), the momentum Eq. (3.444) takes the form:

$$\frac{\partial}{\partial t} (\rho_m \mathbf{v}_m) + \nabla \cdot (\rho_m \mathbf{v}_m \mathbf{v}_m) = -\nabla p_m - \nabla \cdot (\boldsymbol{\sigma}_m + \boldsymbol{\sigma}_{m,t}^{Re} + \boldsymbol{\sigma}_{Vm}) + \rho_m \mathbf{g} + \mathbf{F}_I \quad (3.457)$$

The three stress tensors are defined as:

$$\boldsymbol{\sigma}_m = \sum_k \alpha_k \langle \boldsymbol{\sigma}_k \rangle^{X_k} \quad (3.458)$$

$$\sigma_{m,t}^{Re} = \sum_k \alpha_k \langle \rho_k \mathbf{v}''_k \mathbf{v}''_k \rangle^{X_k} \quad (3.459)$$

$$\sigma_{Vm} = \sum_k \alpha_k \langle \rho_k \rangle^{X_k} \mathbf{v}_{Vk} \mathbf{v}_{Vk} \quad (3.460)$$

These tensors represent the average viscous stress, turbulent stress and drift stress due to the phase slip, respectively.

For systems with constant densities and no phase change, the Favre averaged continuity Eq. (3.438) reduces to:

$$\frac{\partial \alpha_k}{\partial t} + \nabla \cdot (\alpha_k \langle \mathbf{v}_k \rangle^{X_k \rho_k}) = 0 \quad (3.461)$$

By use of the drift velocity (3.454), the continuity equation can be rewritten as:

$$\frac{\partial \alpha_k}{\partial t} + \nabla \cdot (\alpha_k \mathbf{j}_m) + \nabla \cdot (\alpha_k \mathbf{v}_{Vk}) = 0 \quad (3.462)$$

After some manipulations we get:

$$\frac{\partial \alpha_k}{\partial t} + \mathbf{j}_m \cdot \nabla \alpha_k = -\nabla \cdot (\alpha_k \mathbf{v}_{Vk}) \quad (3.463)$$

where the relation  $\nabla \cdot \mathbf{j}_m = 0$  is derived taking the sum of the individual continuity equations for all the phases in the system.

In practice, the drift velocity (3.454) is determined from the slip velocity (3.436) as follows:

$$\begin{aligned} \mathbf{v}_{V,k} &= \langle \mathbf{v}_k \rangle^{X_k \rho_k} - \sum_k \alpha_k \langle \mathbf{v}_k \rangle^{X_k \rho_k} \\ &= [\langle \mathbf{v}_c \rangle^{X_c \rho_c} + \mathbf{v}_{rk}] - \left[ \sum_k \alpha_k (\langle \mathbf{v}_c \rangle^{X_c \rho_c} + \mathbf{v}_{rk}) \right] = \mathbf{v}_{rk} - \sum_k \alpha_k \mathbf{v}_{rk} \end{aligned} \quad (3.464)$$

This form of the mixture model is called the *drift flux* model. In particular cases the flow calculations is significantly simplified when the problem is described in terms of drift velocities, as for example when  $\alpha_d$  is constant or time dependent only. However, in reactor technology this model formulation is restricted to multiphase cold flow studies as the drift-flux model cannot be adopted simulating reactive systems in which the densities are not constants and interfacial mass transfer is required. The drift-flux model equations have been assessed in multiphase flow analysis by several authors [91, 118, 155, 246].

**Fig. 3.7** Sketch of the control volume determining the basis for area-averaging of the two phase equations

### 3.5.6 The Gross Scale Averaged Two-Phase Transport Equations

The area averaging theory described in this section is based on the papers by [12, 18, 24, 26, 48, 50, 51, 121, 144, 244, 258]. The main object in this section is to provide the necessary theorems to derive the cross-sectional averaged equations that coincide with the conventional 1D multiphase chemical reactor model from first principles. To formulate these theorems we chose to adopt the same concepts as were used deriving the corresponding single phase equations in Sect. 1.2.6. Following the approach of Delhay and Achard [51] we proceed performing an analysis of a small volume of a pipe with variable cross-section area containing a two phase mixture and deduce the limiting forms of the Leibnitz' and Gauss' theorems for area considered valid in the limit  $\Delta z \rightarrow 0$ . For this reason it is emphasized that these theorems are actually derived for a volume but reduces to an area formulation introducing certain simplifying approximations.

Given a tube with axis  $Oz$  (unit vector  $\mathbf{e}_z$ ) in which a volume  $V_k$  is limited by a boundary,  $A_I$  and cut by a cross section plane over area,  $A_k$ , as sketched in Fig. 3.7. The lateral dimensions of the control volume extend to the conduit walls. In this notation,  $\mathbf{n}_k$  is the outward directed unit vector normal to the interface of phase  $k$ .  $l_I(t, z)$  is the intersection of interface,  $A_I$ , with the cross sectional plane.  $\mathbf{n}_{l,k}$  is the outward directed unit vector normal to the closed curve of phase  $k$ ,  $l_{W,k}(t, z)$ , in the cross section plane.

The purpose of this derivation is to average the local, instantaneous balance equation over the variable cross-section area of a pipe occupied by the two phases, as sketched in Fig. 3.7.

The local, instantaneous balance equation (1.3) is integrated over the cross section area,  $A_k(t, z)$ , limited by the boundaries,  $l_I(t, z)$ , with the other phase and with the pipe wall boundary,  $l_{W,k}(t, z)$ :

$$\int_{A_k(t,z)} \frac{\partial(\rho_k \psi_k)}{\partial t} da + \int_{A_k(t,z)} \nabla \cdot (\rho_k \mathbf{v}_k \psi_k) da = - \int_{A_k(t,z)} \nabla \cdot \mathbf{J}_k da + \int_{A_k(t,z)} \sum_c \rho_{c,k} \phi_{c,k} da \quad (3.465)$$

To proceed the limiting forms of the Leibnitz and the Gauss theorems,<sup>19</sup> appropriate for two phase flow, are applied. These theorems are considered direct extensions of the single phase theorems examined in Sect. 1.2.6 so no further derivation is given here. In most reactor model formulations the pipe walls are supposed to be fixed and impermeable. In the limit  $z \rightarrow 0$ , the limiting form of the Leibnitz theorem for volume reduces to the following relation for area [47, 51]:

$$\begin{aligned} \frac{\partial}{\partial t} \int_{A_k(t,z)} f(\mathbf{r}, t) da &= \int_{A_k(t,z)} \frac{\partial f(\mathbf{r}, t)}{\partial t} da + \int_{l_I(t,z)} f(\mathbf{r}, t) \mathbf{v}_I \cdot \mathbf{n}_k \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} \\ &+ \int_{l_{W,k}(t,z)} f(\mathbf{r}, t) \mathbf{v}_W \cdot \mathbf{n}_k \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,W}} \end{aligned} \quad (3.466)$$

where  $\mathbf{v}_I \cdot \mathbf{n}_k$  is the displacement velocity of a point on the interface,  $A_I$ , and  $\mathbf{v}_W \cdot \mathbf{n}_k$  is the displacement velocity of a point on the wall boundary face,  $A_W$ .

For the particular case when the phase  $k$  control volume is varying both in time and space at the interface, but in space only at the wall boundary face, this relation is simplified as  $\mathbf{v}_W \cdot \mathbf{n}_W = 0$ :

$$\frac{\partial}{\partial t} \int_{A_k(t,z)} f(\mathbf{r}, t) da = \int_{A_k(t,z)} \frac{\partial f(\mathbf{r}, t)}{\partial t} da + \int_{l_I(t,z)} f(\mathbf{r}, t) \mathbf{v}_I \cdot \mathbf{n}_k \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} \quad (3.467)$$

In the limit  $z \rightarrow 0$ , the limiting form of the Gauss theorem for volume reduces to the following relation for area (where we let  $\mathbf{B}$  be a vector or a tensor):

<sup>19</sup> Area averaging can be considered to be a limiting case of local volume averaging [47, 51, 202]. Thus the phrase *limiting form* refers to the modified forms of the averaging theorems which are applicable to the governing 3D equations to derive a set of equations valid for 1D problems.

$$\int_{A_k(t,z)} \nabla \cdot \mathbf{B} da = \frac{\partial}{\partial z} \int_{A_k(t,z)} \mathbf{e}_z \cdot \mathbf{B} da + \int_{l_I(t,z)} \mathbf{n}_k \cdot \mathbf{B} \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} + \int_{l_{W,k}(t,z)} \mathbf{n}_k \cdot \mathbf{B} \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,W}} \quad (3.468)$$

In the case of  $\mathbf{B}$  being a vector, the component of the vector  $\mathbf{B}$  on  $Oz$  is given by  $\mathbf{e}_z \cdot \mathbf{B} = B_z$ .

If we take  $\mathbf{B} = \mathbf{e}_z$ , we obtain:

$$\int_{A_k(t,z)} \nabla \cdot \mathbf{e}_z da = \frac{\partial}{\partial z} \int_{A_k(t,z)} \mathbf{e}_z \cdot \mathbf{e}_z da + \int_{l_I(t,z)} \mathbf{n}_k \cdot \mathbf{e}_z \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} + \int_{l_{W,k}(t,z)} \mathbf{n}_k \cdot \mathbf{e}_z \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,W}} \quad (3.469)$$

With minor rearrangement this gives the following important result:

$$\frac{\partial A_k(t,z)}{\partial z} = - \int_{l_I(t,z)} \mathbf{n}_k \cdot \mathbf{e}_z \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} - \int_{l_{W,k}(t,z)} \mathbf{n}_k \cdot \mathbf{e}_z \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,W}} \quad (3.470)$$

Introducing these relations into the cross section area averaged equation, gives:

$$\begin{aligned} & \frac{\partial}{\partial t} \int_{A_k(t,z)} (\rho_k \psi_k) da + \frac{\partial}{\partial z} \int_{A_k(t,z)} (\rho_k v_{z,k} \psi_k) da + \frac{\partial}{\partial z} \int_{A_k(t,z)} (\mathbf{e}_z \cdot \mathbf{J}_k) da \\ &= - \int_{l_{W,k}(t,z)} \mathbf{n}_k \cdot \mathbf{J}_k \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,W}} - \int_{l_{W,k}(t,z)} \mathbf{n}_k \cdot (\rho_k \mathbf{v}_k \psi_k) \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,W}} \\ & \quad - \int_{l_I(t,z)} \mathbf{n}_k \cdot \mathbf{J}_k \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} - \int_{l_I(t,z)} \mathbf{n}_k \cdot (\rho_k \mathbf{v}_k \psi_k) \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} \\ & \quad + \int_{l_I(t,z)} \rho_k \psi_k (\mathbf{v}_I \cdot \mathbf{n}_k) \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} + \int_{A_k(t,z)} \sum_c (\rho_{c,k} \phi_{c,k}) da \end{aligned} \quad (3.471)$$

where  $v_{z,k}$  is the  $z$ -component of the velocity vector,  $\mathbf{v}_k$ .

As we assume no mass flow through the pipe wall, the wall convection term is equal to zero as  $\mathbf{n}_k \cdot \mathbf{v}_k = 0$  at the wall. The equation reduces to:

$$\begin{aligned} & \frac{\partial}{\partial t} \int_{A_k(t,z)} (\rho_k \psi_k) da + \frac{\partial}{\partial z} \int_{A_k(t,z)} (\rho_k v_{z,k} \psi_k) da + \frac{\partial}{\partial z} \int_{A_k(t,z)} (\mathbf{e}_z \cdot \mathbf{J}_k) da \\ &= - \int_{l_{W,k}(t,z)} \mathbf{n}_k \cdot \mathbf{J}_k \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,W}} - \int_{l_I(t,z)} \mathbf{n}_k \cdot (\rho_k \mathbf{v}_k \psi_k + \mathbf{J}_k) \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} \\ & \quad + \int_{l_I(t,z)} \rho_k \psi_k (\mathbf{v}_I \cdot \mathbf{n}_k) \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} + \int_{A_k(t,z)} \sum_c (\rho_{c,k} \phi_{c,k}) da \end{aligned} \quad (3.472)$$

With minor manipulation,

$$\begin{aligned}
 & \frac{\partial}{\partial t} \int_{A_k(t,z)} (\rho_k \psi_k) da + \frac{\partial}{\partial z} \int_{A_k(t,z)} (\rho_k v_{z,k} \psi_k) da + \frac{\partial}{\partial z} \int_{A_k(t,z)} (\mathbf{e}_z \cdot \mathbf{J}_k) da \\
 &= - \int_{l_{W,k}(t,z)} \mathbf{n}_k \cdot \mathbf{J}_k \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,W}} - \int_{l_I(t,z)} (m_k \psi_k + \mathbf{n}_k \cdot \mathbf{J}_k) \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} \\
 &+ \int_{A_k(t,z)} \sum_c (\rho_{c,k} \phi_{c,k}) da
 \end{aligned} \tag{3.473}$$

where  $m_k$  is the interfacial mass transfer rate given by (3.145).

Introducing area averaged quantities by use of the area averaging operator defined by:

$$\langle \psi_k \rangle_{A_k} = \frac{1}{A_k} \int_{A_k(t,z)} \psi da, \tag{3.474}$$

The balance equation can be written as:

$$\begin{aligned}
 & \frac{\partial (A_k \langle \rho_k \psi_k \rangle_{A_k})}{\partial t} + \frac{\partial}{\partial z} (A_k \langle \rho_k v_{z,k} \psi_k \rangle_{A_k}) + \frac{\partial}{\partial z} (A_k \langle \mathbf{e}_z \cdot \mathbf{J}_k \rangle_{A_k}) \\
 &= - \int_{l_{W,k}(t,z)} \mathbf{n}_k \cdot \mathbf{J}_k \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,W}} - \int_{l_I(t,z)} (m_k \psi_k + \mathbf{n}_k \cdot \mathbf{J}_k) \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} \\
 &+ \sum_c A_k \langle \rho_{c,k} \phi_{c,k} \rangle_{A_k}
 \end{aligned} \tag{3.475}$$

The cross-section averaged equations governing phase  $k$  are obtained defining the specific values of the generalized variables in (3.475) in accordance with Table 3.1. The instantaneous area-averaged equations for the balance of mass, momentum, total energy, species mass and entropy are given in the sequel:

*The Balance of Mass:*

In this case we define  $\psi_k = 1$ ,  $\mathbf{J}_k = 0$ , and  $\phi_{c,k} = 0$ , hence:

$$\frac{\partial (A_k \langle \rho_k \rangle_{A_k})}{\partial t} + \frac{\partial}{\partial z} (A_k \langle \rho_k v_{z,k} \rangle_{A_k}) = - \int_{l_I(t,z)} m_k \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} = \Gamma_{A_k} A \tag{3.476}$$

$\Gamma_{A_k}$  is the area averaged interfacial mass transfer rate defined by:

$$\Gamma_{A_k} = - \frac{1}{A} \int_{l_I(t,z)} m_k \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} \tag{3.477}$$

*The Balance of Momentum:*

In this case we define  $\psi_k = \mathbf{v}_k$ ,  $\mathbf{J}_k = \mathbf{T}_k$ , and  $\phi_{c,k} = \mathbf{g}_{c,k}$ , thus:

$$\begin{aligned} & \frac{\partial(A_k \langle \rho_k \mathbf{v}_k \rangle_{A_k})}{\partial t} + \frac{\partial}{\partial z}(A_k \langle \rho_k v_{z,k} \mathbf{v}_k \rangle_{A_k}) + \frac{\partial}{\partial z}(A_k \langle \mathbf{e}_z \cdot \mathbf{T}_k \rangle_{A_k}) \\ &= - \int_{l_{W,k}(t,z)} \mathbf{n}_k \cdot \mathbf{T}_k \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,W}} - \int_{l_I(t,z)} (m_k \mathbf{v}_k + \mathbf{n}_k \cdot \mathbf{T}_k) \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} \\ &+ \sum_c A_k \langle \rho_{c,k} \mathbf{g}_{c,k} \rangle_{A_k} \end{aligned} \quad (3.478)$$

Splitting the total stress tensor,  $\mathbf{T}_k$ , into a pressure term,  $p_k \mathbf{e}$ , and a viscous stress tensor,  $\boldsymbol{\sigma}_k$ , we get:

$$\begin{aligned} & \frac{\partial(A_k \langle \rho_k \mathbf{v}_k \rangle_{A_k})}{\partial t} + \frac{\partial}{\partial z}(A_k \langle \rho_k v_{z,k} \mathbf{v}_k \rangle_{A_k}) + \frac{\partial}{\partial z}(A_k \langle p_k \mathbf{e}_z \rangle_{A_k}) \\ &= - \frac{\partial}{\partial z}(A_k \langle \mathbf{e}_z \cdot \boldsymbol{\sigma}_k \rangle_{A_k}) + \sum_c A_k \langle \rho_{c,k} \mathbf{g}_{c,k} \rangle_{A_k} \\ &- \int_{l_{W,k}(t,z)} \mathbf{n}_k \cdot \mathbf{T}_k \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,W}} - \int_{l_I(t,z)} (m_k \mathbf{v}_k + \mathbf{n}_k \cdot \mathbf{T}_k) \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} \end{aligned} \quad (3.479)$$

If we project the terms in (3.479) along the tube axis, we obtain:

$$\begin{aligned} & \frac{\partial(A_k \langle \rho_k v_{z,k} \rangle_{A_k})}{\partial t} + \frac{\partial}{\partial z}(A_k \langle \rho_k v_{z,k} v_{z,k} \rangle_{A_k}) + \frac{\partial}{\partial z}(A_k \langle p_k \rangle_{A_k}) \\ &= - \frac{\partial}{\partial z}(A_k \langle (\mathbf{e}_z \cdot \boldsymbol{\sigma}_k) \cdot \mathbf{e}_z \rangle_{A_k}) + \sum_c A_k \langle \rho_{c,k} g_{c,z,k} \rangle_{A_k} \\ &- \int_{l_{W,k}(t,z)} (\mathbf{n}_k \cdot \mathbf{T}_k) \cdot \mathbf{e}_z \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,W}} - \int_{l_I(t,z)} (m_k \mathbf{v}_k + \mathbf{n}_k \cdot \mathbf{T}_k) \cdot \mathbf{e}_z \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} \end{aligned} \quad (3.480)$$

If we assume that the pressure,  $p_k$ , is constant along  $l_I$  and  $l_W$ , and equal to the averaged pressure,  $\langle p_k \rangle_{A_k}$  over  $A_k$ . Then, by using the definition (3.470), (3.480) can be written as:

$$\begin{aligned} & \frac{\partial(A_k \langle \rho_k v_{z,k} \rangle_{A_k})}{\partial t} + \frac{\partial}{\partial z}(A_k \langle \rho_k v_{z,k} v_{z,k} \rangle_{A_k}) + \frac{\partial}{\partial z}(A_k \langle p_k \rangle_{A_k}) \\ &\approx - \frac{\partial}{\partial z}(A_k \langle (\mathbf{e}_z \cdot \boldsymbol{\sigma}_k) \cdot \mathbf{e}_z \rangle_{A_k}) + \sum_c A_k \langle \rho_{c,k} g_{c,z,k} \rangle_{A_k} \\ &- \int_{l_{W,k}(t,z)} (\mathbf{n}_k \cdot \boldsymbol{\sigma}_k) \cdot \mathbf{e}_z \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,W}} - \int_{l_I(t,z)} (m_k \mathbf{v}_k + \mathbf{n}_k \cdot \boldsymbol{\sigma}_k) \cdot \mathbf{e}_z \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} \end{aligned}$$

$$+ \langle p_k \rangle_{A_k} \frac{\partial A_k}{\partial z} \quad (3.481)$$

or

$$\begin{aligned} & \frac{\partial (A_k \langle \rho_k v_{z,k} \rangle_{A_k})}{\partial t} + \frac{\partial}{\partial z} (A_k \langle \rho_k v_{z,k} v_{z,k} \rangle_{A_k}) + A_k \frac{\partial \langle p_k \rangle_{A_k}}{\partial z} \\ & \approx - \frac{\partial}{\partial z} (A_k \langle (\mathbf{e}_z \cdot \boldsymbol{\sigma}_k) \cdot \mathbf{e}_z \rangle_{A_k}) + \sum_c A_k \langle \rho_{c,k} g_{c,z,k} \rangle_{A_k} \\ & - \int_{l_{W,k}(t,z)} (\mathbf{n}_k \cdot \boldsymbol{\sigma}_k) \cdot \mathbf{e}_z \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,W}} - \int_{l_I(t,z)} (m_k \mathbf{v}_k + \mathbf{n}_k \cdot \boldsymbol{\sigma}_k) \cdot \mathbf{e}_z \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} \end{aligned} \quad (3.482)$$

The interfacial momentum transfer due to phase change is defined by:

$$M_{k,z}^{\Gamma} = - \frac{1}{A} \int_{l_I(t,z)} m_k \mathbf{v}_k \cdot \mathbf{e}_z \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} = \Gamma_{A_k} \langle v_z \rangle_{l_I}^{\Gamma_{A_k}} \quad (3.483)$$

For dispersed flows the interfacial momentum viscous stresses acting on the dispersed phase can be approximated by:

$$M_{z,d}^{\sigma} = - \frac{1}{A} \int_{l_I(t,z)} (\mathbf{n}_d \cdot \boldsymbol{\sigma}_d) \cdot \mathbf{e}_z \frac{dl}{\mathbf{n}_d \cdot \mathbf{n}_{l,d}} \approx - \frac{3}{4} \rho_c \frac{C_D}{d_S} \alpha_d |\langle v_{z,r} \rangle_A| \langle v_{z,r} \rangle_A \quad (3.484)$$

where  $d_S$  is the Sauter mean diameter and  $v_{z,r} = (v_{z,d} - v_{z,c})$  denotes the relative velocity. That is, the averaged drag force is related to the averaged local relative velocity  $\langle v_{z,r} \rangle_A$  and not to the difference between the area averaged velocities of the individual phases [121].

The wall momentum viscous stresses, i.e., the friction drag, yields:

$$\begin{aligned} M_{k,z}^{Drag} &= - \frac{1}{A} \int_{l_{W,k}(t,z)} (\mathbf{n}_k \cdot \boldsymbol{\sigma}_k) \cdot \mathbf{e}_z \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,W}} \\ &\approx - f_{D,W} \frac{1}{2} \rho_k |\langle v_{z,k} \rangle_A| \langle v_{z,k} \rangle_A \frac{S_W}{4A} \end{aligned} \quad (3.485)$$

where  $S_W$  is the perimeter of the wall.

By the principles of material indifference Slattery [210] (pp. 228–230) elucidated the functional relationship between the variables in the empirical friction or drag force parameterizations.<sup>20</sup> It is noted that the dimensionless wall drag or friction

<sup>20</sup> Whitaker [249] (Chap. 8) explains the convention normally used to distinguish between these two types of parameters. The friction factors for dispersed bodies immersed in a flowing fluid is traditionally referred to as dimensionless drag coefficients, whereas the drag force for flow inside closed conduits is generally expressed in terms of a dimensionless friction factor.

factors of Darcy ( $f_D$ ) and Fanning ( $f_F$ ) are related in the following manner (e.g., [132, 255]):

$$f_F = \frac{|\boldsymbol{\sigma}_w|}{\frac{1}{2}\rho v_z^2} = \frac{f_D}{4} \quad (3.486)$$

The friction factor for laminar flow in pipes ( $Re < 2300$ ) is given by  $f_D = 4f_L = \frac{64}{Re}$ . For turbulent flow in rough pipes the friction factors depends on both the Reynolds number and the surface roughness of the tube. Colebrook [39] devised an implicit relation for the Darcy friction factor which reproduce the well known Moody diagram quite well.

$$\frac{1}{\sqrt{f_D}} \approx 1.74 - 2.0 \log\left(2\frac{\epsilon}{D} + \frac{18.7}{Re\sqrt{f_D}}\right) \quad (3.487)$$

Similar parameterizations exist for flows past a flat plate, jets and wakes [255].

*The Balance of Total Energy:*

In this case we define  $\psi_k = (\frac{1}{2}v_{z,k}^2 + e_k)$ ,  $\mathbf{J}_k = (\mathbf{q}_k + \mathbf{T}_k \cdot \mathbf{v}_k)$ ,  $\phi_{c,k} = \mathbf{g}_{c,k} \cdot \mathbf{v}_{c,k}$ , so it follows that:

$$\begin{aligned} & \frac{\partial(A_k \langle \rho_k (\frac{1}{2}v_{z,k}^2 + e_k) \rangle_{A_k})}{\partial t} + \frac{\partial}{\partial z}(A_k \langle \rho_k v_{z,k} (\frac{1}{2}v_{z,k}^2 + e_k) \rangle_{A_k}) \\ &= -\frac{\partial}{\partial z}(A_k \langle (\mathbf{T}_k \cdot \mathbf{v}_k) \cdot \mathbf{e}_z \rangle_{A_k}) - \frac{\partial}{\partial z}(A_k \langle \mathbf{q}_k \cdot \mathbf{e}_z \rangle_{A_k}) \\ &+ \sum_c A_k \langle \rho_{c,k} \mathbf{g}_{c,k} \cdot \mathbf{v}_{c,k} \rangle_{A_k} - \int_{l_{W,k}(t,z)} \frac{\mathbf{q}_k \cdot \mathbf{n}_k}{\mathbf{n}_k \cdot \mathbf{n}_{l,W}} dl \\ &- \int_{l_I(t,z)} (m_k (\frac{1}{2}v_{z,k}^2 + e_k) + \mathbf{n}_k \cdot (\mathbf{T}_k \cdot \mathbf{v}_k) + \mathbf{q}_k \cdot \mathbf{n}_k) \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} \end{aligned} \quad (3.488)$$

By introducing the enthalpy per unit of mass,  $h_k = e_k + \frac{p_k}{\rho_k}$ , we obtain:

$$\begin{aligned} & \frac{\partial(A_k \langle \rho_k (\frac{1}{2}v_{z,k}^2 + e_k) \rangle_{A_k})}{\partial t} + \frac{\partial}{\partial z}(A_k \langle \rho_k v_{z,k} (\frac{1}{2}v_{z,k}^2 + h_k) \rangle_{A_k}) \\ &= -\frac{\partial}{\partial z}(A_k \langle (\boldsymbol{\sigma}_k \cdot \mathbf{v}_k) \cdot \mathbf{e}_z \rangle_{A_k}) - \frac{\partial}{\partial z}(A_k \langle \mathbf{q}_k \cdot \mathbf{e}_z \rangle_{A_k}) \\ &+ \sum_c A_k \langle \rho_{c,k} \mathbf{g}_{c,k} \cdot \mathbf{v}_{c,k} \rangle_{A_k} - \int_{l_{W,k}(t,z)} \frac{\mathbf{q}_k \cdot \mathbf{n}_k}{\mathbf{n}_k \cdot \mathbf{n}_{l,W}} dl \\ &- \int_{l_I(t,z)} (m_k (\frac{1}{2}v_{z,k}^2 + e_k) + \mathbf{n}_k \cdot (\mathbf{T}_k \cdot \mathbf{v}_k) + \mathbf{q}_k \cdot \mathbf{n}_k) \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} \end{aligned} \quad (3.489)$$

The interfacial energy transfer due to phase change is defined by:

$$E_{k,z}^{\Gamma} = -\frac{1}{A} \int_{l_I(t,z)} m_k \left( \frac{1}{2} v_z^2 + e \right)_k \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} = \Gamma_{Ak} \langle \left( \frac{1}{2} v_z^2 + e \right)_k \rangle_{l_I}^{\Gamma_{Ak}} \quad (3.490)$$

The interfacial energy source yields:

$$E_{k,I}^E = -\frac{1}{A} \int_{l_I(t,z)} (\mathbf{n}_k \cdot \mathbf{q}_k) \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} = a_I \langle \mathbf{n}_k \cdot \mathbf{q}_k \rangle_{l_I} \quad (3.491)$$

The interfacial work by viscous and pressure forces yield:

$$E_{k,I}^W = -\frac{1}{A} \int_{l_I(t,z)} \mathbf{n}_k \cdot (\mathbf{T}_k \cdot \mathbf{v}_k) \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} \quad (3.492)$$

The external wall heat transfer is expressed as:

$$E_{k,Wall}^E = -\frac{1}{A} \int_{l_{W,k}(t,z)} (\mathbf{n}_k \cdot \mathbf{q}_k) \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,W}} = \langle \mathbf{n}_k \cdot \mathbf{q}_k \rangle_W \frac{S_W}{A} \quad (3.493)$$

*The Entropy equation:*

In this case we define:

$$\begin{aligned} \psi_k &= s_k, \\ \mathbf{J}_k &= \frac{\mathbf{q}_k - \sum_c \mu_{c,k} \mathbf{j}_{c,k}}{T_k}, \text{ and} \\ \frac{\phi_k}{\rho_k} &= -\frac{1}{T_k \rho_k} \left[ \frac{1}{T_k} (\mathbf{q}_k \cdot \nabla T_k) + \sum_c \mathbf{j}_{c,k} \cdot (T_k \nabla \left( \frac{\mu_{c,k}}{T_k} \right) - \mathbf{F}_{c,k}) + \boldsymbol{\sigma}_k : \nabla \mathbf{v}_k \right. \\ &\quad \left. + \sum_r A_{r,k} r_{r,k} \right] \end{aligned} \quad (3.494)$$

Hence, it follows that:

$$\begin{aligned} &\frac{\partial (A_k \langle \rho_k s_k \rangle_{A_k})}{\partial t} + \frac{\partial}{\partial z} (A_k \langle \rho_k v_{z,k} s_k \rangle_{A_k}) \\ &+ \frac{\partial}{\partial z} (A_k \langle \left( \frac{\mathbf{q}_k - \sum_c \mu_{c,k} \mathbf{j}_{c,k}}{T_k} \right) \cdot \mathbf{e}_z \rangle_{A_k}) \\ &+ \int_{l_{W,k}(t,z)} \left( \frac{\mathbf{q}_k - \sum_c \mu_{c,k} \mathbf{j}_{c,k}}{T_k} \right) \cdot \mathbf{n}_k \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,W}} \end{aligned}$$

$$\begin{aligned}
& + \int_{l_I(t,z)} \left( m_k s_k + \left( \frac{\mathbf{q}_k - \sum_c \mu_{c,k} \mathbf{j}_{c,k}}{T_k} \right) \cdot \mathbf{n}_k \right) \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} - \frac{1}{T_k} \left[ \frac{1}{T_k} (\mathbf{q}_k \cdot \nabla T_k) \right. \\
& \left. + \sum_c \mathbf{j}_{c,k} \cdot (T_k \nabla (\frac{\mu_{c,k}}{T_k}) - \mathbf{g}_{c,k}) + \boldsymbol{\sigma}_k : \nabla \mathbf{v}_k + \sum_r A_{r,k} r_{r,k} \right] = 0 \quad (3.495)
\end{aligned}$$

The final form of the entropy equation is consistent with the formulation given for one component fluids by [145].

*The Species Mass Balance:*

In this case we define  $\psi_k = \omega_{k,s}$ ,  $\mathbf{J}_k = \mathbf{j}_{k,s}$ , and  $\phi_{c,k} = R_{c,s}/\rho_{k,c}$ , and we get:

$$\begin{aligned}
& \frac{\partial (A_k \langle \rho_k \omega_{k,s} \rangle_{A_k})}{\partial t} + \frac{\partial}{\partial z} (A_k \langle \rho_k \omega_{k,s} v_{z,k} \rangle_{A_k}) \\
& = - \frac{\partial}{\partial z} (A_k \langle \mathbf{e}_z \cdot \mathbf{j}_{k,s} \rangle_{A_k}) - \int_{l_{W,k}(t,z)} \mathbf{n}_k \cdot \mathbf{j}_{k,s} \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,W}} \\
& \quad - \int_{l_I(t,z)} (m_k \omega_{k,s} + \mathbf{n}_k \cdot \mathbf{j}_{k,s}) \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} + A_k \langle R_{s,k} \rangle_{A_k} \quad (3.496)
\end{aligned}$$

The interfacial species mass transfer due to phase change is defined by:

$$J_{k,s}^{\Gamma} = - \frac{1}{A} \int_{l_I(t,z)} m_k \omega_{k,s} \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} \approx \Gamma_{A_k} \langle \omega_{k,s} \rangle_{l_I}^{\Gamma_{A_k}} \quad (3.497)$$

The other interfacial mass transfer fluxes are given by:

$$J_{k,s}^j = - \frac{1}{A} \int_{l_I(t,z)} \mathbf{n}_k \cdot \mathbf{j}_{k,s} \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,k}} \approx a_I \langle \mathbf{n}_k \cdot \mathbf{j}_{k,s} \rangle_{l_I} \quad (3.498)$$

in which  $\langle \mathbf{n}_k \cdot \mathbf{j}_{k,s} \rangle_{l_I}$  denotes the averaged interfacial mass transfer flux.

The area averaged wall mass transfer flux of species  $s$  is given by:

$$J_{k,s}^{\text{Wall}} = - \frac{1}{A} \int_{l_{W,k}(t,z)} \mathbf{n}_k \cdot \mathbf{j}_{k,s} \frac{dl}{\mathbf{n}_k \cdot \mathbf{n}_{l,W}} \quad (3.499)$$

but normally vanishes as we consider impermeable walls only.

In the present state of knowledge numerous hypothesis are generally admitted to achieve a solvable set of equations [12, 50, 244, 258]. The fairly rigorous set of equations are thus simplified neglecting both the time—and spatial covariance terms, so the average of products are approximated by the products of average. In addition, it is assumed that the EOS valid for local quantities apply to averaged quantities.

Besides, as often adopted in chemical reactor analysis, in vertical flows the pressure is considered constant over the cross-section. Moreover, as the reactor flows are assumed to be symmetrical with respect to a straight line, the vectorial momentum equation reduces to its projection on the symmetry axis. It is further noted that the area phase fraction,  $\alpha_k$ , is defined by:

$$\alpha_k = \frac{A_k}{A} \quad (3.500)$$

which can be introduced into the equations eliminating the phase cross sectional area,  $A_k$ , variable [144].

On the basis of these hypotheses, the set of modeled equations used in chemical engineering practice are obtained as follows, as we drop the cross-sectional averaging sign  $\langle \dots \rangle_{A_k}$  for convenience, expressing the necessary balances:

*The Balance of Mass:*

The fairly rigorous Eq. (3.476) is modeled as:

$$\frac{\partial(\alpha_k \rho_k)}{\partial t} + \frac{1}{A} \frac{\partial}{\partial z} (\alpha_k \rho_k v_{z,k} A) = \Gamma_{A_k} \quad (3.501)$$

*The Balance of Momentum:*

The fairly rigorous Eq. (3.482) is modeled as:

$$\begin{aligned} & \frac{\partial(\alpha_k \rho_k v_{z,k})}{\partial t} + \frac{1}{A} \frac{\partial}{\partial z} (\alpha_k \rho_k v_{z,k} v_{z,k} A) + \alpha_k \frac{\partial p_k}{\partial z} \\ & \approx - \frac{1}{A} \frac{\partial}{\partial z} (\alpha_k (\mathbf{e}_z \cdot \boldsymbol{\sigma}_k) \cdot \mathbf{e}_z A) + \sum_c \alpha_k \rho_{c,k} g_{c,z,k} + \Gamma_{A_k} \langle v_z \rangle_{l_I}^{\Gamma_{A_k}} + M_{z,k}^{\sigma} \\ & - f_{D,W} \frac{1}{2} \rho_k |v_{z,k}| v_{z,k} \frac{S_W}{4A} \end{aligned} \quad (3.502)$$

*The Balance of Total Energy:*

The modeled form of the energy Eq. (3.503) can be expressed as:

$$\begin{aligned} & \frac{\partial(\alpha_k \rho_k (\frac{1}{2} v_{z,k}^2 + e_k))}{\partial t} + \frac{1}{A} \frac{\partial}{\partial z} (\alpha_k \rho_k v_{z,k} (\frac{1}{2} v_{z,k}^2 + e_k) A) \\ & = - \frac{1}{A} \frac{\partial}{\partial z} (\alpha_k \langle (\mathbf{T}_k \cdot \mathbf{v}_k) \cdot \mathbf{e}_z \rangle_{A_k} A) - \frac{1}{A} \frac{\partial}{\partial z} (\alpha_k \langle \mathbf{q}_k \cdot \mathbf{e}_z \rangle_{A_k} A) \\ & + \sum_c \alpha_k \rho_{c,k} \mathbf{g}_{c,k} \cdot \mathbf{v}_{c,k} + \langle \mathbf{n}_k \cdot \mathbf{q}_k \rangle_W \frac{S_W}{A} \\ & + \Gamma_{A_k} \langle (\frac{1}{2} v_z^2 + e)_k \rangle_{l_I}^{\Gamma_{A_k}} + E_{k,I}^W + a_I \langle \mathbf{n}_k \cdot \mathbf{q}_k \rangle_{l_I} \end{aligned} \quad (3.503)$$

### *The Species Mass Balance:*

The modeled form of the species mass balance (3.496) can be expressed as:

$$\begin{aligned} \frac{\partial(\alpha_k \rho_k \omega_{k,s})}{\partial t} + \frac{1}{A} \frac{\partial}{\partial z} (\alpha_k \rho_k \omega_{k,s} v_{z,k} A) \\ = - \frac{1}{A} \frac{\partial}{\partial z} (\alpha_k j_{z,k,s} A) + \Gamma_{Ak} \langle \omega_{k,s} \rangle_{I_I}^{\Gamma_{Ak}} + a_I \langle \mathbf{n}_k \cdot \mathbf{j}_{k,s} \rangle_{I_I} + \alpha_k R_{s,k} \end{aligned} \quad (3.504)$$

The governing 1D two phase flow equations assessed in this section are very often used in industry, academia and in engineering research. For example, these 1D area-averaged equations (with slightly different constitutive equations) determine the basis for the commercial dynamic two-fluid model simulator named *OLGA* developed at the Institute for Energy Technology (IFE) at Kjeller in Norway [18] for the oil and gas processing industry. The model is intended for dynamic simulations of two-phase oil and gas flows in pipelines. It has been used analyzing terrain slugging, pipeline startup and shut-in, production rates, and pigging. These simulations have been performed for pipelines of several kilometers length with time spans ranging from hours to weeks.

### **3.5.7 Heterogeneous Dispersion Models**

In chemical reaction engineering the two phase or heterogeneous versions of the dispersion models discussed in Sect. 1.2.6 are frequently used simulating multiphase reactor like fixed bed, fluidized bed and slurry bubble column reactors. However, this model is most successfully applied to fixed bed reactors as the flow profile in these reactors is being fairly flat. For such reactors the effective dispersion coefficient typically considers both molecular—and turbulent diffusion, and the gross scale dispersion caused by the packing of catalyst particles. Besides, in reactor simulations the cross section averaged enthalpy and temperature equations are required for non-isothermal systems. These two balance equations can with minor struggle be deduced from the total energy equation following the same steps as examined for single phase flows in Sect. 1.2.6. In a heterogeneous model the effective thermal conductivity contains various contributions, such as conduction in the solid and in the fluid, and radiation in gas-filled voids between solid surfaces.

#### **3.5.7.1 Heterogeneous Axial Dispersion Models**

The axial dispersion model equations for the continuous phase is developed based on the 1D form of the governing equations given in Sect. 3.5.6. However, the instantaneous area averaged model equations are also Reynolds averaged to enable reactor simulations with practicable time resolutions. For the time after area averaged models, the instantaneous variables are decomposed and Reynolds averaged in the standard way. If we drop the averaging signs, the basic 1D species mass balance

deduced from (3.504) is given by:

$$\frac{\partial}{\partial t}(\alpha_k \rho_k \omega_{k,s}) + \frac{\partial}{\partial z}(\alpha_k \rho_k v_{z,k} \omega_{k,s}) = \frac{\partial}{\partial z}(\alpha_k \rho_k D_{z,k,\text{eff}} \frac{\partial \omega_{k,s}}{\partial z}) + \Gamma_{Ak} \langle \omega_{k,s} \rangle_{I_l}^{\Gamma_{Ak}} \quad (3.505)$$

in which it is customary to define the superficial velocity by  $v_{z,k}^S = \alpha_k v_{z,k}$ . The interfacial mass transfer term  $\Gamma_{Ak} \langle \omega_{k,s} \rangle_{I_l}^{\Gamma_{Ak}}$  has to be parameterized for the chemical process in question, normally a simple film model suffices.

The corresponding heat or temperature equation can be derived following a similar procedure as adopted formulating the single phase Eq. (1.305). The result is:

$$\begin{aligned} \alpha_k \rho_k C_{p,k} \left( \frac{\partial T_k}{\partial t} + v_{z,k} \frac{\partial T_k}{\partial z} \right) &= \frac{\partial}{\partial z}(\alpha_k k_{z,k,\text{eff}} \frac{\partial T_k}{\partial z}) + \Gamma_{Ak} \langle h_k \rangle_{I_l}^{\Gamma_{Ak}} \\ &+ \frac{4U}{d_r} (T_{\text{sur}} - T) \end{aligned} \quad (3.506)$$

where the interfacial heat transfer rate has to be parameterized for the chemical process in question, normally a simple film model suffice. The effective transport coefficients are included as a reminder that the temporal covariances resulting from the Reynolds averaging procedure are normally modeled adopting the gradient hypothesis and the Boussinesq turbulent viscosity concept.

There are several ways of describing the solid phase processes. One way of treating the solid phase is to consider the packed bed as a porous media and simply adopt a similar set of model equations for the solid phase, as put up for the fluid, noting that the solid phase is often fixed so there is no convection. A more common modeling approach in chemical reaction engineering is to investigate the intra-particle processes formulating a diffusion model for a single representative particle. The alternative pseudo-homogeneous model is a kind of mixture model (see Sect. 3.5.5) which is achieved by taking the sum of the individual equations for the two phases. The initial conditions used for dynamics reactor simulations depend upon the start-up procedure adopted in industry for each particular chemical process. A possible set of initial conditions corresponds to uniform variable fields given by the inlet values as outlined in Sect. 1.2.6. The standard Danckwerts [43] boundary conditions are normally applied.

### 3.6 Mathematical Model Formulation Aspects

The well-posedness of the two-fluid model has been a source of controversy reflected by the large number of papers on this issue that can be found in the literature. This issue is linked with analysis of the characteristics, stability and wavelength phenomena in multi-phase flow equation systems. The controversy originates primarily from the fact that with the present level of knowledge, there is no general way to determine

whether the 3D multi-fluid model is well posed as an initial-boundary value problem. The mathematical theory of well posedness for systems of partial differential equations describing dispersed chemical reacting flows needs to be examined.

Introductory work has however been made to analyze the mathematical properties of the equations. In their pioneer work Gidaspow [90] and Lyckowski et al. [154] consider the 1D, incompressible, in-viscid two-fluid flow equations with no added mass or lift effects given by:

$$\frac{\partial \alpha_k}{\partial t} + \frac{\partial(\alpha_k \langle v_k \rangle v_k)}{\partial x} = 0 \quad (3.507)$$

$$\alpha_k \rho_k \left( \frac{\partial \langle v_k \rangle v_k}{\partial t} + \langle v_k \rangle v_k \frac{\partial \langle v_k \rangle v_k}{\partial x} \right) = -\alpha_k \frac{\partial \langle p_k \rangle v_k}{\partial x} + F_{x,k} \quad (3.508)$$

where  $F_{x,g} = -F_{x,l} = K_l(v_g - v_l)$ , and  $K_l$  is assumed to be constant.

If the characteristics of the system of equations are found to be complex, the initial-value problem is said to be ill-posed [191]. A physical interpretation of this mathematical statement can be found by analyzing the flow instabilities predicted by this set of model equations. The instabilities predicted by a *well-posed model system* has some realistic physical meaning, while the instability always present in an *ill-posed system* is a mathematical mode having no physical origin indicating that the model is not treating small-scale phenomena correctly. Traditionally, this so-called ill-posed nature of the model makes it desirable to seek physical modifications of the simple model to find a well-posed mode. Several attempts have thus been made to improve the mathematical properties of the equations by re-examining some of the basic assumptions made in the derivation of the model equations. *The idea is that by introducing more physical and exact formulations into the description, the final set of equations will be well posed.*

Ramshaw and Trapp [185] incorporated surface tension effects, which had traditionally been ignored. Travis et al. [234] considered viscous stresses, Lahey et al. [143] considered the added mass force, Prosperetti and Wijngaarden [180] considered compressibility effects. Trapp [233] considered Reynolds stresses, while Stuhmiller [227], Bourè [24], Pauchon and Banerjee [173, 174], Sha and Soo [201], Prosperetti and Jones [181] and Holm and Kupersmidt [115] have put their main focus on the adoption and interpretation of the interfacial pressure forces (see Sects. 3.5.1 and 3.5.6). The simplest choice for the interfacial pressure distribution  $\langle p_k \rangle_{A_I}$  is to assume that it is equal to the fluid bulk pressure. This implies that  $\langle p_g \rangle_{v_g} = \langle p_l \rangle_{v_l} = \langle p_g \rangle_{A_I} = \langle p_l \rangle_{A_I}$  for a two-phase system and as a result the current engineering practice is obtained (e.g., [127, 133, 181]). However, this approach leads to an equation set involving a single pressure, which has real characteristics only when the two fluid velocities are equal [233]. Considering low-pressure bubbly flows a slightly more general assumption is that the interfacial pressure in the gas phase is related to the average pressure of the gas phase by:

$$\langle p_g \rangle_{A_I} - \langle p_g \rangle_{v_g} \approx 0 \quad (3.509)$$

because the averaged pressure within the spheres will be very close to the average interfacial pressure [145, 152, 173, 227]. In contrast, the difference between the interfacial averaged pressure and the mean pressure in the liquid phase is, for a non-pulsating bubble, given by [227]:

$$\langle p_l \rangle_{A_l} - \langle p_l \rangle_{V_l} = \xi \rho_l (\langle \mathbf{v}_g \rangle_{V_g} - \langle \mathbf{v}_l \rangle_{V_l})^2 \quad (3.510)$$

It was shown that this approach gives real characteristics only if  $\langle p_l \rangle_{A_l}$  is lower than  $\langle p_l \rangle_{V_l}$ . A value of  $\xi = -\frac{1}{4}$  is used by several researchers [145, 173]. However, Drew [58] also discusses this approach and argues that this formulation is questionable, as it may not be consistent with the interfacial drag parameterizations used.

Sha and Soo [201] dealt with essentially the same problem from a more physical angle. Their discussion focuses on what form the  $\nabla(\alpha_k \langle p_k \rangle_{V_k})$  term in the momentum equation should take. They gave an overview of the terms  $\nabla(\alpha_k \langle p_k \rangle_{V_k}) = \alpha_k \nabla \langle p_k \rangle_{V_k} + \langle p_k \rangle_{V_k} \nabla \alpha_k$  and divided the literature approaches into three groups. These includes those who favor (1) dropping  $\langle p_k \rangle_{V_k} \nabla \alpha_k$  for the reason of being canceled out by the interfacial source term in the momentum equation when the bulk mean pressure is assumed equal to the interfacial mean pressure. Those who favor (2) retaining a part of it as a stabilizing force. Sha and Soo [201] argued that the physical effect of the  $\langle p_k \rangle_{V_k} \nabla \alpha_k$  term is to spread the dispersed phase which has an initial concentration gradient. They proposed to replace the term by:

$$\alpha_k \nabla \langle p_k \rangle_{V_k} + (1 - B) \langle p_k \rangle_{V_k} \nabla \alpha_k \quad (3.511)$$

where  $B$ ,  $0 \leq B \leq 1$ , is a displacement factor which is a function of the flow configuration. The last group, those who favor (3) retaining  $\langle p_k \rangle_{V_k} \nabla \alpha_k$  for the reason of an extension of the continuum mechanics, as a compressive force to fulfill the laws of thermodynamics.

In an attempt to close the non-constructive controversy, Bourè [25] claims that both forms of the pressure terms are acceptable. The occurrence of complex roots in the momentum equations is not related to the correct use of the pressure terms, but is primarily a problem of mathematical form of the constitutive terms.

In reaction engineering the 2D and 3D multi-fluid model equations used are obviously solvable although with certain struggle, hence to some extent affected by the mathematical model properties reflected by the simplified model equations examined in the above mentioned work. Besides, in some cases numerical problems occurred due to the inadequate mathematical properties reflected by the constitutive equations used in particular in the limit as  $\alpha_k \rightarrow 0$  or  $\alpha_k \rightarrow 1$ . Another source of problem encountered in dense reactor flows is the highly recirculating flow patterns located at the outlets making consistent formulations of the necessary boundary conditions difficult, especially for reactive variable density flows. Further analysis of the mathematical properties of the model equations are still considered useful, in the sense that this can assist in developing novel closure laws having more appropriate properties and to ensure that the need for ad hoc tricks to obtain somewhat ill-conditioned solutions can be avoided.

## Chapter 4

# Flows of Granular Materials

In this chapter the derivation of the governing macroscopic two-fluid equations of granular flow are examined. The standard references for the kinetic theory of granular flows consist of the papers by Savage and Jeffrey [126], Jenkins and Savage [68], Lun et al. [102], Jenkins and Richman [69], Johnson and Jackson [75], Johnson et al. [76], Ding and Gidaspow [30] and the book of Gidaspow [49]. In addition, several reviews of the kinetic theory of granular flow and papers presenting locally averaged equations of motion for a mixture of identical spherical particles might be suggested as supplementary reading. Among these reports are Anderson and Jackson [4], Campbell [17], Jenkins [71], Elghobashi [35], Boemer et al. [16], Crow et al. [26, 27], Sinclair [139], Hrenya and Sinclair [60], Jackson [64], Peirano and Leckner [117], and van Wachem et al. [152, 153].

A *granular material* is defined as a collection of a large number of discrete solid particles in a vacuum. Granular flow might thus be referred to as a flow of a powder in a vacuum [49]. Nevertheless, at more relevant pressures the interstices between the particles are filled with at least one fluid, and thus, an industrial granular flow is a multiphase process. However, if the particles are closely packed or if they are much denser than the interstitial fluid, the particles alone, and not the fluid or the fluid-particle interactions, will play the greatest role in momentum transport within the material, in which case the interstitial fluid can be ignored in describing the flow behavior [17]. Flows of granular material are generally taken to fall into this limiting category and thus may be considered dispersed single-phase rather than multiphase flows. On the other hand, even so, for reactive systems like fluidized beds the interstitial fluid is normally of outmost importance because the interstitial fluid contains one or more of the reactants hence the transport processes within this phase has to be described in an appropriate manner to determine the chemical process operation.

In a granular material there are primarily three mechanisms by which the bulk stresses are generated. These are (i) dry friction, (ii) transport of momentum by particle translation like in dilute gases, and (iii) momentum transport by particle interactions like in dense gases and liquids. In the past it was usually assumed that

although all three mechanisms co-exist in most flow regimes, one of them will normally play a predominant role. Depending on the local stress conditions, a granular material may behave either as an elastic solid or a fluid [17, 131]. The load supported by the elastic-solid systems is held locally by frictional bonds between the particles so the system's strength is limited to the loads that those bonds can support. When a sufficient number of the bonds have been overcome, the system will fail and begin to flow. The initial failure will consist of many-particle blocks moving relative to one another along shear bands that roughly follow stress characteristics through the material. If the motion occurs slowly, particles will stay in contact and interact frictionally with their neighbors over long periods of time. The failure will continue in this manner as long as the deformation remains fairly slow. This particle motion is characterized as the *quasi-static regime* of granular flow [17]. The dry friction stresses are of the quasi-static, rate independent, Coulomb, type as described in the soil mechanics literature [75, 76, 112, 127, 129, 141]. However, these quasi-static motions are not of primary interest for chemical reaction engineers and will thus be disregarded in the subsequent discussion. Nevertheless, there are several flows of practical interest that fall into the intermediate regime where both frictional contacts (1), particle translation (2) and particle-particle collisions (3) are all significant. To model such flows the momentum equation is normally extended including an extra stress so that the total stress is the linear sum of frictional, kinetic and collisional contributions, each calculated independently from constitutive expressions derived for the limits of pure frictional, pure kinetic, and pure collisional interactions, respectively. It is noted that the quasi-static stress models are still of empirical nature. Due to these additional stresses, the boundary conditions might also be adapted to the particular application. The other extreme is the *rapid-flow regime* which corresponds to high-speed flows, far beyond the initial failure [17]. In this case each particle moves freely instead of moving in many-particle blocks. This flow regime evolves naturally from the quasi-static regime if the motion becomes rapid enough to transfer enough energy to the particles in the vicinity of the local slip regions to break these particles free of their blocks. In this way the rapid flow regime regions might expand until every particle in the granular mass is moving independently. These flows are of great interest to chemical reactor engineers because the fluidized bed reactors are operated within this regime. To model the latter type of flows an analogy between particle collisions in suspensions and molecular collisions in dense gases as described by the kinetic theory was proposed by Bagnold [5] in 1954. By employing a simple expression for the collision frequency of particles, Bagnold derived a relation for the repulsive pressure of particles for uniform shear flow. Nevertheless, the importance of the velocity fluctuations and the means by which they could be included in a properly formulated continuum theory were first exploited by Ogawa [113] and Ogawa et al. [114]. Ogawa et al. [114] considered an analogy between the random motion of the granular particles and the thermal motion of molecules in the kinetic-theory picture of gases. In this view the velocity of each particle is decomposed into a sum of the mean velocity of the bulk material and an apparently random component to describe the motion of the particle relative to the mean. Furthermore, a fluctuation particle temperature, commonly referred to as the *granular temperature*, was defined

as the mean kinetic energy of the particle velocity fluctuations. Moreover, they postulated that the mechanical energy of a granular flow is first transformed into random particle motion and then dissipated into internal energy. Based on this hypothesis a balance law was formulated for the granular temperature that related the rate of change to the production by the mean flow shear, the heat like flux from one point to another in the flow, and the dissipation into thermal energy. The energy transport in granular flows can thus be interpreted as follows. The source of all the energy is the work done on the system, either by body forces or through the motion of the system boundaries. Shear work, as given by the product of the shear stress and the velocity gradient, performed on the system converts some of the kinetic energy of the mean motion into granular temperature which is the kinetic energy associated with the random particle velocities. Finally, the inelastic collisions between particles will dissipate away the granular temperature into thermodynamic heat. The magnitude of the granular temperature thus depends on the ratio of the temperature generation by shear work and its dissipation by collisional in-elasticity. To close the granular temperature equation the granular conductivity, granular dissipation and the mean granular stress must be related by constitutive assumptions to the mean density, mean velocity and the granular temperature in order to complete the theory. In many ways the thermodynamic and granular temperatures play similar roles in governing the behavior of their respective systems. In particular, both temperatures generate pressures and govern the internal transport rates of mass, momentum, and energy. Although no granular temperature equation was considered, Savage and Jeffrey [126] were the first to suggest that the kinetic theory for dense gases as proposed by Enskog [38] might be useful determining the stress tensor in a granular flow. In particular, Savage and Jeffery [126] considered a collection of smooth, rigid, *elastic*, spherical particles in Couette flow. From elementary kinetic theory they recognize that in order to deduce explicit expressions for the stress tensor, it is necessary to determine the form of the complete pair-distribution function  $f^{(2)}$  at collision. It was assumed that the  $f^{(2)}$ -function can be expressed as a product of a configurational pair-correlation function and two single particle distribution functions. The configurational pair-correlation function represents a generalization of the more familiar radial distribution function. Bear in mind that the latter function is restricted to a gas at equilibrium in which there are no mean deformation so spatial homogeneity of the mean flow prevails. For non-equilibrium shear flows a simple correction for anisotropy in the configurational pair-correlation function was made based on kinematic arguments. Furthermore, the single distribution function of each particle was approximated by the Maxwellian [69]. Jenkins and Savage [68] extended the preliminary kinetic theory of Savage and Jeffrey [126] considering slightly *inelastic* particles. Jenkins and Savage used Maxwell's [109] equations of transfer to derive local expressions for the balance of granular mass, granular linear momentum, granular temperature, and integral expressions for the stress, energy flux and energy dissipation terms therein. In order to evaluate these integrals and thereby close the transport equations it is again necessary to determine the complete pair-distribution function. In this case the preliminary distribution function proposed by Savage and Jeffrey [126] for elastic particles was modified reformulating the configurational pair-correlation function expression so

that it depends linearly upon the rate of deformation. Besides, the granular temperature equation was taken into account to determine the local rate of change of the fluctuating energy considering the energy dissipation rate due to inelastic particle collisions. Moreover, to calculate the mean collisional rate of change of  $\psi$  per unit volume,  $\int_{-\infty}^{\infty} \psi (\frac{\partial f}{\partial t})_{\text{Collision}} d\mathbf{c}$ , several approximative closure relationships were introduced. Among these constitutive relations, the relative velocity component normal to the plane of contact is approximated and related to the corresponding component prior to the collision through (2.110). In addition, the complete pair-distribution function is approximated by a symmetric average obtained shifting the pair of spatial points at which it is evaluated through a first order Taylor expansion. Lun et al. [102] reviewed several granular flow theories for dense flows and proposed that the application of the classical granular theory might be extended making a unified model valid for both dilute and dense flows. A generalized model was thus established by incorporating the kinetic stresses and the kinetic fluctuation-energy flux in addition to the collisional stresses, the collisional fluctuation-energy flux and the collision rate of dissipation per unit volume in the classical dense flow formulation. The constitutive relations used were deduced assuming that the spherical particles are uniform, smooth, but slightly inelastic requiring that the coefficient of restitution is about unity. In addition, the component of relative velocity  $\mathbf{g}_{12}$  in the direction of  $\mathbf{k}$  was approximated by (2.110) in accordance with the work of Jenkins and Savage [68]. However, in contrast to previous work, in order to calculate the unknown fluxes by the concept of kinetic theory, Lun et al. [102] adopted the Enskog [38] dense gas pair-distribution function approximation. The collisional single distribution function therein was approximated using a scheme inspired by the Chapman-Enskog expansion method [25]. However, in this approach the parameters in the trail function were calculated by satisfying a few moment equations generated from an extended form of the Maxwell equation instead of using a Boltzmann type of equation.

It is emphasized that in the pioneering papers, mentioned above, simplified kinetic theories based on mechanically derived or intuitive relationships were used to determine the distribution function in place of the Boltzmann equation. The complexity of formulating the Boltzmann equation accounting for the inter-particle collisions was a severe bottleneck that prevented the use of more rigorous kinetic theories describing the behavior of inelastic solid particles. In particular, the analogous results in kinetic theory of dense gases obtained using the reversibility of collisions are not valid anymore and must be re-derived. A more elaborated extension of the kinetic theory of granular flows was proposed by Jenkins and Richman [69]. They showed that Grads [53] method of moments for determining the single particle distribution function of elastic molecular particles in dilute gases might be adapted and applied to dense systems of inelastic particles. By use of this method they extended the theory of Jenkins and Savage [68] and determined a supposedly more accurate form of the balance laws including the collisional transfers and productions of the velocity moments. Hence, as for the more familiar kinetic theory of a dilute gas, two distinct directions in the subsequent research on granular flow modeling emerged. One group of scientists followed closely the modeling ideas of Enskog [38] and solved

the resulting Enskog equation by use of the Chapman-Enskog approximate method [25]. A second group of researchers followed roughly the modeling ideas of Enskog [38] but solved the Enskog like equations by the Grads [53] method of moments. During the subsequent two or three decades a number of investigators include the drag into the governing equations for granular flows to generalize the treatment to multiphase flow [30, 49, 86, 123, 137]. In this case the inter-facial momentum coupling is normally taken into account through the external force term. In general, the  $\mathbf{F}$  term includes the gravity, the external pressure gradient, the steady drag force, the added mass force, and several lift forces. The governing equations for the interstitial fluid phase are derived based on the continuum multi-fluid formulation and averaged in an appropriate manner as examined in Sect. 3.3. Ding and Gidaspow [30], for example, derived a two-phase flow model starting with the Boltzmann equation for the distribution function of particles and incorporated fluid-particle interactions into the macroscopic equations. The governing equations were derived using the classical concepts of kinetic theory. However, to determine the constitutive equations they used the ad hoc distribution functions proposed by Savage and Jeffery [126]. The resulting macroscopic equations contain both kinetic—and collisional pressures but only the collisional deviatoric stresses. The model is thus primarily intended for dense particle flows.

Gidaspow [49] extended the work of Ding and Gidaspow [30] by deriving a modified set of approximative macroscopic conservation equations supposedly applicable for describing both dilute and dense granular flows. Again, following the classical concepts in kinetic theory, the Maxwell-Enskog transport equation was formulated by the moment method starting out from the Boltzmann equation. Unlike the approach of Ding and Gidaspow [30], in this work the kinetic and collisional transfer fluxes occurring in the governing equations were calculated in accordance with the Chapman-Enskog expansion method. However, each total transfer flux is approximated as a linear sum of the kinetic flux valid for dilute flows (i.e., as derived in accordance with the Enskog [38] dense gas approach) and the collisional flux contributions for dense flows. To determine the kinetic transfer fluxes for dilute suspensions the distribution function was determined from the Boltzmann equation with an inherent Enskog [38] dense gas collision operator considering *elastic* particles, whereas the collisional transfer fluxes were determined by approximating the distribution function from the modeled Boltzmann equation for dense suspensions consisting of *inelastic* particles. The available continuum models for dispersed multiphase flows thus follow one of two asymptotic approaches. The *dilute phase approach* is formulated based on the continuum mechanical principles in terms of the local conservation equations for each of the phases. A macroscopic model is then obtained by averaging the local equations based on an appropriate averaging procedure. In the *dense phase approach*, on the other hand, a kinetic theory description is adopted for the dispersed particulate phase (granular material), whereas an averaged continuum model formulation is adopted for the interstitial phase.

## 4.1 Two-Fluid Model with Kinetic Theory of Granular Flow Closures

The two-fluid model with granular flow (KTGF) closures for the solid particle fluid is formulated applying the classical Eulerian continuum concept for the continuous phase, while the governing equations of the particle phase are developed in accordance with the principles of kinetic theory. In this theory it is postulated that the particulate system can be represented considering a collection of identical, smooth, rigid spheres, adapting a Boltzmann type of equation. This microscopic balance describes the rate of change of the distribution function with respect to position and time. The Boltzmann equation is generally expressed as [25]:

$$\frac{\partial f}{\partial t} + \mathbf{c} \cdot \nabla f + \nabla_{\mathbf{c}} \cdot (\mathbf{F}f) = \left(\frac{\partial f}{\partial t}\right)_{\text{Collision}} \quad (4.1)$$

The moment method can then be employed to derive a generalized equation of change for a mean particle property  $\langle \psi \rangle_M$  in the same manner as described in Chap. 2 for molecular systems. In particular, the generalized transport equation for  $\langle \psi(\mathbf{r}, t) \rangle_M$  is derived multiplying (4.1) by a microscopic quantity  $\psi(\mathbf{r}, \mathbf{c}, t)$  and integrating the resulting relation over the whole velocity space.

Suppose that  $\psi$  and  $f$  are expressed as functions of  $(\mathbf{r}, \mathbf{c}, t)$ , then a mathematical moment can be defined by the following ensemble average:

$$\langle \psi(\mathbf{r}, t) \rangle_M = \frac{1}{n(\mathbf{r}, t)} \int_{-\infty}^{\infty} \psi(\mathbf{r}, \mathbf{c}, t) f(\mathbf{r}, \mathbf{c}, t) d\mathbf{c} \quad (4.2)$$

where  $n$  is the number density of the particles. The moment  $\langle \psi(\mathbf{r}, t) \rangle_M$  denotes a macroscopic quantity.

To examine the derivation of the macroscopic equation thoroughly some further comments are needed. If we multiply (4.1) by  $\psi(t, \mathbf{r}, \mathbf{c})$  and thereafter apply the chain rule to re-write the terms on the LHS, the intermediate result is:

$$\frac{\partial}{\partial t}(\psi f) - f \frac{\partial \psi}{\partial t} + \nabla \cdot (\mathbf{c} \psi f) - \mathbf{c} \cdot f \nabla \psi + \nabla_{\mathbf{c}} \cdot (\mathbf{F} \psi f) - (\mathbf{F} f) \cdot \nabla_{\mathbf{c}} \psi = \psi \left(\frac{\partial f}{\partial t}\right)_{\text{Collision}} \quad (4.3)$$

Integration over the whole velocity space yields:

$$\begin{aligned} & \frac{\partial}{\partial t} \int_{-\infty}^{\infty} (\psi f) d\mathbf{c} - \int_{-\infty}^{\infty} f \frac{\partial \psi}{\partial t} d\mathbf{c} + \nabla \cdot \int_{-\infty}^{\infty} (\mathbf{c} \psi f) d\mathbf{c} - \int_{-\infty}^{\infty} \mathbf{c} \cdot f \nabla \psi d\mathbf{c} \\ & + \int_{-\infty}^{\infty} \nabla_{\mathbf{c}} \cdot (\mathbf{F} \psi f) d\mathbf{c} - \int_{-\infty}^{\infty} \mathbf{F} \cdot f \nabla_{\mathbf{c}} \psi d\mathbf{c} = \int_{-\infty}^{\infty} \psi \left(\frac{\partial f}{\partial t}\right)_{\text{Collision}} d\mathbf{c} \end{aligned} \quad (4.4)$$

The fifth term on LHS vanishes because  $[F_i f \psi]_{c_i=-\infty}^{c_i=\infty} = 0$ . It is assumed that the distribution function  $f$  converges to zero when the velocity in direction  $i$  becomes infinite.

In terms of moments on the form (4.2), relation (4.4) can be re-written as:

$$\begin{aligned} \frac{\partial}{\partial t}(n\langle\psi\rangle_M) + \nabla \cdot (n\langle\mathbf{c}\psi\rangle_M) - n \left( \frac{\partial\langle\psi\rangle_M}{\partial t} + \langle\mathbf{c} \cdot \nabla\psi\rangle_M + \langle\mathbf{F} \cdot \nabla\mathbf{c}\psi\rangle_M \right) \\ = \int_{-\infty}^{\infty} \psi \left( \frac{\partial f}{\partial t} \right)_{\text{Collision}} d\mathbf{c} \end{aligned} \quad (4.5)$$

in which  $\int_{-\infty}^{\infty} \psi \left( \frac{\partial f}{\partial t} \right)_{\text{Collision}} d\mathbf{c}$  denotes the collisional rate of change of the macroscopic variable  $\langle\psi\rangle_M$ .

It is noted that in cases where the net external force  $\mathbf{F}$  is independent of  $\mathbf{c}$  it can be moved outside the averaging bracket. However, for granular flow the net external force is generally considered dependent on  $\mathbf{c}$  thus  $\mathbf{F}$  is kept inside the averaging operator.

### 4.1.1 Collisional Rate of Change Derivate Flux and Source Terms

In this section the derivation of the collision operators for dilute and dense suspensions are examined. Introductory the established formulas for dilute and dense gases consisting of elastic particles are outlined. Thereafter the kinetic theory of inelastic particles are considered.

#### 4.1.1.1 Dilute and Dense Gas Collision Densities and Collision Operators

It is explained in Chap. 2 that the Boltzmann equation is an equation of motion for the one-particle distribution function and is appropriate to a rare gas [103, 155]. In this particular case appropriate expressions for the collision operator  $\left( \frac{\partial f}{\partial t} \right)_{\text{Collision}}$  can be derived since the nature of the elastic interactions between the colliding particles is known. Enskog [38] extended the kinetic theory of dilute mono-atomic gases to slightly higher densities, as described in Sect. 2.12. In this approach Enskog [38] adopted the molecular billiard ball model which assumes that the gas consists of a collection of identical, rigid, smooth and perfectly elastic spheres. To elucidate the extended theory we refer to the derivation of the dilute gas collision operator and explain the important modifications that have to be introduced for dense gases. Basically, in order to calculate the collision rate of change we adopt similar principles as outlined for dilute gases in Sect. 2.4.2. However, a modified expression for the collision frequency is required. To deduce the formula for the dense gas collision frequency a modified relation for the volume of the collision cylinder is required.

### *Dilute Gas Collision Density and Collision Operator*

As mentioned in Chap. 2, to derive the relation for the collision density it is customary to consider the motion of particles 2 relative to the center of particles 1 (see Fig. 2.3, p. 251). For a binary molecular collision to occur the center of particle 2 must lie on the sphere of influence with radius  $d_{12}$  about the center of particle 1 (see Fig. 2.7, p. 258). The radius of influence of the sphere is defined by (2.142). Besides, it is convenient to introduce the unit vector  $\mathbf{k}$  along the apse-line which, in the case of rigid spherical molecules, is the line joining the centers of the two molecules at the instant of contact (see Fig. 2.7). Since  $\mathbf{k}$  makes the angle  $\psi = (\pi - \theta)/2$  with  $\mathbf{g}_{21}$ , and the plane through  $\mathbf{k}$  and  $\mathbf{g}_{21}$  makes an angle  $\phi$  with a reference plane through  $\mathbf{g}_{21}$ ,  $\psi$  and  $\phi$  are polar coordinates specifying the direction of  $\mathbf{k}$  on the unit sphere. Then, since a simple geometrical analysis reveals that  $b = d_{12} \sin \psi$  (hence  $db = d_{12} \cos \psi d\psi$ ) and  $\mathbf{g}_{21} \cdot \mathbf{k} = g \cos \psi$ , it follows from (2.650) that the factor  $gbdbd\phi$  in the Boltzmann equation collision term is equal to  $d_{12}^2 (\mathbf{g}_{21} \cdot \mathbf{k}) d\mathbf{k}$ .

The base area of the rectangle may thus be approximated as:

$$\text{single base area} = da = b d\phi db = d_{12}^2 \sin \psi d\phi d\psi = d_{12}^2 d\mathbf{k} \quad (4.6)$$

in which the infinitesimal solid angle  $d\mathbf{k}$  is centered about the apse-line  $\mathbf{k}$ .

If such a collision occurs in a time  $dt$  so short that the possibility for the same particle to collide more than once during  $dt$  is negligible, then at the beginning of  $dt$  the particle must lie somewhere inside a cylinder with  $da$  as base. The sides of such a cylinder may not necessarily be perpendicular to the face  $da$ , hence the height is expressed as  $dl = (\mathbf{g}_{21} \cdot \mathbf{k}) dt = g_{21} dt \cos \psi$ . The volume of a single collision cylinder can thus be expressed by  $dV_{\text{cylinder}} = dl \times da = [(\mathbf{g}_{21} \cdot \mathbf{k}) dt] \times (d_{12}^2 d\mathbf{k})$ . Such a cylinder is associated with each of the  $f_1 d\mathbf{c}_1 d\mathbf{r}$  particles of the first kind having velocity within the range  $\mathbf{c}_1$  to  $\mathbf{c}_1 + d\mathbf{c}_1$  and being located in  $d\mathbf{r}$ . If  $da$  is small, it might be assumed that the cylinders do not overlap to any significant extent, so that the volume of all the cylinders  $dV_{\text{total}}$  is given by:

$$dV_{\text{total}} = (f_1 d\mathbf{c}_1 d\mathbf{r}) \times dV_{\text{cylinder}} = f_1 (\mathbf{g}_{21} \cdot \mathbf{k}) d_{12}^2 d\mathbf{k} d\mathbf{c}_1 d\mathbf{r} dt \quad (4.7)$$

In many of these tiny cylinders there might be no particle of the second kind having velocity within the range  $\mathbf{c}_2$  to  $\mathbf{c}_2 + d\mathbf{c}_2$ . If  $da$  and  $d\mathbf{c}_2$  are sufficiently small, the possibility of two particles of type 2 in any of these cylinders can be neglected. Therefore, the total number of particles of type 2 in the whole gas volume  $dV_{\text{total}}$ , which we imagine consist of a set of tiny cylinders containing a particle of type 1, is determined by  $f_2 d\mathbf{c}_2 dV_{\text{total}}$ . In this way each collision cylinder in the gas which contains a particle of type 2 coincides with a collision of the specified type within  $d\mathbf{r}$  during the time period  $t$  to  $t + dt$ . Inserting the above expression for  $dV_{\text{total}}$  into  $f_2 d\mathbf{c}_2 dV_{\text{total}}$  and dividing by  $dt$ , the collision density can be calculated as:

$$N_{12} = \iiint f_1 f_2 (\mathbf{g}_{21} \cdot \mathbf{k}) d_{12}^2 d\mathbf{k} d\mathbf{c}_1 d\mathbf{c}_2 \quad (4.8)$$

This relation is consistent with (2.159), after dividing the latter relation by  $dt$ , and denotes the basis for the dense gas extensions made by Enskog as explained in Sect. 2.12.

To generalize the formulation of the collision frequency a collisional *pair distribution function*  $f^{(2)}(\mathbf{r}_1, \mathbf{c}_1, \mathbf{r}_2, \mathbf{c}_2, t)$  is sometimes introduced, following a slightly different approach than the one used in Sect. 2.12. This function is defined such that  $f^{(2)} d\mathbf{c}_1 d\mathbf{c}_2 d\mathbf{r}_1 d\mathbf{r}_2$  is the probability of finding a pair of particles 1 and 2 centered at  $\mathbf{r}_1, \mathbf{r}_2$  with a velocity  $\mathbf{c}_1, \mathbf{c}_2$  in the volume element  $d\mathbf{r}_1, d\mathbf{r}_2$  and the velocity range  $d\mathbf{c}_1, d\mathbf{c}_2$ , respectively.

For a dilute gas molecular chaos is assumed so the velocities of the two colliding particles are uncorrelated. The pair distribution function can then be expressed as the product of two single particle distribution functions  $f^{(2)} \approx f_1^{(1)} f_2^{(1)}$ . The number of binary collisions per unit time per unit volume,  $N_{12}$ , can then be expressed as follows:

$$N_{12} = \iiint f^{(2)}(\mathbf{r}_1, \mathbf{c}_1, \mathbf{r}_2, \mathbf{c}_2, t) (\mathbf{g}_{21} \cdot \mathbf{k}) d_{12}^2 d\mathbf{k} d\mathbf{c}_1 d\mathbf{c}_2 \quad (4.9)$$

A similar representation of the collision frequency is used in Sect. 2.4.2 deriving the Boltzmann equation for a dilute gas in a generalized manner.

In accordance with the ideas presented in Sect. 2.4.2, the corresponding dilute gas collision operator can be expressed analogous to (2.184). However, the operator is reformulated and defined in terms of  $\mathbf{k}$  as is allowable because the billiard ball molecular model is adopted. The details of the transformation is explained in Sect. 2.12. The result is:

$$\begin{aligned} & \left( \frac{\partial f}{\partial t} \right)_{\text{Collision}} \\ &= \iint [f'^{(2)}(\mathbf{r}'_1, \mathbf{c}'_1, \mathbf{r}'_2, \mathbf{c}'_2, t) - f^{(2)}(\mathbf{r}_1, \mathbf{c}_1, \mathbf{r}_2, \mathbf{c}_2, t)] d_{12}^2 (\mathbf{g}_{21} \cdot \mathbf{k}) d\mathbf{k} d\mathbf{c}_1 \end{aligned} \quad (4.10)$$

where the primed velocities are determined by (2.133) and (2.134).

#### *Dense Gas Collision Density and Collision Operator*

Enskog [38] made two modifications to (4.9) in order to describe the frequency of collisions in a dense gas assumed to consist of rigid spheres, but the assumption of molecular chaos still prevails. Firstly, due to the finite size of the colliding molecules, the centers of the two molecules are not at the same point any more. For two particles of equal diameters the collision contact point is now located at  $\mathbf{r}_1 + \frac{1}{2}d_{12}\mathbf{k}$ . The collision density is thus expressed as [38]:

$$N_{12} = \iiint f^{(2)}(\mathbf{r}_1, \mathbf{c}_1, \mathbf{r}_1 + d_{12}\mathbf{k}, \mathbf{c}_2, t) (\mathbf{g}_{21} \cdot \mathbf{k}) d_{12}^2 d\mathbf{k} d\mathbf{c}_1 d\mathbf{c}_2 \quad (4.11)$$

Secondly, for a dense gas the volume of the molecules is comparable with the total volume occupied by the gas, so the free interstitial volume in which the center of any one molecule might be placed is reduced. The net effect is to increase the probability of a collision.

The pair distribution function approximation for dilute gas is thus modified by a volume correction function (see e.g., [38] and [25], Sects. 16.2–16.4):

$$f^{(2)}(\mathbf{r}_1, \mathbf{c}_1, \mathbf{r}_1 + d_{12}\mathbf{k}, \mathbf{c}_2, t) = \chi(\mathbf{r}_1 + \frac{1}{2}d_{12}\mathbf{k}) f_1^{(1)}(\mathbf{r}_1, \mathbf{c}_1, t) f_2^{(1)}(\mathbf{r}_1 + d_{12}\mathbf{k}, \mathbf{c}_2, t) \quad (4.12)$$

where  $\chi$  is a quantity that is unity for ordinary gases, and increases with increasing density, becoming infinite as the gas approaches the state in which the molecules are packed so closely that motion is impossible (e.g., [25], Sect. 16.2). The position of the point of collision can be expressed in different ways depending on the choice of origin, normally the center point of particle 1 is used.

The dense gas collision operator is also formulated in accordance with the ideas presented in Sect. 2.4.2, but in this case the generalized form (2.183) is adopted. After expressing the operator in terms of  $\mathbf{k}$ , the result is:

$$\begin{aligned} \left(\frac{\partial f}{\partial t}\right)_{\text{Collision}} &= \iint f'^{(2)}(\mathbf{r}'_1, \mathbf{c}'_1, \mathbf{r}'_2, \mathbf{c}'_2, t)(\mathbf{g}'_{21} \cdot \mathbf{k}) d^2_{12} d\mathbf{k} d\mathbf{c}_1 \\ &\quad - \iint f^{(2)}(\mathbf{r}_1, \mathbf{c}_1, \mathbf{r}_2, \mathbf{c}_2, t)(\mathbf{g}_{21} \cdot \mathbf{k}) d^2_{12} d\mathbf{k} d\mathbf{c}_1 \\ &= \iint (f'^{(2)}(\mathbf{g}'_{21} \cdot \mathbf{k}) - f^{(2)}(\mathbf{g}_{21} \cdot \mathbf{k})) d^2_{12} d\mathbf{k} d\mathbf{c}_1 \end{aligned} \quad (4.13)$$

This operator formulation is similar to the one used in the Enskog equation (2.662). However, the simplifying assumption that the collisions are elastic is not yet introduced making the relation more general (i.e., at this stage  $\mathbf{g}'_{21}$  is not necessarily equal to  $\mathbf{g}_{21}$ ).

#### 4.1.1.2 Particle Collision Density and Collision Operator

Savage and Jeffrey [126] and Jenkins and Savage [68] performed much of the pioneering work considering an extrapolation of the Enskog dense gas kinetic theory to granular flows. The collision operator of Enskog was modified because, as distinct from the elastic molecules, the particles are smooth but inelastic with a restitution coefficient  $e$ , ranging between zero and one [68]. On the other hand, the Enskog pair distribution function (4.12) was adopted in its original form. However, Savage and Jeffrey [126] associated the  $\chi$ -factor with a configurational pair-correlation function which for a gas at equilibrium reduces to the radial distribution function denoting the ratio of the local number density at a distance  $r = |\mathbf{r}_2 - \mathbf{r}_1|$  from the central particle to the bulk number density. In other words, the radial distribution function,  $g_0 \geq 1$ , accounts for the increase of the binary collision probability when the suspension becomes denser. There are no way to determine an exact formula for this function, so numerous empirical parameterizations have been proposed.

Ding and Gidaspow [30], for example, proposed an empirical relation being a function of the particulate phase volume fraction to be used for granular flows in fluidized beds given by:

$$\chi(\mathbf{r}_1 + \frac{1}{2}d_{12}\mathbf{k}) = g_0(\alpha_s) = [1 - (\frac{\alpha_s}{\alpha_{s,max}})^{1/3}]^{-1} \quad (4.14)$$

To calculate the collisional rate of change for dense suspensions Gidaspow [49] adopted the dense gas collision operator (4.13), because in this case the particles are inelastic so  $\mathbf{g}'_{21}$  is related to  $\mathbf{g}_{21}$  through the empirical relation (2.110). The kinetic fluxes for dilute suspensions were determined adopting the dilute gas collision operator (4.10), valid for elastic particles, instead. For dense suspensions the kinetic fluxes were approximated by those deduced for dilute suspensions.

The collisional rate of change  $\int_{-\infty}^{\infty} \psi (\frac{\partial f}{\partial t})_{\text{Collision}} d\mathbf{c}$  of any particle property  $\psi$  is the integral over all possible binary collisions of the change in  $\psi$  in a particular collision multiplied by the probability frequency of such a collision. In order to calculate the collisional rate of change for solid particles, we must examine further the details of a binary inelastic solid particle collision. Following closely the modeling approach of Chapman and Cowling [25] for an elastic dense gas binary molecular collision, a solid particle with velocity  $\mathbf{c}_1$  located at  $\mathbf{r}_1$  is considered. For a second solid particle traveling with velocity  $\mathbf{c}_2$  to collide with the first one in a time interval  $dt$  in such a way that, at collision, the line of centers between the two solid particles that can be expressed by  $\mathbf{r}_2 - \mathbf{r}_1 = d_{21}\mathbf{k}$  is within the solid angle  $d\mathbf{k}$  centered at  $\mathbf{k}$ , it is necessary that the center of the second solid particle lies in a collision cylinder of volume  $d_{21}^2 (\mathbf{g}_{12} \cdot \mathbf{k}) d\mathbf{k} dt$ . Hence, particle 1 gains  $\psi'_1 - \psi_1$  of the microscopic property  $\psi$  during the collision with particle 2. To determine the probability frequency at the instant of a collision between particles labeled 1 and 2 we take the center of the first particle to be located at position  $\mathbf{r}_1$  and the center of particle 2 to be at  $\mathbf{r}_1 + d_{12}\mathbf{k}$ . The primed and unprimed variables still refer to values of  $\psi$  after and before the collision. Thus, the net gain of  $\psi$  for particle 1 per unit volume and time for dilute systems becomes:

$$\begin{aligned} & \int_{-\infty}^{\infty} \psi_1 (\frac{\partial f}{\partial t})_{\text{Collision}} d\mathbf{c}_2 \\ &= \int_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} (\psi'_1 - \psi_1) f^{(2)}(\mathbf{r}_1, \mathbf{c}_1, \mathbf{r}_1 + d_{12}\mathbf{k}, \mathbf{c}_2, t) (\mathbf{g}_{21} \cdot \mathbf{k}) d_{12}^2 d\mathbf{k} d\mathbf{c}_1 d\mathbf{c}_2 \quad (4.15) \end{aligned}$$

where  $\mathbf{g}_{21} \cdot \mathbf{k} > 0$  indicates that the integration is to be taken over all values of  $\mathbf{k}$ ,  $\mathbf{c}_1$ , and  $\mathbf{c}_2$  considering only particles that are about to collide [68, 69, 102].

To ensure that the spatial shifting is correct Lun et al. [102] introduced a new position vector without label, defined such that  $\mathbf{r} = \mathbf{r}_1$  and  $\mathbf{r}_2 = \mathbf{r} + d_{12}\mathbf{k}$ . After the new position vector was introduced in (4.15), an expression similar to (4.15) for the collisional rate of change of solid particle 2 was derived. To solve this task Lun et al. [102] did utilize the collision symmetry properties such that this relation is

achieved by interchanging the labels 1 and 2 in (4.15) and replacing  $\mathbf{k}$  by  $-\mathbf{k}$ . This approach represents a collision dynamically identical but statistically different from the previous one [68, 69, 102]. The result is:

$$\begin{aligned} & \int_{-\infty}^{\infty} \psi_2 \left( \frac{\partial f}{\partial t} \right)_{\text{Collision}} d\mathbf{c}_2 \\ &= \int_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} (\psi'_2 - \psi_2) f^{(2)}(\mathbf{r} - d_{12}\mathbf{k}, \mathbf{c}_1, \mathbf{r}, \mathbf{c}_2, t) (\mathbf{g}_{21} \cdot \mathbf{k}) d_{12}^2 d\mathbf{k} d\mathbf{c}_1 d\mathbf{c}_2 \end{aligned} \quad (4.16)$$

Each of the integrals equals the collisional rate of change  $\int_{-\infty}^{\infty} \psi \left( \frac{\partial f}{\partial t} \right)_{\text{Collision}} d\mathbf{c}$ , but a more symmetric expression of  $\int_{-\infty}^{\infty} \psi \left( \frac{\partial f}{\partial t} \right)_{\text{Collision}} d\mathbf{c}$  might be achieved taking one half of the sum of (4.15) and (4.16) [68, 69]. The values of  $f^{(2)}$  separated by a distance  $d_{12}\mathbf{k}$  in (4.15) and (4.16) were then related to each other by means of a Taylor series expansion [102]:

$$\begin{aligned} f^{(2)}(\mathbf{r} - d_{12}\mathbf{k}, \mathbf{c}_1, \mathbf{r}, \mathbf{c}_2, t) &= f^{(2)}(\mathbf{r}, \mathbf{c}_1, \mathbf{r} + d_{12}\mathbf{k}, \mathbf{c}_2, t) \\ &- [d_{12}\mathbf{k} \cdot \nabla - \frac{1}{2!}(d_{12}\mathbf{k} \cdot \nabla)^2 + \frac{1}{3!}(d_{12}\mathbf{k} \cdot \nabla)^3 + \dots] f^{(2)}(\mathbf{r}, \mathbf{c}_1, \mathbf{r} + d_{12}\mathbf{k}, \mathbf{c}_2, t) \end{aligned} \quad (4.17)$$

Gidaspow [49] introduced a more compact notation for the same expansion:

$$\begin{aligned} f^{(2)}(\mathbf{r} - d_{12}\mathbf{k}, \mathbf{c}_1, \mathbf{r}, \mathbf{c}_2, t) &= f^{(2)}(\mathbf{r}, \mathbf{c}_1, \mathbf{r} + d_{12}\mathbf{k}, \mathbf{c}_2, t) \\ &- (d_{12}\mathbf{k} \cdot \nabla) \sum_{m=0}^{\infty} \frac{(-d_{12}\mathbf{k} \cdot \nabla)^m}{(m+1)!} f^{(2)}(\mathbf{r}, \mathbf{c}_1, \mathbf{r} + d_{12}\mathbf{k}, \mathbf{c}_2, t) \end{aligned} \quad (4.18)$$

Disregarding terms involving spatial derivatives higher than the first (i.e.,  $m=0$ ), the Taylor expansion (4.17) or (4.18) reduces to [102]:

$$\begin{aligned} f^{(2)}(\mathbf{r} - d_{12}\mathbf{k}, \mathbf{c}_1, \mathbf{r}, \mathbf{c}_2, t) &= f^{(2)}(\mathbf{r}, \mathbf{c}_1, \mathbf{r} + d_{12}\mathbf{k}, \mathbf{c}_2, t) \\ &- d_{12}\mathbf{k} \cdot \nabla f^{(2)}(\mathbf{r}, \mathbf{c}_1, \mathbf{r} + d_{12}\mathbf{k}, \mathbf{c}_2, t) \end{aligned} \quad (4.19)$$

Following the approach of Jenkins and Savage [68], inserting  $f^{(2)}(\mathbf{r}, \mathbf{c}_1, \mathbf{r} + d_{12}\mathbf{k}, \mathbf{c}_2, t)$  from (4.19) into (4.15), adding the intermediate result to (4.16) and divide by 2, Lun et al. [102] obtained a symmetric approximation of the binary solid particle collision operator:

$$\begin{aligned} \int_{-\infty}^{\infty} \psi \left( \frac{\partial f}{\partial t} \right)_{\text{Collision}} d\mathbf{c}_2 &= \frac{1}{2} \left( \int_{-\infty}^{\infty} \psi_1 \left( \frac{\partial f}{\partial t} \right)_{\text{Collision}} d\mathbf{c}_2 + \int_{-\infty}^{\infty} \psi_2 \left( \frac{\partial f}{\partial t} \right)_{\text{Collision}} d\mathbf{c}_2 \right) \\ &= \Omega(\psi) - \nabla \cdot \Phi(\psi) \end{aligned} \quad (4.20)$$

### The Flux Term

The flux term represents the transfer of  $\psi$  between particles during collisions. It can be approximated as [49, 102]:

$$\begin{aligned}
 \Phi(\psi) &= -\frac{d_{12}^3}{2} \int_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} (\psi'_1 - \psi_1) \mathbf{k} \sum_{m=0}^{\infty} \frac{(-d_{12} \mathbf{k} \cdot \nabla)^m}{(m+1)!} \\
 &\quad \times f^{(2)}(\mathbf{r}, \mathbf{c}_1, \mathbf{r} + d_{12} \mathbf{k}, \mathbf{c}_2, t) (\mathbf{g}_{21} \cdot \mathbf{k}) d\mathbf{k} d\mathbf{c}_1 d\mathbf{c}_2 \\
 &\approx -\frac{d_{12}^3}{2} \int_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} (\psi'_1 - \psi_1) \mathbf{k} f^{(2)}(\mathbf{r}, \mathbf{c}_1; \mathbf{r} + d_{12} \mathbf{k}, \mathbf{c}_2, t) (\mathbf{g}_{21} \cdot \mathbf{k}) d\mathbf{k} d\mathbf{c}_1 d\mathbf{c}_2 \\
 &\approx -\frac{d_{12}^3}{2} \int_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} (\psi'_1 - \psi_1) \mathbf{k} f^{(2)}\left(\mathbf{r} - \frac{1}{2} d_{12} \mathbf{k}, \mathbf{c}_1; \mathbf{r} + \frac{1}{2} d_{12} \mathbf{k}, \mathbf{c}_2, t\right) d\mathbf{z} \quad (4.21)
 \end{aligned}$$

where the set of integration variables is defined as  $d\mathbf{z} = (\mathbf{g}_{21} \cdot \mathbf{k}) d\mathbf{k} d\mathbf{c}_1 d\mathbf{c}_2$ .

The last relationship is the same expression as given by Chapman and Cowling [25], Sect. 16.4, for the collisional transfer of molecular properties. However, the last relation in (4.21) represents a zeroth order approximation of the relation given by Lun et al. [102] (second last relation) for the flux by use of a Taylor expansion similar to (4.18). The given result, relating the last and the second last relations in (4.21), can be achieved by shifting reference point  $\mathbf{r}$  to the mean point of impact instead of the mean position of the particle with index 1, i.e.,  $\mathbf{r}_1 = \mathbf{r} - \frac{1}{2} d_{21} \mathbf{k}$ . Neglecting all the terms containing derivatives, the Taylor expansion reduces to:

$$\begin{aligned}
 f^{(2)}(\mathbf{r}, \mathbf{c}_1, \mathbf{r} + d_{12} \mathbf{k}, \mathbf{c}_2, t) &\approx f^{(2)}\left(\mathbf{r} - \frac{1}{2} d_{21} \mathbf{k}, \mathbf{c}_1, \mathbf{r} + \frac{1}{2} d_{12} \mathbf{k}, \mathbf{c}_2, t\right) \\
 &\quad - \frac{1}{2} d_{12} \mathbf{k} \cdot \nabla f^{(2)}\left(\mathbf{r} - \frac{1}{2} d_{21} \mathbf{k}, \mathbf{c}_1, \mathbf{r} + \frac{1}{2} d_{12} \mathbf{k}, \mathbf{c}_2, t\right) + \dots \\
 &\approx f^{(2)}\left(\mathbf{r} - \frac{1}{2} d_{21} \mathbf{k}, \mathbf{c}_1, \mathbf{r} + \frac{1}{2} d_{12} \mathbf{k}, \mathbf{c}_2, t\right) \quad (4.22)
 \end{aligned}$$

It follows that the latter form of the pair distribution function can be approximated as:

$$\begin{aligned}
 f^{(2)}\left(\mathbf{r} - \frac{1}{2} d_{12} \mathbf{k}, \mathbf{c}_1; \mathbf{r} + \frac{1}{2} d_{12} \mathbf{k}, \mathbf{c}_2, t\right) &\approx g_0(\alpha_d) \\
 &\quad \times f_1^{(1)}\left(\mathbf{r} - \frac{1}{2} d_{12} \mathbf{k}, \mathbf{c}_1, t\right) f_2^{(1)}\left(\mathbf{r} + \frac{1}{2} d_{12} \mathbf{k}, \mathbf{c}_2, t\right) \quad (4.23)
 \end{aligned}$$

Lun et al. [102] proposed that a more physical approximation of the flux,  $\Phi(\psi)$ , can be obtained by expanding the two single distribution functions  $f_1^{(1)}$  and  $f_2^{(1)}$  in a Taylor series and by dropping the derivative terms of order higher than the first. Hence, the pair distribution function can be approximated as:

$$f^{(2)}(\mathbf{r} - \frac{1}{2}d_{12}\mathbf{k}, \mathbf{c}_1; \mathbf{r} + \frac{1}{2}d_{12}\mathbf{k}, \mathbf{c}_2, t) \approx g_0(\alpha_d)f_1^{(1)}(\mathbf{r}, \mathbf{c}_1, t)f_2^{(1)}(\mathbf{r}, \mathbf{c}_2, t) - \frac{1}{2}d_{12}\mathbf{k} \cdot (f_2^{(1)}(\mathbf{r}, \mathbf{c}_2, t)\nabla f_1^{(1)}(\mathbf{r}, \mathbf{c}_1, t) - f_1^{(1)}(\mathbf{r}, \mathbf{c}_1, t)\nabla f_2^{(1)}(\mathbf{r}, \mathbf{c}_2, t)) \quad (4.24)$$

This approximate relationship can be written in a more convenient form as:

$$\begin{aligned} f^{(2)} &\approx g_0(\alpha_d) \left[ f_1^{(1)}f_2^{(1)} - \frac{1}{2}d_{12}\mathbf{k} \cdot (f_2^{(1)}\nabla f_1^{(1)} + f_1^{(1)}\nabla f_2^{(1)}) \right] \\ &= g_0(\alpha_d) \left[ f_1^{(1)}f_2^{(1)} + \frac{1}{2}f_1^{(1)}f_2^{(1)}d_{12}\mathbf{k} \cdot \nabla \ln \frac{f_2^{(1)}}{f_1^{(1)}} \right] \end{aligned} \quad (4.25)$$

Substitution of (4.25) into the last relationship in (4.21) gives an extended expression for the collisional part of the flux vector of  $\psi$ :

$$\begin{aligned} \Phi(\psi) &\approx -\frac{d_{12}^3}{2}g_0(\alpha_d) \int_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} (\psi'_1 - \psi_1)\mathbf{k}f_1^{(1)}(\mathbf{r}, \mathbf{c}_1, t)f_2^{(1)}(\mathbf{r}, \mathbf{c}_2, t)d\mathbf{z} \\ &\quad - \frac{d_{12}^4}{4}g_0(\alpha_d) \int_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} (\psi'_1 - \psi_1)\mathbf{k}f_1^{(1)}(\mathbf{r}, \mathbf{c}_1, t)f_2^{(1)}(\mathbf{r}, \mathbf{c}_2, t)\mathbf{k} \cdot \nabla \ln \frac{f_2^{(1)}}{f_1^{(1)}}d\mathbf{z} \end{aligned} \quad (4.26)$$

where the set of integration variables  $d\mathbf{z}$  is defined as  $d\mathbf{z} = (\mathbf{g}_{21} \cdot \mathbf{k})d\mathbf{k}d\mathbf{c}_1d\mathbf{c}_2$ .

For convenience, following the approach of Chapman and Cowling [25], Sect. 16.32, the single distribution functions  $f_1^{(1)}$  and  $f_2^{(1)}$  to be determined at the point  $\mathbf{r}$  as occurring in the second term of (4.26), were replaced by the Maxwellian distribution function (4.40).

### The Source Term

The source term  $\Omega(\psi)$  represents the loss of  $\psi$  caused by inelastic collisions. This term was defined by [102]:

$$\Omega(\psi) = \frac{d_{12}^2}{2} \int_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} \Delta\psi f^{(2)}(\mathbf{r} - d_{12}\mathbf{k}, \mathbf{c}_1, \mathbf{r}, \mathbf{c}_2, t)(\mathbf{g}_{21} \cdot \mathbf{k})d\mathbf{k}d\mathbf{c}_1d\mathbf{c}_2 \quad (4.27)$$

with  $\Delta\psi = (\psi'_2 + \psi'_1) - (\psi_2 + \psi_1)$ . The pair distribution function  $f^{(2)}$  might be approximated by an expansion similar to (4.12).

Ding and Gidaspow [30, 49] suggested that the  $f^{(2)}$  approximation (4.25) might be employed deriving a convenient expression for the source term as well. The source term was thus approximated as:

$$\begin{aligned}
\Omega(\psi) &\approx \frac{d_{12}^2}{2} \int_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} \Delta\psi f^{(2)}(\mathbf{r} - \frac{1}{2}d_{12}\mathbf{k}, \mathbf{c}_1, \mathbf{r} + \frac{1}{2}d_{12}\mathbf{k}, \mathbf{c}_2, t)(\mathbf{g}_{21} \cdot \mathbf{k})d\mathbf{k}d\mathbf{c}_1d\mathbf{c}_2 \\
&\approx \frac{d_{12}^2}{2} g_0(\alpha_d) \int_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} \Delta\psi f_1^{(1)}(\mathbf{r}, \mathbf{c}_1, t) f_2^{(1)}(\mathbf{r}, \mathbf{c}_2, t)(\mathbf{g}_{21} \cdot \mathbf{k})d\mathbf{k}d\mathbf{c}_1d\mathbf{c}_2 \\
&\quad + \frac{d_{12}^3}{4} g_0(\alpha_d) \int_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} \Delta\psi f_1^{(1)}(\mathbf{r}, \mathbf{c}_1, t) f_2^{(1)}(\mathbf{r}, \mathbf{c}_2, t) \mathbf{k} \cdot \nabla \ln \frac{f_2^{(1)}}{f_1^{(1)}}(\mathbf{g}_{21} \cdot \mathbf{k})d\mathbf{k}d\mathbf{c}_1d\mathbf{c}_2
\end{aligned} \tag{4.28}$$

To calculate the integrals defining the source- and the flux terms, appropriate expressions for  $\Delta\psi$  and  $\psi'_1 - \psi_1$  have to be determined from an analysis of the inelastic binary particle collision dynamics as is provided in Sect. 4.1.2.

#### 4.1.1.3 Properties of the Maxwellian State

##### *Maxwellian Distribution of Particles*

To derive the constitutive equations to close the governing transport equations, the Maxwellian velocity distribution function for the particles is required. This distribution function is derived in the sequel [30, 68, 126].

Assuming that the velocity distribution function follows a normal distribution about its mean, the Gaussian probability density function  $f_N$  for scalar properties is expressed as:

$$f_N(r_x, c_x, t) = \frac{1}{\sqrt{2\pi\sigma_x^2}} \exp \left[ -\frac{[c_x - \langle c_x \rangle(r_x, t)]^2}{2\sigma_x^2} \right] \tag{4.29}$$

In statistics, the variance  $\sigma_x^2$  is given by:

$$\sigma_x^2 = \langle (c_x - \langle c_x \rangle)^2 \rangle = \int_{-\infty}^{\infty} C_x^2 f_N(r_x, c_x, t) dc_x \tag{4.30}$$

The probability distribution function has the normalized property:

$$\int_{-\infty}^{\infty} f_N(r_x, c_x, t) dc_x = 1 \tag{4.31}$$

In three dimensions, the velocity distribution function is proportional to the velocity probability density function:

$$f_N(\mathbf{r}, \mathbf{c}, t) = \frac{f(\mathbf{r}, \mathbf{c}, t)}{\int_{-\infty}^{\infty} f(\mathbf{r}, \mathbf{c}, t) d\mathbf{c}} = \frac{f(\mathbf{r}, \mathbf{c}, t)}{n(\mathbf{r}, t)} \tag{4.32}$$

The Maxwell-Boltzmann velocity distribution of the three-dimensional molecular velocity vector for a system at equilibrium with zero fluid velocity is equal to the product of each of the three independent normal distributions of the three independent velocity components:

$$\begin{aligned} f(\mathbf{r}, \mathbf{c}, t) &= n(\mathbf{r}, t) f_N(\mathbf{r}, \mathbf{c}, t) = n(\mathbf{r}, t) f_{N,x}(r_x, c_x, t) f_{N,y}(r_y, c_y, t) f_{N,z}(r_z, c_z, t) \\ &= f_x(r_x, c_x, t) f_y(r_y, c_y, t) f_z(r_z, c_z, t) \end{aligned} \quad (4.33)$$

For three-dimensional space equipartition of energy is assumed. This means the one-dimensional probability distributions are multiplicative. The variance of the square of the three dimensional velocity about a zero mean velocity is thus defined in terms of the mean of the peculiar velocity:

$$\sigma_{\mathbf{c}}^2 = \langle (\mathbf{c} - \langle \mathbf{c} \rangle) \cdot (\mathbf{c} - \langle \mathbf{c} \rangle) \rangle = \frac{\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} C^2 f_x f_y f_z d\mathbf{c}}{\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f_x f_y f_z d\mathbf{c}} = \langle C^2 \rangle \quad (4.34)$$

The square of the speed is defined as:

$$C^2 = C_x^2 + C_y^2 + C_z^2 \quad (4.35)$$

Moreover, the equipartition of energy requires:

$$C_x^2 = C_y^2 = C_z^2 \quad (4.36)$$

Thus,

$$\langle C^2 \rangle = \langle C_x^2 + C_y^2 + C_z^2 \rangle = 3\langle C_x^2 \rangle \quad (4.37)$$

It follows that the normal distribution of the one-dimensional velocity, can be written as:

$$\begin{aligned} f_x(r_x, c_x, t) &= [n(\mathbf{r}, t)]^{\frac{1}{3}} f_{N,x}(r_x, c_x, t) \\ &= [n(\mathbf{r}, t)]^{\frac{1}{3}} \left[ \frac{3}{2\pi\langle C^2 \rangle} \right]^{\frac{1}{2}} \exp \left[ -\frac{C_x^2}{2\langle C^2 \rangle} \right] \end{aligned} \quad (4.38)$$

Introducing the granular temperature variable (4.70) (defined later), the one dimensional distribution function becomes:

$$f_x(r_x, c_x, t) = [n(\mathbf{r}, t)]^{\frac{1}{3}} \left[ \frac{1}{2\pi\theta} \right]^{1/2} \exp \left[ -\frac{C_x^2}{2\theta} \right] \quad (4.39)$$

The Maxwellian distribution for particles in three dimensions is:

$$f(\mathbf{r}, \mathbf{c}, t) = f_x(r_x, c_x, t) f_y(r_y, c_y, t) f_z(r_z, c_z, t) = \frac{n(\mathbf{r}, t)}{(2\pi\theta)^{3/2}} \exp \left[ -\frac{C^2}{2\theta} \right] \quad (4.40)$$

**Fig. 4.1** Probability of existence of particles in the speed range between  $c$  and  $c + dc$

### *Particle Mean Speed of the Maxwellian State*

The mean speed of the particles in equilibrium might be computed as a property of the Maxwellian state:

$$\langle c \rangle(\mathbf{r}, t) = \frac{1}{n(\mathbf{r}, t)} \int c f(\mathbf{r}, \mathbf{c}, t) d\mathbf{c} = \frac{1}{(2\pi\theta)^{3/2}} \int C \exp\left[-\frac{C^2}{2\theta}\right] d\mathbf{c} \quad (4.41)$$

The particle speed is defined as:

$$c = |\mathbf{c}| = \sqrt{c_x^2 + c_y^2 + c_z^2} \quad (4.42)$$

As shown in Fig. 4.1, we use a system of spherical polar coordinates in the velocity space with  $c_x$ ,  $c_y$ ,  $c_z$ -axes. The shaded spherical shell in Fig. 4.1 has a radius  $c$  and thickness  $dc$ . With spherical symmetry, the increment of volume in velocity space is:

$$d\mathbf{c} = dc_x dc_y dc_z = c^2 \int_0^{2\pi} \int_0^\pi \sin\psi d\psi d\phi dc = 4\pi c^2 dc \quad (4.43)$$

The probability of existence of particles in the range of speed between  $c$  and  $c + dc$  can be obtained by integrating  $f(c_x, c_y, c_z) dc_x dc_y dc_z$  with respect to  $c_x$ ,  $c_y$  and  $c_z$  in the range between  $c$  and  $c + dc$ .

Hence, since the equilibrium state is associated with a zero mean velocity, the result is:

$$\langle c \rangle(\mathbf{r}, t) = \frac{1}{n(\mathbf{r}, t)} \int_{-\infty}^{\infty} c f(\mathbf{r}, \mathbf{c}, t) d\mathbf{c} = \frac{4\pi}{(2\pi\theta)^{3/2}} \int_0^{\infty} c \exp\left[-\frac{c^2}{2\theta}\right] c^2 dc \quad (4.44)$$

By use of an integral theorem (E.6b) proposed by Chapman and Cowling [25], the integral can be evaluated as:

$$\int_0^\infty c^3 \exp\left[-\frac{c^2}{2\theta}\right] dc = \frac{1}{2} \left(\frac{1}{2\theta}\right)^{-2} \quad (4.45)$$

Thus, the mean particle speed becomes:

$$\langle c \rangle = \frac{4\pi}{(2\pi\theta)^{3/2}} \int_0^\infty c^3 \exp\left[-\frac{c^2}{2\theta}\right] dc = \frac{4\pi \times 2\theta^2}{(2\pi\theta)^{3/2}} = \sqrt{\frac{8\theta}{\pi}}. \quad (4.46)$$

### 4.1.2 Dynamics of Inelastic Binary Collisions

In this section the dynamics of inelastic binary particle collisions are examined. The theory represents a semi-empirical extension of the binary collision theory of elastic particles described in Sect. 2.4.2. The aim is to determine expressions for the total change in the first and second moments of the particle velocity to be used deriving expressions for the collisional source (4.27) and flux (4.26) terms.

Consider an inelastic collision between two smooth identical spherical particles 1 and 2, of mass  $m$  and diameter  $d_p = d_{12}$  [69, 117]. If  $\mathbf{J}_{12}$  is the impulse of the force exerted by particle 1 on particle 2, the linear momentum balances over a collision relate the velocity vectors of the center of each sphere just before and after the collision through [102]:

$$m\mathbf{c}_1 = m\mathbf{c}'_1 - \mathbf{J}_{12} \quad (4.47)$$

$$m\mathbf{c}_2 = m\mathbf{c}'_2 + \mathbf{J}_{12} \quad (4.48)$$

where  $\mathbf{c}'_1$  and  $\mathbf{c}'_2$  are the velocities of the particles just after the collision and  $\mathbf{c}_1$  and  $\mathbf{c}_2$  just before the collision.

The relative velocities of the centers of the spheres immediately before and after a collision are still given by (2.111). For these inelastic particle collisions it is required that the relative particle velocity component normal to the plane of contact,  $\mathbf{g}_{21} \cdot \mathbf{k}$  (before collision) and  $\mathbf{c}'_{21} \cdot \mathbf{k}$  (after collision) satisfy the empirical relation (2.110) [68]. If the restitution coefficient therein is equal to one, the collision is elastic, which means that there is no energy loss during collision. Otherwise the collision is inelastic, which means that there is energy dissipation during collision. It is required that the component of the relative velocity perpendicular to the apse line should be unchanged in a collision, thus the impulse  $\mathbf{J}_{12}$  must act entirely in the  $\mathbf{k}$  direction. On this demand,  $\mathbf{J}_{12}$  can be determined from (4.47), (4.48) and (2.110).

The impulse of the force exerted by particle 1 on particle 2 is given by:

$$\begin{aligned} 2\mathbf{J}_{12} &= m(\mathbf{c}_1 - \mathbf{c}_2) + m(\mathbf{c}'_2 - \mathbf{c}'_1) = m\mathbf{g}_{12} - m\mathbf{g}'_{12} \\ &= m(\mathbf{g}_{12} \cdot \mathbf{k})\mathbf{k} - m(\mathbf{g}'_{12} \cdot \mathbf{k})\mathbf{k} = m(1 + e)(\mathbf{g}_{21} \cdot \mathbf{k})\mathbf{k} \end{aligned} \quad (4.49)$$

The particle velocities just after collision can be expressed in terms of those just before collision in accordance with (4.47) and (4.48) [102]:

$$\mathbf{c}'_1 = \mathbf{c}_1 - \frac{1}{2}(1+e)(\mathbf{g}_{12} \cdot \mathbf{k})\mathbf{k} \quad (4.50)$$

$$\mathbf{c}'_2 = \mathbf{c}_2 + \frac{1}{2}(1+e)(\mathbf{g}_{12} \cdot \mathbf{k})\mathbf{k} \quad (4.51)$$

These relations for the total change in the velocities, i.e.,  $\psi' - \psi$ , can be used in (4.26). Expressions for the change in the velocity moments can thus be generated by repeated multiplication of the velocity quantities in (4.50) and (4.51). The change in the first and second moments are:

$$\mathbf{c}'_1 - \mathbf{c}_1 = -\frac{1}{m}\mathbf{J}_{12} = -\frac{1}{2}(1+e)(\mathbf{g}_{21} \cdot \mathbf{k})\mathbf{k} \quad (4.52)$$

$$\mathbf{c}'_1 \mathbf{c}'_1 - \mathbf{c}_1 \mathbf{c}_1 = \frac{1}{2}(1+e)(\mathbf{g}_{12} \cdot \mathbf{k}) \left( \frac{1}{2}(1+e)(\mathbf{g}_{12} \cdot \mathbf{k})\mathbf{k}\mathbf{k} - [\mathbf{k}\mathbf{c}_1 + (\mathbf{k}\mathbf{c}_1)^T] \right) \quad (4.53)$$

Similar expressions can be derived for the change in the velocity moments of particle 2.

The translational kinetic energy change during a binary particle collision  $\Delta E$  can be determined as the difference between the LHS and RHS of (2.102). After re-writing the result by use of (2.113), the collisional energy change can be expressed as [49]:

$$2\Delta E = m_1 c_1'^2 + m_2 c_2'^2 - m_1 c_1^2 - m_2 c_2^2 = \frac{m_1 m_2}{m_c} (g_{12}'^2 - g_{12}^2) \quad (4.54)$$

Then, using (2.110) yields:

$$\Delta E = \frac{1}{2} \frac{m_1 m_2}{m_c} (e^2 - 1) (\mathbf{k} \cdot \mathbf{g}_{12})^2 \quad (4.55)$$

For the case of equal mass particles,  $m_1 = m_2 = m$ , the formula reduces to:

$$\Delta E = m(c_1'^2 + c_2'^2 - c_1^2 - c_2^2) = \frac{1}{4}m(e^2 - 1)(\mathbf{k} \cdot \mathbf{g}_{12})^2 \quad (4.56)$$

This expression coincides with the result of Jenkins and Savage [68].

The total change in the velocity moments can be deduced from (4.52) and (4.53), and expressed as:

$$\Delta(\mathbf{c}) = \mathbf{c}'_1 - \mathbf{c}_1 + \mathbf{c}'_2 - \mathbf{c}_2 = 0 \quad (4.57)$$

$$\begin{aligned}
\Delta(\mathbf{c}\mathbf{c}) &= \mathbf{c}'_1 \mathbf{c}'_1 - \mathbf{c}_1 \mathbf{c}_1 + \mathbf{c}'_2 \mathbf{c}'_2 - \mathbf{c}_2 \mathbf{c}_2 \\
&= \frac{1}{2}(1+e)(\mathbf{g}_{12} \cdot \mathbf{k}) \left( (1+e)(\mathbf{g}_{12} \cdot \mathbf{k}) \mathbf{k} \mathbf{k} - [\mathbf{k} \mathbf{g}_{12} + (\mathbf{k} \mathbf{g}_{12})^T] \right) \quad (4.58)
\end{aligned}$$

These relations for the total change in the velocity moments,  $\Delta\psi$ , can be used in (4.28). Similar expressions can also be derived for the fluctuating velocities. Further details were given by Lindborg [97] p 135.

### 4.1.3 Maxwell's Transport Equation for $\psi(\mathbf{c})$ and Balance Laws

The Maxwell transport equation can be derived from (4.5) requiring that  $\psi(\mathbf{c})$  is a function of  $\mathbf{c}$  only. With (4.20), the Maxwell transport equation can be written as:

$$\frac{\partial}{\partial t}(n\langle\psi\rangle_M) + \nabla \cdot (n\langle\mathbf{c}\psi\rangle_M) - n\langle\mathbf{F} \cdot \nabla_{\mathbf{c}}\psi\rangle_M = \Omega(\psi) - \nabla \cdot \Phi(\psi) \quad (4.59)$$

in which  $\Phi(\psi)$  is given by (4.26) and  $\Omega(\psi)$  by (4.28). Moreover, it is noted that the terms  $\frac{\partial\psi}{\partial t}$  and  $\nabla\psi$  in (4.5) vanish because the local  $\psi(\mathbf{c})$  is now independent of  $t$  and  $\mathbf{r}$ . Further details on the derivation of the source and flux relations are given in Sect. 4.1.5.

#### 4.1.3.1 Continuity

Taking  $\psi = m$  in (4.59) yields the local form of the continuity equation for the granular material:

$$\frac{\partial\rho_d}{\partial t} + \nabla \cdot (\rho_d \mathbf{v}_d) = 0 \quad (4.60)$$

From (4.26) and (4.28) we conclude that  $\Omega(m) = \Phi(m) = 0$ .

#### 4.1.3.2 Momentum

Taking  $\psi = m\mathbf{c}$  in (4.59) yields the local form of the balance of linear momentum:

$$\frac{\partial}{\partial t}(\rho_d \mathbf{v}_d) + \nabla \cdot (\rho_d \langle \mathbf{c}\mathbf{c} \rangle_M) - \rho_d \langle \mathbf{F} \rangle_M = \Omega(m\mathbf{c}) - \nabla \cdot \Phi(m\mathbf{c}) \quad (4.61)$$

It is customary to introduce a total pressure tensor defined as the sum of the kinetic and collisional pressure tensors:

$$\mathbf{p}_d = \mathbf{p}_d^{\text{kin}} + \mathbf{p}_d^{\text{coll}} = \rho_d \langle \mathbf{C}\mathbf{C} \rangle_M + \Phi(m\mathbf{c}) \quad (4.62)$$

in which the collisional pressure tensor is denoted by  $\mathbf{p}_d^{\text{coll}} = \Phi(m\mathbf{c})$ . The kinetic pressure tensor,  $\mathbf{p}_d^{\text{kin}} = \rho_d \langle \mathbf{C}\mathbf{C} \rangle_M$ , can be deduced from the second term in the momentum balance after introducing the peculiar velocity (2.65).

The second moment term is reformulated as follows:

$$\rho_d \langle \mathbf{c}\mathbf{c} \rangle_M = \rho_d \langle (\mathbf{C} + \mathbf{v}_d)(\mathbf{C} + \mathbf{v}_d) \rangle_M = \rho_d \langle \mathbf{C}\mathbf{C} \rangle_M + \rho_d \mathbf{v}_d \mathbf{v}_d \quad (4.63)$$

The second last term on the RHS denotes kinetic pressure and the last term the convective momentum flux. From (4.28) it is immediately concluded that  $\Omega(m\mathbf{c}) = 0$  because the  $m\mathbf{c}$  is a summational invariant (i.e., in a particle collision the momentum is conserved).

The net force exerted on a particle can be expressed on the form [49, 86, 123, 137]:

$$\mathbf{F} = \mathbf{F}_D - \frac{1}{\rho_d} \nabla p_c + \mathbf{g} \quad (4.64)$$

where the first term on the RHS is the steady drag term. The second term on RHS denotes the ratio of the macroscopic fluid pressure gradient and the density of the dispersed phase. The last term denotes the gravitational acceleration.

For granular flow (as distinct from the classical kinetic theory for a dilute gas) the net external force acting on the particle depends on the microscopic velocity because of the phase interaction terms introduced to consider the interstitial fluid behavior. However, the net force can be divided into two types of contributions, a set of external forces  $\mathbf{F}_e$  which are independent of  $\mathbf{c}$  and a separate steady drag force  $\mathbf{F}_D$ . Hence, the net force exerted on a particle is re-written as:

$$\mathbf{F} = \mathbf{F}_D + \mathbf{F}_e = \frac{1}{\tau_{cd}} (\mathbf{v}_c - \mathbf{c}) + \mathbf{F}_e \quad (4.65)$$

where  $\mathbf{F}_D = \frac{1}{\tau_{cd}} (\mathbf{v}_c - \mathbf{c})$  and  $\mathbf{F}_e = -\frac{1}{\rho_d} \nabla p_c + \mathbf{g}$ . The  $\mathbf{v}_c$  is the local instantaneous velocity of the interstitial fluid, and  $\tau_{cd}$  is the particle-to-fluid relaxation time.

For multiphase flows perturbed by the presence of particles to obtain a turbulence like behavior the local instantaneous velocity of the continuous phase can for example be decomposed adopting the Reynolds averaging procedure (i.e., other methods including time-, volume-, ensemble-, and Favre averaging have been used as well) and expressed as:  $\mathbf{v}_c = \mathbf{v}'_c + \langle \mathbf{v} \rangle_{M,c}$ , where  $\mathbf{v}'_c$  is the fluctuating component of the continuous phase velocity. Introducing the peculiar velocity for the dispersed phase this relation can be re-arranged as:

$$\mathbf{F} = \frac{1}{\tau_{cd}} (\langle \mathbf{v} \rangle_{M,c} - \mathbf{v}_d) + \frac{1}{\tau_{cd}} (\mathbf{v}'_c - \mathbf{C}) + \mathbf{F}_e \quad (4.66)$$

The second term on the RHS is often neglected due to a general lack of knowledge about the physics it represents.

After introducing the derived fluxes from (4.62) and (4.63) and the forces from (4.64) into the momentum balance, we get:

$$\frac{\partial}{\partial t}(\rho_d \mathbf{v}_d) + \nabla \cdot (\rho_d \mathbf{v}_d \mathbf{v}_d) = -\nabla p_c - \nabla \cdot \mathbf{p}_d^{\text{kin}} - \nabla \cdot \mathbf{p}_d^{\text{coll}} - \rho_d (\langle \mathbf{F}_D \rangle - \mathbf{g}) \quad (4.67)$$

Further details of the derivation of the relation for the kinetic pressure,  $\mathbf{p}_d^{\text{kin}}$ , and the collisional pressure,  $\mathbf{p}_d^{\text{coll}}$ , are given in Sect. 4.1.5 starting out from (4.106) at p. 628 and (4.117) at p. 630, respectively.

#### 4.1.3.3 The Granular Temperature (Microscopic Specific Kinetic Energy)

Taking  $\psi = \frac{1}{2}mc^2$  in (4.59) gives the local form of the total energy equation (i.e., the sum of the macroscopic—and microscopic kinetic energy forms, including the potential energy of the particle fluid due to the external gravity force):

$$\frac{\partial}{\partial t} \left( \frac{\rho_d}{2} \langle c^2 \rangle_M \right) + \nabla \cdot \left( \frac{\rho_d}{2} \langle \mathbf{c} c^2 \rangle_M \right) - \frac{\rho_d}{2} \langle \mathbf{F} \cdot \nabla_{\mathbf{c}} (c^2) \rangle_M = \Omega \left( \frac{1}{2} m c^2 \right) - \nabla \cdot \Phi \left( \frac{1}{2} m c^2 \right) \quad (4.68)$$

Introducing the peculiar velocity (2.65) we can re-write the terms to obtain more common forms. We first note that:

$$c^2 = \mathbf{c} \cdot \mathbf{c} = (\mathbf{C} + \mathbf{v}_d) \cdot (\mathbf{C} + \mathbf{v}_d) = C^2 + 2\mathbf{C} \cdot \mathbf{c} + v_d^2 \quad (4.69)$$

Then, in analogy to the thermal temperature in kinetic theory of gases, the granular temperature is defined in terms of the specific kinetic energy of the granular fluid velocity fluctuations constituting the Maxwellian average microscopic translational particle fluctuation velocity energy [49]:

$$\theta = \frac{1}{3} \langle C^2 \rangle_M \quad (4.70)$$

It is further noted that the flux term can be manipulated as:

$$\begin{aligned} \Phi \left( \frac{1}{2} m c^2 \right) &= \Phi \left( \frac{1}{2} m [C^2 + 2\mathbf{C} \cdot \mathbf{c} + v_d^2] \right) \\ &= \Phi \left( \frac{1}{2} m C^2 \right) + \Phi (m \mathbf{C} \cdot \mathbf{c}) + \Phi \left( \frac{1}{2} m v_d^2 \right) = \mathbf{v}_d \cdot \mathbf{p}_d^{\text{coll}} + \mathbf{q}_d^{\text{coll}} \end{aligned} \quad (4.71)$$

In accordance with (4.26), the following relationships hold:

$$\mathbf{q}_d^{\text{coll}} = \Phi\left(\frac{1}{2}mC^2\right) \quad (4.72)$$

$$\mathbf{v}_d \cdot \mathbf{p}_d^{\text{coll}} = \Phi\left(\frac{1}{2}m[2\mathbf{C} \cdot \mathbf{c}]\right) \quad (4.73)$$

$$\Phi\left(\frac{1}{2}mv_d^2\right) = 0 \quad (4.74)$$

The last relationship is true because the macroscopic velocity is not changed in a microscopic particle collision, i.e.,  $\mathbf{v}'_d = \mathbf{v}_d$ , thus the macroscopic particle fluid kinetic energy is conserved (i.e.,  $\frac{1}{2}m[v_d'^2 - v_d^2] = 0$ , as the macroscopic fluid velocities before and after a particle collision are equal).

The collisional source term  $\Omega(\frac{1}{2}mc^2)$  is given by (4.28) and expressed as:

$$\gamma = -\Omega\left(\frac{1}{2}mc^2\right) \quad (4.75)$$

where  $\gamma$  is the rate of energy dissipation per unit volume due to inelastic collisions of smooth particles. It is noted that the total kinetic energy is not conserved as there is a sink term in the transport equation for the microscopic kinetic energy.

The kinetic part of the flux of fluctuation energy can be deduced from the convective term in (4.68) and is defined by:

$$\mathbf{q}_d^{\text{kin}} = \frac{1}{2}\rho\langle\mathbf{C}\mathbf{C}^2\rangle_M \quad (4.76)$$

Inserting the manipulated flux terms and the source into the Maxwell equation (4.59) with  $\psi = \frac{1}{2}mc^2$ , the result is:

$$\begin{aligned} \frac{\partial}{\partial t}\left(\rho d\left(\frac{3}{2}\theta + \frac{1}{2}v_d^2\right)\right) + \nabla \cdot \left(\mathbf{q}_d + \rho d\mathbf{v}_d\frac{3}{2}\theta + \mathbf{v}_d \cdot \mathbf{p}_d + \rho d\mathbf{v}_d\frac{1}{2}v_d^2\right) \\ = \rho\langle\mathbf{F} \cdot \mathbf{c}\rangle_M - \gamma \end{aligned} \quad (4.77)$$

The total energy fluctuating flux is denoted by:

$$\mathbf{q}_d = \mathbf{q}_d^{\text{kin}} + \mathbf{q}_d^{\text{coll}} \quad (4.78)$$

An equation for the granular temperature can then be achieved by subtracting the macroscopic kinetic or mechanical energy equation from the above equation for the sum of the microscopic and macroscopic or mean kinetic energy forms.

As shown for single phase flows in Chap. 1, the mechanical energy balance is obtained by taking the scalar vector product between the macroscopic velocity and the local momentum balance:

$$\mathbf{v}_d \cdot \left\{ \frac{\partial}{\partial t}(\rho d\mathbf{v}_d) + \nabla \cdot (\rho d\mathbf{v}_d\mathbf{v}_d) - \rho d\mathbf{F} = -\nabla \cdot \mathbf{p}_d \right\} \quad (4.79)$$

With some manipulation, the resulting relation can be written as:

$$\frac{\partial}{\partial t}(\rho_d \frac{1}{2} v_d^2) + \nabla \cdot (\rho_d \mathbf{v}_d \frac{1}{2} v_d^2) = -\mathbf{v}_d \cdot \nabla \cdot \mathbf{p}_d + \rho_d \mathbf{v}_d \cdot \mathbf{F} \quad (4.80)$$

A convenient short notation can be introduced in terms of the double dot tensor product [13]:

$$\mathbf{p}_d : \nabla \mathbf{v}_d = \nabla \cdot (\mathbf{p}_d \cdot \mathbf{v}_d) - \mathbf{v}_d \cdot \nabla \cdot \mathbf{p}_d \quad (4.81)$$

The conventional form of the macroscopic kinetic energy equation is then obtained:

$$\frac{\partial}{\partial t}(\rho_d \frac{1}{2} v_d^2) + \nabla \cdot (\rho_d \mathbf{v}_d \frac{1}{2} v_d^2) = \mathbf{p}_d : \nabla \mathbf{v}_d - \nabla \cdot (\mathbf{p}_d \cdot \mathbf{v}_d) + \rho_d \mathbf{v}_d \cdot \mathbf{F} \quad (4.82)$$

The transport equation for the microscopic kinetic energy expressed in terms of the granular temperature is achieved by subtracting the equation for the macroscopic kinetic energy from the equation for the sum of the microscopic- and macroscopic kinetic energy forms. The result is [30, 49]:

$$\begin{aligned} \frac{\partial}{\partial t} \left( \rho_d \frac{3}{2} \theta \right) + \nabla \cdot \left( \rho_d \mathbf{v}_d \frac{3}{2} \theta \right) = & -\nabla \cdot \mathbf{q}_d - \mathbf{p}_d : \nabla \mathbf{v}_d \\ & + \rho_d \langle \mathbf{F} \cdot \mathbf{c} \rangle_M - \rho_d \mathbf{v}_d \cdot \langle \mathbf{F} \rangle_M - \gamma \end{aligned} \quad (4.83)$$

The external force terms are retained in the given form to ensure that the effects of the interstitial fluid are included in a consistent manner. The two terms on the LHS denotes the transient term and the convective transport term. The terms on the RHS denote the rate of total energy input by conduction per unit volume, production of translational energy (fluctuations) by shear, production due to the interaction with fluid turbulence and dissipation due to interaction with fluid through the drag, and energy dissipation due to inelastic collisions, respectively.

Further details of the derivation of the closure relations for the energy dissipation source term,  $\gamma$ , and the kinetic and collisional energy fluxes,  $\mathbf{q}_d^{\text{kin}}$  and  $\mathbf{q}_d^{\text{coll}}$  are given in Sect. 4.1.5 starting out from (4.179) at p. 642 and from (4.175) at p. 641, respectively.

#### 4.1.4 Enskog's Transport Equation for $\psi(\mathbf{C})$ and Balance Laws

In this section an alternative derivation of the governing equations for granular flow is examined. In this alternative method the peculiar velocity  $\mathbf{C}$  is used, instead of the microscopic particle velocity  $\mathbf{c}$ , as the independent variable in the particle property and distribution functions. The transformation of these functions and the governing equation follows standard mathematical procedures for changing the reference frame. The translational motion of an individual particle may be specified either by its microscopic velocity  $\mathbf{c}$  relative to a fixed or Galilean frame of reference, or by its

velocity relative to a frame of reference moving with the local velocity of the granular fluid  $\mathbf{v}_d$ .

Experience has shown that one might benefit substantially from deriving the governing transport equations after having transformed the property and distribution functions so that they are dependent on the peculiar velocity variable (2.65) instead of the microscopic particle velocity  $\mathbf{c}$ . This means that the basic functions  $\psi(\mathbf{r}, \mathbf{c}, t)$  and  $f(\mathbf{r}, \mathbf{c}, t)$  in which  $(\mathbf{r}, \mathbf{c}, t)$  are the independent variables, have to be replaced by  $\psi(\mathbf{r}, \mathbf{C} + \mathbf{v}_d, t)$  and  $f(\mathbf{r}, \mathbf{C} + \mathbf{v}_d, t)$  where  $(\mathbf{r}, \mathbf{C}, t)$  are now the independent variables. Compared to the previous derivation of the transport equations starting out from (4.5), the generalized balance formulation in the alternative frame is simpler because all the terms containing time and space derivatives of  $\psi$  vanish as the relevant properties are functions of  $\mathbf{C}$  only. This is particularly the case for the velocity moments of order 2 and higher because all the terms in the resulting equation appear directly in their desired form and do not require further manipulations. To transform the mathematical operators when changing the reference frame, let  $f = f(\mathbf{r}, \mathbf{c}, t)$ ,  $f_C = f(\mathbf{r}, \mathbf{C}, t)$  and  $f(\mathbf{r}, \mathbf{c}, t) = f_C(\mathbf{r}, \mathbf{C}, t)$ . It is noted that by performing this frame transformation the interpretations of the mathematical operators  $\partial/\partial t$  and  $\nabla$  in the Boltzmann equation will change as well, because  $\mathbf{C}$ , not  $\mathbf{c}$ , is to be kept constant while performing the differentiation. Accordingly, due to the implicit dependence of  $f$  upon  $t$  and  $\mathbf{r}$  through the dependence of  $\mathbf{C}$  upon  $\mathbf{v}_d(\mathbf{r}, t)$  as expressed by (2.65), the chain rule theorem (e.g., [32], p. 105 ; [25], pp. 48–49; [49]) has to be invoked to re-formulate the operators in an appropriate manner. The chain rule provides a relation between the partial derivative of  $f$  with respect to the individual particle velocity  $\mathbf{c}$  and the partial derivative of  $f_C$  with respect to the peculiar velocity  $\mathbf{C}$ . To understand the forthcoming transformation it might be informative to specify explicitly the meaning of the partial derivatives.

Considering that  $f_C = f_C(\mathbf{r}, \mathbf{C}, t)$ , the total differential of  $f_C$  can be expressed as:

$$df_C = \nabla_r f_C \cdot d\mathbf{r} + \nabla_C f_C \cdot d\mathbf{C} + \frac{\partial f_C}{\partial t} dt = df \quad (4.84)$$

By use of the chain rule we may deduce the following term transformations as stated in tensor notation:

$$\begin{aligned} \sum_i \frac{\partial f}{\partial c_i} |_{\mathbf{r}, c_j, t} &= \sum_i \frac{\partial f_C}{\partial C_i} |_{\mathbf{r}, C_j, t} \frac{\partial C_i}{\partial c_i} |_{\mathbf{r}, c_j, t} + \sum_i \frac{\partial f_C}{\partial r_i} |_{\mathbf{r}, \mathbf{C}, t} \frac{\partial r_i}{\partial c_i} |_{\mathbf{r}, c_j, t} \\ &+ \sum_i \frac{\partial f_C}{\partial t} |_{\mathbf{r}, \mathbf{C}} \frac{\partial t}{\partial c_i} |_{\mathbf{r}, c_j} = \sum_i \frac{\partial f_C}{\partial C_i} \end{aligned} \quad (4.85)$$

where  $j \neq i$ . The terms  $\frac{\partial r_i}{\partial c_i} |_{\mathbf{r}, c_j, t}$  and  $\frac{\partial t}{\partial c_i} |_{\mathbf{r}, c_j}$  are zero by definition and  $\frac{\partial C_i}{\partial c_i} |_{\mathbf{r}, c_j, t}$  is calculated from (2.65) which defines the relationships between the variables  $\mathbf{C}$ ,  $\mathbf{c}$ ,  $\mathbf{r}$ , and  $t$ .

In vector notation the result can be written as:

$$\nabla_c f = \nabla_C f_C \quad (4.86)$$

The chain rule can also be used to obtain a relation between the partial derivative of  $f$  with respect to time,  $t$ , and the partial derivative of  $f_C$  with respect to time,  $t$ . In tensor notation, the theorem can be written as:

$$\begin{aligned} \frac{\partial f}{\partial t}|_{\mathbf{r},\mathbf{c}} &= \sum_i \frac{\partial f_C}{\partial C_i}|_{\mathbf{r},C_j,t} \frac{\partial C_i}{\partial t}|_{\mathbf{r},\mathbf{c}} + \sum_i \frac{\partial f_C}{\partial r_i}|_{r_j,\mathbf{C},t} \frac{\partial r_i}{\partial t}|_{r_j,\mathbf{c}} + \frac{\partial f_C}{\partial t}|_{\mathbf{r},\mathbf{C}} \frac{\partial t}{\partial t}|_{\mathbf{r},\mathbf{c}} \\ &= \sum_i \frac{\partial f_C}{\partial C_i}|_{\mathbf{r},C_j,t} \frac{\partial (c_i - v_{i,d})}{\partial t}|_{\mathbf{r},\mathbf{c}} + 0 + \frac{\partial f_C}{\partial t}|_{\mathbf{r},\mathbf{C}} \\ &= - \sum_i \frac{\partial f_C}{\partial C_i} \frac{\partial v_{i,d}}{\partial t} + \frac{\partial f_C}{\partial t} \end{aligned} \quad (4.87)$$

where  $r_i$  is the space coordinate in direction  $i$  that should not be confused with the position vector  $\mathbf{r} = \mathbf{r}(t)$ . The terms  $\frac{\partial r_i}{\partial t}|_{r_j,\mathbf{c}}$  are zero by definition,  $\frac{\partial t}{\partial t}|_{\mathbf{r},\mathbf{c}} = 1$  and  $\frac{\partial C_i}{\partial t}|_{\mathbf{r},\mathbf{c}}$  is calculated from (2.65) which defines the relationships between the variables  $\mathbf{C}$ ,  $\mathbf{c}$ ,  $\mathbf{r}$ , and  $t$ .

In vector notation the result can be written as:

$$\frac{\partial f}{\partial t} = \frac{\partial f_C}{\partial t} - \nabla_C f_C \cdot \frac{\partial \mathbf{v}_d}{\partial t} \quad (4.88)$$

To deduce a relation between the partial derivative of  $f$  with respect to the physical space coordinates,  $r_i$ , and the partial derivative of  $f_C$  with respect to the physical space coordinates,  $r_i$ , the chain rule is invoked again.

In tensor notation we may write the theorem as:

$$\begin{aligned} \sum_i \frac{\partial f}{\partial r_i}|_{r_j,\mathbf{c},t} &= \sum_i \frac{\partial f_C}{\partial C_i}|_{\mathbf{r},C_j,t} \frac{\partial C_i}{\partial r_i}|_{r_j,\mathbf{c},t} + \sum_i \frac{\partial f_C}{\partial r_i}|_{r_j,\mathbf{C},t} \frac{\partial r_i}{\partial r_i}|_{r_j,\mathbf{c},t} + \sum_i \frac{\partial f_C}{\partial t}|_{\mathbf{r},\mathbf{C}} \frac{\partial t}{\partial r_i}|_{r_j,\mathbf{c}} \\ &= \sum_i \frac{\partial f_C}{\partial C_i}|_{\mathbf{r},C_j,t} \frac{\partial (c_i - v_{i,d})}{\partial r_i}|_{r_j,\mathbf{c},t} + \sum_i \frac{\partial f_C}{\partial r_i}|_{r_j,\mathbf{C},t} + 0 \\ &= - \sum_i \frac{\partial f_C}{\partial C_i} \frac{\partial v_{i,d}}{\partial r_i} + \sum_i \frac{\partial f_C}{\partial r_i} \end{aligned} \quad (4.89)$$

The terms  $\frac{\partial t}{\partial r_i}|_{r_j,\mathbf{c},t}$  are zero by definition,  $\frac{\partial r_i}{\partial r_i}|_{\mathbf{c},t} = 1$  and  $\frac{\partial C_i}{\partial r_i}|_{r_j,\mathbf{c},t}$  is calculated from (2.65) which defines the relationships between the variables  $\mathbf{C}$ ,  $\mathbf{c}$ ,  $\mathbf{r}$ , and  $t$ .

In vector notation the result can be written as:

$$\nabla f = \nabla f_C - \nabla_C f_C \cdot \nabla \mathbf{v}_d \quad (4.90)$$

By use of (4.86), (4.88) and (4.90), the LHS of the Boltzmann equation (4.1) can be expressed as:

$$\frac{\partial f_C}{\partial t} - \nabla_C f_C \cdot \frac{\partial \mathbf{v}_d}{\partial t} + (\mathbf{C} + \mathbf{v}_d) \cdot (\nabla f_C - \nabla_C f_C \cdot \nabla \mathbf{v}_d) + \nabla_C \cdot (\mathbf{F} f_C) \quad (4.91)$$

Introducing the substantial derivative, defined by the average velocity  $\mathbf{v}_d$ , one obtains:

$$\frac{Df_C}{Dt} + \mathbf{C} \cdot \nabla f_C - \frac{D\mathbf{v}_d}{Dt} \cdot \nabla_C f_C - (\mathbf{C} \nabla_C f_C) : \nabla \mathbf{v}_d + \nabla_C \cdot (\mathbf{F} f_C) \quad (4.92)$$

in which we have used a relationship given by Chapman and Cowling [25], Eq. (1.32,7):

$$\mathbf{C} \cdot (\nabla_C f_C \cdot \nabla \mathbf{v}_d) = (\mathbf{C} \nabla_C f_C) : \nabla \mathbf{v}_d \quad (4.93)$$

Subsequently, a modified transport equation for a quantity  $\psi(\mathbf{C})$  can be derived by the moment method. To proceed we multiply the LHS of the modified Boltzmann equation (4.92) with  $\psi$  and thereafter integrate the resulting equation over the peculiar velocity space  $d\mathbf{C}$ . Integration over  $\mathbf{C}$  is equivalent to integration over  $\mathbf{c}$ , as the two vectors differ only by a vector which is independent of  $\mathbf{c}$  and  $\mathbf{C}$ , and the integration is performed over the whole velocity space [58] (p. 457).

The various integral terms deduced from (4.92) can be transformed by means of the following relations:

$$\begin{aligned} \int_{-\infty}^{\infty} \psi \frac{Df_C}{Dt} d\mathbf{C} &= \frac{D}{Dt} \int_{-\infty}^{\infty} \psi f_C d\mathbf{C} - \int_{-\infty}^{\infty} f_C \frac{D\psi}{Dt} d\mathbf{C} \\ &= \frac{D}{Dt} n \langle \psi \rangle_M - n \left\langle \frac{D\psi}{Dt} \right\rangle_M \end{aligned} \quad (4.94)$$

$$\begin{aligned} \int_{-\infty}^{\infty} \psi \mathbf{C} \cdot \nabla f_C d\mathbf{C} &= \nabla \cdot \int_{-\infty}^{\infty} \psi \mathbf{C} f_C d\mathbf{C} - \int_{-\infty}^{\infty} f_C \nabla \cdot (\mathbf{C} \psi(\mathbf{C})) d\mathbf{C} \\ &= \nabla \cdot n \langle \psi \mathbf{C} \rangle_M - n \langle \mathbf{C} \cdot \nabla \psi \rangle_M \end{aligned} \quad (4.95)$$

$$\begin{aligned} \int_{-\infty}^{\infty} \psi \nabla_C f_C d\mathbf{C} &= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} [\psi f_C]_{-\infty}^{\infty} dC_y dC_z - \int_{-\infty}^{\infty} f_C \nabla_C \psi d\mathbf{C} \\ &= -n \langle \nabla_C \psi \rangle_M \end{aligned} \quad (4.96)$$

Since  $\mathbf{C}$  is now regarded as independent of  $\mathbf{r}$ , the variable  $C$  is not included in the differentiation with respect to  $\mathbf{r}$  in (4.95) [25] (pp. 48–49). In (4.96) integration by

parts is performed and the first term vanishes because, by hypothesis,  $\psi f_C$  tends to zero as  $C_x$  tends to infinity in either direction. By use of a similar argument, the following relation is valid:

$$\begin{aligned} \int_{-\infty}^{\infty} \psi \mathbf{C} \nabla_C f_C &= -n \langle \nabla_C (\psi \mathbf{C}) \rangle_M \\ &= -n \langle \psi \rangle_M \mathbf{e} - n \langle \mathbf{C} \nabla_C \psi \rangle_M \end{aligned} \quad (4.97)$$

where  $\mathbf{e}$  is the unit tensor.

Multiplying the RHS of the Boltzmann equation (4.1) with  $\psi d\mathbf{C}$  and thereafter integrating the resulting term over the velocity space, one obtains the rate of change by collisions in the property  $\psi$  summed over all the particles in a unit volume ([25], Sect. 3.11):

$$\int_{-\infty}^{\infty} \psi \left( \frac{\partial f}{\partial t} \right)_{\text{Collision}} d\mathbf{C} \quad (4.98)$$

To complete the reformulation of the Boltzmann equation replacing the microscopic particle velocity,  $\mathbf{c}$ , with the peculiar velocity,  $\mathbf{c}$ , the collisional rate of change term has to be modified accordingly. The approximate collision operator formula proposed by Jenkins and Richman [69] is thus expressed as:

$$\begin{aligned} \int_{-\infty}^{\infty} \psi \left( \frac{\partial f}{\partial t} \right)_{\text{Collision}} d\mathbf{C} &= \frac{1}{2} \left( \int_{-\infty}^{\infty} \psi_1 \left( \frac{\partial f}{\partial t} \right)_{\text{Collision}} d\mathbf{C} + \int_{-\infty}^{\infty} \psi_2 \left( \frac{\partial f}{\partial t} \right)_{\text{Collision}} d\mathbf{C} \right) \\ &= \Omega(\psi) - \nabla \cdot \Phi(\psi) - \Phi(\nabla_C \psi) : \nabla \mathbf{v}_d \end{aligned} \quad (4.99)$$

In the derivation of this expression, several manipulations are made [117]. The chain rule is applied, and the integral operator and the derivative operator in (4.18) are commuted. The order in which these operations are performed can be inverted because the Taylor series expansion is written for a fixed point in space. The third term in (4.99) occurs after the peculiar velocity is introduced. The symbol  $\Phi$  corresponds to the tensor equivalent of  $\Psi$  valid for the particular case in which the argument is a vector, both calculated in accordance with (4.21).

By use of the transformation formulas (4.92)–(4.97) and (4.99), the equation of change for the average property  $\langle \psi \rangle_M$  can be deduced from the Boltzmann equation (4.1):

$$\begin{aligned} \frac{D}{Dt} (n \langle \psi \rangle_M) + n \langle \psi \rangle_M \nabla \cdot \mathbf{v}_d + \nabla \cdot n \langle \psi \mathbf{C} \rangle_M - n \langle \mathbf{F} \cdot \nabla_C \psi \rangle_M \\ - n \left\langle \frac{D\psi}{Dt} \right\rangle_M - n \langle \mathbf{C} \cdot \nabla \psi \rangle_M + n \frac{D\mathbf{v}_d}{Dt} \cdot \langle \nabla_C \psi \rangle_M \\ + n \langle \mathbf{C} \nabla_C \psi \rangle_M : \nabla \mathbf{v}_d = \Omega(\psi) - \nabla \cdot \Phi(\psi) - \Phi(\nabla_C \psi) : \nabla \mathbf{v}_d \end{aligned} \quad (4.100)$$

In the particular case in which  $\psi(\mathbf{C})$  is a function of the peculiar velocity only, the given relation reduces to:

$$\begin{aligned} & \frac{D}{Dt}(n\langle\psi\rangle_M) + n\langle\psi\rangle_M \nabla \cdot \mathbf{v}_d + \nabla \cdot n\langle\psi\mathbf{C}\rangle_M - n\langle\mathbf{F} \cdot \nabla_C \psi\rangle_M \\ & + n \frac{D\mathbf{v}_d}{Dt} \cdot \langle\nabla_C \psi\rangle_M + n\langle\mathbf{C} \nabla_C \psi\rangle_M : \nabla \mathbf{v}_d \\ & = \Omega(\psi) - \nabla \cdot \Phi(\psi) - \Phi(\nabla_C \psi) : \nabla \mathbf{v}_d \end{aligned} \quad (4.101)$$

By introducing the modified external force expression (4.66) into (4.101), the transport equation for the property  $\langle\psi\rangle_M$  can be re-written as:

$$\begin{aligned} & \frac{D}{Dt}(n\langle\psi\rangle_M) + n\langle\psi\rangle_M \nabla \cdot \mathbf{v}_d \\ & = -\nabla \cdot [n\langle\psi\mathbf{C}\rangle_M + \Phi(\psi)] \\ & \quad - [n\langle\mathbf{C} \nabla_C \psi\rangle_M + \Phi(\nabla_C \psi)] : \nabla \mathbf{v}_d \\ & \quad + n \left( \mathbf{F}_e + \frac{1}{\tau_{cd}} (\langle\mathbf{v}\rangle_{M,c} - \mathbf{v}_d) - \frac{D\mathbf{v}_d}{Dt} \right) \cdot \langle\nabla_C \psi\rangle_M \\ & \quad + n \left\langle \frac{1}{\tau_{cd}} (\mathbf{v}'_c - \mathbf{C}) \cdot \nabla_C \psi \right\rangle_M + \Omega(\psi) \end{aligned} \quad (4.102)$$

The corresponding peculiar velocity dependent flux term  $\Phi(\psi)$  is computed from a modified form of (4.26) and the corresponding source term  $\Omega(\psi)$  is calculated from a modified form of (4.28). The flux- and source term formulas are modified by exchanging the microscopic particle velocity  $\mathbf{c}$  with the peculiar velocity  $\mathbf{C}$  in accordance with the collisional operator definition (4.99). Further details on the derivation of the source and flux relations are given in Sect. 4.1.5.

#### 4.1.4.1 Balance Laws Derived From the Enskog Transport Equation

The derivation of the balance laws can be more convenient starting out from the Enskog's transport equation expressed in terms of  $\mathbf{C}$  instead of the Maxwell's transport equation expressed in terms of  $\mathbf{c}$ . By use of the chain rules for the distribution function, Chapman and Cowling [25] outlined the derivation in paragraph 3.11–3.13. The resulting Transport equation is representing a generalization of Maxwell's equation of transfer was referred to as the Enskog equation of change of  $\langle\psi\rangle_M$  in which  $\psi = \psi(\mathbf{r}, \mathbf{C}, t)$ . Hence, since (4.102) is formulated in terms of  $\mathbf{C}$ , we ambiguously call it the Enskog's Transport Equation to distinguish it from the basic form of the Maxwell's equation of transfer.

#### 4.1.4.2 The Mass Conservation Equation

The mass balance is obtained from (4.102) with  $\psi = m$ :

$$\frac{\partial}{\partial t}(\alpha_d \rho_d) + \nabla \cdot (\alpha_d \rho_d \mathbf{v}_d) = 0 \quad (4.103)$$

where  $\rho_d \alpha_d = nm$  is the local bulk density of the dispersed phase. All the terms like  $\Omega(m)$ ,  $\Phi(m)$  and  $\Phi(m)$  vanish because  $m$  is an invariant and constant quantity.

#### 4.1.4.3 The Momentum Equation

The momentum balance is obtained with  $\psi = m\mathbf{C}$  in (4.102):

$$\alpha_d \rho_d \frac{D\mathbf{v}_d}{Dt} = -\nabla \cdot (\mathbf{p}_d^{\text{kin}} + \mathbf{p}_d^{\text{coll}}) - \frac{\alpha_d \rho_d}{\tau_{cd}} (\mathbf{v}_d - \mathbf{v}_c) - \alpha_d \nabla p_d + \alpha_d \rho_d \mathbf{g} \quad (4.104)$$

where  $\mathbf{p}_d^{\text{kin}} = \alpha_d \rho_d \langle \mathbf{C}\mathbf{C} \rangle_M$  is the kinetic pressure tensor and  $\mathbf{p}_d^{\text{coll}} = \Phi(m\mathbf{C})$  is the collisional pressure tensor of the granular material as defined by (4.26). These terms represent the transport of momentum by particle velocity fluctuations and by particle collisions, respectively. At low particle fluid volume fractions the kinetic pressure tensor dominates since the particles travels relatively long distances between collisions. The collisional pressure tensor dominates at high particle phase volume fractions because the particle collisions are frequent. The term  $\Omega(m\mathbf{C})$  defined by (4.28) becomes zero because  $m\mathbf{C}$  is an invariant quantity according to (4.57).

The local instantaneous pressure of the continuous phase,  $p_c$ , might be decomposed as the sum of a mean pressure  $\bar{p}_c$  and a pressure fluctuation  $p'_c$ . However, the pressure covariance terms are normally neglected in gas–solid flows [9].

#### 4.1.4.4 The Granular Temperature (Microscopic Specific Kinetic Energy)

A transport equation for the granular temperature is obtained with  $\psi = \frac{1}{2}mC^2$  in (4.102):

$$\begin{aligned} \frac{3}{2} \left( \frac{\partial}{\partial t} (\alpha_d \rho_d \theta) + \nabla \cdot (\alpha_d \rho_d \theta \mathbf{v}_d) \right) &= -\nabla \cdot (\mathbf{q}_d^{\text{kin}} + \mathbf{q}_d^{\text{coll}}) \\ &\quad - (\mathbf{p}_d^{\text{kin}} + \mathbf{p}_d^{\text{coll}}) : \nabla \mathbf{v}_d - \frac{\alpha_d \rho_d}{\tau_{cd}} (3\theta - \langle \mathbf{v}'_c \cdot \mathbf{C} \rangle_M) - \gamma \end{aligned} \quad (4.105)$$

The physical interpretations of the terms in (4.105) can be outlined as follows. The terms on the LHS denotes the time dependent term and the convective term. The first two terms on the RHS represent the transport of energy by particle velocity fluctuations and by particle collisions, respectively. The term  $\mathbf{q}_d^{\text{kin}} = \frac{1}{2} \alpha_d \rho_d \langle \mathbf{C}\mathbf{C}^2 \rangle_M$  denotes the kinetic heat flux and  $\mathbf{q}_d^{\text{coll}} = \Phi(\frac{1}{2}mC^2)$  represents the collisional heat flux. The third and fourth terms represent production of energy by the mean velocity gradient. The fifth and sixth terms represent the different interactions with the continuous phase. The fifth term denotes a dissipation term due to the drag force ( $3\theta$ ), and the sixth term denotes production due to the interaction with the fluid turbulence ( $\langle \mathbf{v}'_c \cdot \mathbf{C} \rangle_M$ ). The last term  $\Omega(\frac{1}{2}mC^2) = -\gamma$  represents the energy dissipation due to collisions.

The details on the derivation of the source and flux relations are discussed in Sect. 4.1.5. The main advantage of expressing the generalized transport equation, and the fluxes and sources in terms of the peculiar particle velocity instead of the microscopic particle velocity is that the derivation of the granular temperature equation becomes simpler. That is, the macroscopic translational kinetic energy equation is not included in the model derivation.

A dissension is observed in the literature concerning whether the granular fluid translational energy is representing a local fluid property or a continuum flow phenomenon. In one view it is noted that the properties reflected by the granular temperature  $\theta$  are quite different from those of the thermal temperature  $T$ . The granular temperature is not representing a noticeable sensible heat because the magnitude of the translational energy ( $\frac{1}{2}mC^2$ ) of granular flows is similar to the average translational kinetic energy ( $\frac{1}{2}m\mathbf{v}_d^2$ ). For comparison, in a gas the peculiar velocity of the molecules are much larger than the average gas velocity, i.e.,  $\mathbf{C}_g \gg \mathbf{v}_g$ . However, the translational energy associated with a granular material is assumed characterized by scales comparable to the particle size being considerable smaller than the microscopic length scales of the flow. Therefore, the particle fluctuations in granular flows is considered a local fluid property [93]. In this interpretation the granular temperature must not be confused with the turbulent kinetic energy which is a continuum flow phenomenon. In a second view, the particles are assumed to be characterized by scales comparable to the macroscopic length scales of the flow, thus the granular temperature is associated with the turbulent kinetic energy which is a continuum fluid flow phenomenon [29, 36, 37, 49, 117].

### 4.1.5 Granular Transport Coefficient, Source and Flux Closures

In this section the transport coefficients and flux closures derived by Ding and Gidaspow [30] and Gidaspow [49] are defined. For further details on the Enskog dense gas approach and the Chapman-Enskog approximate solution method the interested reader is referred to the original literature presented in Chap. 2, and in particular to the books of Gidaspow [49] and Chapman and Cowling [25], Sects. 7 and 16. The granular material closures presented in this section lead to a typical, or even the standard reference, dense phase model used for simulating fluidized bed reactor flows.

#### 4.1.5.1 The Kinetic Pressure Tensor

The kinetic pressure tensor represents the momentum transfer due to the free translational motions of the solid particles between particle collisions. The pressure tensor closure is derived by use of the same modeling concepts and approximate solution method as employed in the kinetic theory of dilute gases. The kinetic pressure tensor

is thus one out of the two pressure tensor components that is calculated by use of the KTGF.

By use of the Chapman-Enskog approximate solution method [25], the granular fluid kinetic pressure tensor can thus be approximated as [49]:

$$\begin{aligned} p_d^{\text{kin}} &= \alpha_d \rho_d \langle \mathbf{CC} \rangle_M = \alpha_d \rho_d \int \mathbf{CC} f d\mathbf{C} = \alpha_d \rho_d \int \mathbf{CC} f^0 (1 + \Phi) d\mathbf{C} \\ &= \alpha_d \rho_d \langle \mathbf{CC} \rangle_M^{(0)} + \alpha_d \rho_d \langle \mathbf{CC} \rangle_M^{(1)} = \alpha_d \rho_d \theta \mathbf{e} + \alpha_d \boldsymbol{\sigma}_d^{\text{kin}} \\ &= p_d^{\text{kin}} \mathbf{e} + \alpha_d \boldsymbol{\sigma}_d^{\text{kin}} \end{aligned} \quad (4.106)$$

The kinetic pressure is defined as:

$$p_d^{\text{kin}} = \alpha_d \rho_d \langle \mathbf{CC} \rangle_M^{(0)} = \alpha_d \rho_d \theta \quad (4.107)$$

The  $\boldsymbol{\sigma}_d^{\text{kin}} = \rho_d \langle \mathbf{CC} \rangle_M^{(1)}$  denotes the deviatoric pressure tensor defined by:

$$\boldsymbol{\sigma}_d^{\text{kin}} = -2\mu_d^{\text{kin}} \mathbf{S}_d = -\frac{2\mu_d^{\text{dilute}}}{\alpha_d \frac{1}{2} (1+e) g_0(\alpha_d)} \left( 1 + \frac{4}{5} \alpha_d g_0(\alpha_d) (1+e) \right) \mathbf{S}_d \quad (4.108)$$

for  $e$  near unity.

The kinetic viscosity is thus defined as:

$$\mu_d^{\text{kin}} = \frac{2\mu_d^{\text{dilute}}}{\alpha_d (1+e) g_0(\alpha_d)} \left( 1 + \frac{4}{5} \alpha_d g_0(\alpha_d) (1+e) \right) \quad (4.109)$$

The  $\mathbf{S}_d$  denotes the *rate of shear tensor* given by:

$$\mathbf{S}_d = \frac{1}{2} \left( \nabla \mathbf{v}_d + (\nabla \mathbf{v}_d)^T \right) - \frac{1}{3} (\nabla \mathbf{v}_d : \mathbf{e}) \mathbf{e} \quad (4.110)$$

This pressure tensor closure (4.106) was derived by Gidaspow [49] in analogy with the Enskog dense gas theory presented by Chapman and Cowling [25], Chap. 16. That is, with the restitution coefficient,  $e$ , equal to one, (4.108) corresponds to the Chapman and Cowling's [25] Eq. (16.34–2), where the  $\chi$  factor used for dense gases is substituted by  $\frac{1}{2} g_0(\alpha_d) (1+e)$  for solid particles, and  $b\rho = 4\alpha_d$ .

In the dilute gas Chapman-Enskog expansion the perturbation function,  $\Phi$ , is approximated by the trail function (4.111), corresponding to Eq. (7.31,7) in Chapman and Cowling [25]. For dense gases the perturbation function  $\Phi$  differs from the corresponding trail function (4.111) for a dilute gas only in the term involving  $\nabla \mathbf{v}$  is multiplied by  $(1 + \frac{2}{5} b\rho\chi)/\chi$ , and that involving  $\nabla \ln T$  by  $(1 + \frac{3}{5} b\rho\chi)/\chi$ . In analogy to the perturbation function for dense gas, Gidaspow [49] derived an expression for the perturbation function for solid particles on the same form:

$$\Phi = -\frac{1}{n}\mathbf{A} \cdot \nabla \ln \theta - \frac{1}{n}\mathbf{B} : \nabla \mathbf{v} + \alpha \psi \quad (4.111)$$

where  $\mathbf{A} = A(\mathbf{C})\mathbf{C}$ ,  $\mathbf{B} : \nabla \mathbf{v} = B(\mathbf{C})\mathbf{CC} : \mathbf{S}_d$  and  $\alpha = 0$ . The functions  $A(\mathbf{C})$  and  $B(\mathbf{C})$  are determined in terms of polynomials [25].

The perturbation function,  $\Phi$ , can be expressed as [49]:

$$\Phi = -\frac{1}{n}A(\mathbf{C})\mathbf{C} \cdot \nabla \ln \theta - \frac{1}{n}B(\mathbf{C})\mathbf{CC} : \mathbf{S}_d \quad (4.112)$$

The limiting viscosity for the dilute regime can be approximated from the dilute mono atomic gas relation (2.620) by converting the molecular temperature (2.200) to the granular temperature (4.70). The result is [49]:

$$\mu_d^{\text{dilute}} = \frac{5}{96}\rho_d d_{12}\sqrt{\pi\theta} \quad (4.113)$$

Except for the adaption to granular temperature, this relation coincides with the dilute mono-atomic gas viscosity closure given by the bracket integral (7.41-1) and the first approximation (10.21,1) in Chapman and Cowling [25].

Using the given relation for  $\mu_d^{\text{dilute}}$  Laux [93] (Sect. 2.3.2) experienced numerical problems in regions of very dilute flow. The numerical problems were connected with the non-zero dilute viscosity obtained when  $\alpha_d \rightarrow 0$ . These problems were avoided introducing a modified semi-empirical expression for  $\mu_d^{\text{dilute}}$ . The modified dilute viscosity was defined by [93]:

$$\mu_d^{\text{dilute}} = \frac{30\sqrt{2}}{96}\rho_d \alpha_d \min |l_p, l_d^{\text{max}}| \sqrt{\pi\theta} \quad (4.114)$$

This relation for  $\mu_d^{\text{dilute}}$  becomes zero when  $\alpha_d < \alpha_d^{\text{min}}$ .

The modified dilute viscosity is approximated based on the relation  $\mu_d^{\text{dilute}} \propto \rho_B^d l_p \sqrt{\theta}$ . The bulk density is proportional to  $\alpha_d$ , whereas the mean free path  $l_p$  is inversely proportional to  $\alpha_d$ . A typical value,  $\alpha_{d,\text{min}} = 1 \times 10^{-5}$ , was used to limit the mean free path in an unconfined flow. The limit  $l_d^{\text{max}}$  was thus either given as a characteristic dimension of the flow geometry, or calculated from  $\alpha_{d,\text{min}}$  as  $l_d^{\text{max}} = \frac{1}{6\sqrt{2}} \frac{d_{12}}{\alpha_{d,\text{min}}}$ .

#### 4.1.5.2 The Collisional Pressure Tensor

The collisional pressure tensor represents the instantaneous momentum transfer at binary particle collisions, over the distance separating the centers of the two colliding particles. The pressure tensor closure is derived based on an extension of the kinetic theory of dense gases. The collisional pressure tensor is thus the second out of the two pressure tensor components that is calculated by use of the KTGF.

Following the Enskog [38] dense gas approach as described by Chapman and Cowling [25] Chap. 16.4, the collisional momentum flux is defined in accordance with (4.26):

$$\begin{aligned} \Phi(m\mathbf{c}) \approx & -\frac{d_{12}^3}{2} g_0(\alpha_d) m \int_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} (\mathbf{c}'_1 - \mathbf{c}_1) \mathbf{k} f_1^{(1)}(\mathbf{r}, \mathbf{c}_1, t) f_2^{(1)}(\mathbf{r}, \mathbf{c}_2, t) d\mathbf{z} \\ & - \frac{d_{12}^4}{4} g_0(\alpha_d) m \int_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} (\mathbf{c}'_1 - \mathbf{c}_1) \mathbf{k} f_1^{(1)}(\mathbf{r}, \mathbf{c}_1, t) f_2^{(1)}(\mathbf{r}, \mathbf{c}_2, t) \mathbf{k} \cdot \nabla \ln \frac{f_2^{(1)}}{f_1^{(1)}} d\mathbf{z} \end{aligned} \quad (4.115)$$

in which the set of integration variables is defined as  $d\mathbf{z} = (\mathbf{g}_{21} \cdot \mathbf{k}) d\mathbf{k} d\mathbf{c}_1 d\mathbf{c}_2$ .

By use of (4.50), the sum of the two integrals in (4.115) can be manipulated as:

$$\begin{aligned} \frac{\Phi(m\mathbf{c})}{\frac{d_{12}^3}{4} g_0(\alpha_d) m (1+e)} \approx & \int_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} (\mathbf{k} \cdot \mathbf{g}_{12}) \mathbf{k} \mathbf{k} f_1^{(1)}(\mathbf{r}, \mathbf{c}_1, t) f_2^{(1)}(\mathbf{r}, \mathbf{c}_2, t) d\mathbf{z} \\ & + \frac{d_{12}}{2} \int_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} (\mathbf{k} \cdot \mathbf{g}_{12}) \mathbf{k} \mathbf{k} f_1^{(1)}(\mathbf{r}, \mathbf{c}_1, t) f_2^{(1)}(\mathbf{r}, \mathbf{c}_2, t) \mathbf{k} \cdot \nabla \ln \frac{f_2^{(1)}}{f_1^{(1)}} d\mathbf{z} \end{aligned} \quad (4.116)$$

Hence, a closure for the collisional pressure tensor,  $\mathbf{p}_d^{\text{coll}}$ , can be derived from the collisional momentum flux,  $\Phi(m\mathbf{c})$ , and expressed on the form:

$$\mathbf{p}_d^{\text{coll}} = \mathbf{p}_d^{\text{coll},1} + \mathbf{p}_d^{\text{coll},2} = p_d^{\text{coll},1} \mathbf{e} + \alpha_d (\boldsymbol{\sigma}_d^{\text{coll},1} + \boldsymbol{\sigma}_d^{\text{coll},2}) = \Phi(m\mathbf{c}) \quad (4.117)$$

The two integral terms in (4.116) give rise to two pressure tensors defined as:

$$\begin{aligned} \mathbf{p}_d^{\text{coll},1} &= p_d^{\text{coll},1} \mathbf{e} + \alpha_d \boldsymbol{\sigma}_d^{\text{coll},1} \\ &\approx \frac{d_{12}^3}{4} g_0(\alpha_d) m (1+e) \int_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} (\mathbf{k} \cdot \mathbf{g}_{12}) \mathbf{k} \mathbf{k} f_1^{(1)}(\mathbf{r}, \mathbf{c}_1, t) f_2^{(1)}(\mathbf{r}, \mathbf{c}_2, t) d\mathbf{z} \end{aligned} \quad (4.118)$$

$$\begin{aligned} \mathbf{p}_d^{\text{coll},2} &= \alpha_d \boldsymbol{\sigma}_d^{\text{coll},2} = \frac{d_{12}^4}{8} g_0(\alpha_d) m (1+e) \times \\ &\quad \int_{\mathbf{g}_{21} \cdot \mathbf{k} > 0} (\mathbf{k} \cdot \mathbf{g}_{12}) \mathbf{k} \mathbf{k} f_1^{(1)}(\mathbf{r}, \mathbf{c}_1, t) f_2^{(1)}(\mathbf{r}, \mathbf{c}_2, t) \mathbf{k} \cdot \nabla \ln \frac{f_2^{(1)}}{f_1^{(1)}} d\mathbf{z} \end{aligned} \quad (4.119)$$

To evaluate the first collisional integral (E.2) for  $\mathbf{p}_d^{\text{coll},1}$ , the integration with respect to  $\mathbf{k}$  can be carried out with integral theorem (E.2), given in App E. The result is:

$$\mathbf{p}_d^{\text{coll},1} = \frac{\pi}{30} (1+e) d_{12}^3 g_0(\alpha_d) m \int \int f_1^{(1)} f_2^{(1)} (2\mathbf{g}_{12} \mathbf{g}_{12} + g_{12}^2 \mathbf{e}) d\mathbf{c}_1 d\mathbf{c}_2 \quad (4.120)$$

Moreover, from the definition of the mean of a function  $\psi$ , the following relations are obtained:

$$\int f_1^{(1)} \psi d\mathbf{c}_1 = \int f_2^{(1)} \psi d\mathbf{c}_2 = n \langle \psi \rangle_M \quad (4.121)$$

It is noted that the average of the peculiar velocity is zero. Thus, by assuming equilibrium flow for which  $\mathbf{v} = 0$ , the first part of the remaining integral in (4.120) reduces to:

$$\begin{aligned} & 2 \int \int f_1^{(1)} f_2^{(1)} \mathbf{g}_{12} \mathbf{g}_{12} d\mathbf{c}_1 d\mathbf{c}_2 \\ &= 2n^2 \langle \langle \mathbf{C}_1 \mathbf{C}_1 \rangle_M \rangle_M - 4n^2 \langle \mathbf{C}_1 \rangle_M \langle \mathbf{C}_2 \rangle_M + 2n^2 \langle \langle \mathbf{C}_2 \mathbf{C}_2 \rangle_M \rangle_M = 4n^2 \langle \mathbf{C} \mathbf{C} \rangle_M \end{aligned} \quad (4.122)$$

The second part of the integral in (4.120) can be evaluated as:

$$\int \int f_1^{(1)} f_2^{(1)} g_{12}^2 \mathbf{e} d\mathbf{c}_1 d\mathbf{c}_2 = n^2 \langle \langle g_{12}^2 \rangle_M \rangle_M \mathbf{e} = 2n^2 \langle C^2 \rangle_M \mathbf{e} \quad (4.123)$$

Thus, by substitution of the integral approximations, (4.120) becomes:

$$\mathbf{p}_d^{\text{coll},1} = \frac{\pi}{15} (1 + e) m d_{12}^3 g_0(\alpha_d) n^2 (2 \langle \mathbf{C} \mathbf{C} \rangle_M + \langle C^2 \rangle_M \mathbf{e}) \quad (4.124)$$

By use of the Chapman-Enskog approximate solution method [25], the first collisional pressure tensor part,  $\mathbf{p}_d^{\text{coll},1}$ , can be written as:

$$\begin{aligned} \mathbf{p}_d^{\text{coll},1} &= \frac{2}{5} \alpha_d^2 \rho_d g_0(\alpha_d) (1 + e) (2 \langle \mathbf{C} \mathbf{C} \rangle_M + \langle C^2 \rangle_M \mathbf{e}) \\ &\approx \frac{2}{5} \alpha_d^2 \rho_d g_0(\alpha_d) (1 + e) (2 \langle \mathbf{C} \mathbf{C} \rangle_M^{(0)} + 2 \langle \mathbf{C} \mathbf{C} \rangle_M^{(1)} + \langle C^2 \rangle_M \mathbf{e}) \\ &\approx 2 \alpha_d^2 \rho_d g_0(\alpha_d) (1 + e) \theta \mathbf{e} - \frac{2}{(1 + e) g_0(\alpha_d)} \\ &\quad \times \left( 1 + \frac{4}{5} \alpha_d g_0(\alpha_d) (1 + e) \right) \frac{4}{5} \alpha_d^2 \rho_d g_0(\alpha_d) (1 + e) 2 \mu_d^{\text{dilute}} \mathbf{S}_d \end{aligned} \quad (4.125)$$

The granular temperature is defined by (4.70), and the volume fraction is related to the particle number density by:

$$\alpha_d = n \times \frac{\pi}{6} d_{12}^3 \quad (4.126)$$

It is further recognized that the first term in the resulting formula for  $\mathbf{p}_d^{\text{coll},1}$  contains the collisional pressure determined by the Maxwellian distribution, defined by:

$$\begin{aligned}
 p_d^{\text{coll},1} \mathbf{e} &= \frac{2}{5} \alpha_d^2 \rho_d g_0(\alpha_d) (1+e) (2 \langle \mathbf{CC} \rangle_M^{(0)} + \langle C^2 \rangle_M \mathbf{e}) \\
 &= 2 \alpha_d^2 \rho_d g_0(\alpha_d) (1+e) \theta \mathbf{e}
 \end{aligned} \tag{4.127}$$

where the relationship  $\langle \mathbf{CC} \rangle_M^{(0)} = \theta \mathbf{e}$  is obtained from (4.107).

For a non-Maxwellian distribution, the  $\langle \mathbf{CC} \rangle_M^{(1)}$  term can be approximated by the Chapman-Enskog solution of the Boltzmann equation as presented in detail in Chap. 16 in Chapman and Cowling [25]. The same approach was adapted for solid particles by Gidaspow [49]. The result is:

$$\alpha_d \sigma_d^{\text{coll},1} = -2 \alpha_d \mu_d^{\text{coll},1} = \frac{2}{5} \alpha_d g_0(\alpha_d) (1+e) (2 \alpha_d \rho_d \langle \mathbf{CC} \rangle_M^{(1)}) \tag{4.128}$$

where

$$\alpha_d \rho_d \langle \mathbf{CC} \rangle_M^{(1)} = -\frac{2}{(1+e)g_0(\alpha_d)} \left( 1 + \frac{4}{5} \alpha_d g_0(\alpha_d) (1+e) \right) 2 \mu_d^{\text{dilute}} \mathbf{S}_d \tag{4.129}$$

These two relations may be combined giving an estimate of the first part of the collisional viscosity:

$$\mu_d^{\text{coll},1} = \frac{8}{5} \mu_d^{\text{dilute}} \left( 1 + \frac{4}{5} \alpha_d g_0(\alpha_d) (1+e) \right) \tag{4.130}$$

Employing the concepts presented by Chapman and Cowling [25] Chap. 16.4, an expression for  $\mathbf{p}^{\text{coll},2}$ , as defined by (4.119), is obtained by using integral theorem (E.5) in App E:

$$\begin{aligned}
 \mathbf{p}_d^{\text{coll},2} &\approx \frac{d_{12}^4 \pi}{96} g_0(\alpha_d) m (1+e) \\
 &\times \int \int f_1^{(0)} f_2^{(0)} \left[ \nabla \ln \frac{f_2^{(0)}}{f_1^{(0)}} \cdot \mathbf{g}_{12} (\mathbf{g}_{12} \mathbf{g}_{12} + g_{12}^2 \mathbf{e}) / g_{12} \right. \\
 &\quad \left. + g_{12} \left( \mathbf{g}_{12} \nabla \ln \frac{f_2^{(0)}}{f_1^{(0)}} + \nabla \ln \frac{f_2^{(0)}}{f_1^{(0)}} \mathbf{g}_{12} \right) \right] d\mathbf{c}_1 d\mathbf{c}_2
 \end{aligned} \tag{4.131}$$

Moreover, by assuming equilibrium flow the Maxwellian distribution can be used to simplify the derivation, thus [49]:

$$\ln \frac{f_2^{(0)}}{f_1^{(0)}} = \frac{1}{2\theta} (C_2^2 - C_1^2) \tag{4.132}$$

$$\nabla \ln \frac{f_2^{(0)}}{f_1^{(0)}} = -\frac{1}{2\theta} (C_2^2 - C_1^2) \nabla \theta + \frac{1}{\theta} \nabla \mathbf{v} \cdot (\mathbf{C}_2 - \mathbf{C}_1) \tag{4.133}$$

Considering the integral in (4.131), the first two terms in (4.133) involving  $\nabla\theta$  vanish in integration since they are odd functions of  $\mathbf{C}$ . The integral in (4.131) can then be manipulated as:

$$\begin{aligned}
 \mathbf{p}_d^{\text{coll},2} &\approx -\frac{d_{12}^4\pi}{96\theta}g_0(\alpha_d)m(1+e) \\
 &\quad \times \int \int f_1^{(0)}f_2^{(0)} \left[ (\nabla\mathbf{v} \cdot \mathbf{g}_{12}) \cdot \mathbf{g}_{12}(\mathbf{g}_{12}\mathbf{g}_{12} + g_{12}^2\mathbf{e})/g_{12} \right. \\
 &\quad \left. + g_{12}((\nabla\mathbf{v} \cdot \mathbf{g}_{12})\mathbf{g}_{12} + \mathbf{g}_{12}(\nabla\mathbf{v} \cdot \mathbf{g}_{12})) \right] d\mathbf{c}_1 d\mathbf{c}_2 \\
 &\approx -\frac{d_{12}^4\pi}{96\theta}g_0(\alpha_d)m(1+e) \\
 &\quad \times \int \int f_1^{(0)}f_2^{(0)} \left[ \nabla\mathbf{v} : \mathbf{g}_{12}\mathbf{g}_{12}(\mathbf{g}_{12}\mathbf{g}_{12} + g_{12}^2\mathbf{e})/g_{12} \right. \\
 &\quad \left. + g_{12}((\nabla\mathbf{v} \cdot \mathbf{g}_{12})\mathbf{g}_{12} + \mathbf{g}_{12}(\nabla\mathbf{v} \cdot \mathbf{g}_{12})) \right] d\mathbf{c}_1 d\mathbf{c}_2
 \end{aligned} \tag{4.134}$$

where  $\nabla\mathbf{v} : \mathbf{g}_{12}\mathbf{g}_{12} = -\mathbf{g}_{12} \cdot (\nabla\mathbf{v} \cdot \mathbf{g}_{12}) + \mathbf{g}_{12} \cdot \nabla\mathbf{v} \cdot \mathbf{g}_{12} = \mathbf{g}_{12} \cdot \nabla\mathbf{v} \cdot \mathbf{g}_{12}$  [25, 49].

To evaluate the integrals in relation (4.134) for  $\mathbf{p}^{\text{coll},2}$ , Gidaspow [49] did transform the variables  $\mathbf{c}_1, \mathbf{c}_2$  to  $\mathbf{g}_{12}, \mathbf{G}$  by use of (2.113) following the same procedures as outlined by Chapman and Cowling [25] for dense gases. The microscopic particle velocities are thus expressed in terms of the velocity of the center of mass,  $\mathbf{G}$ , as:

$$\mathbf{c}_1 = \mathbf{G} + \left(\frac{m_2}{m_c}\right)\mathbf{g}_{12} \tag{4.135}$$

$$\mathbf{c}_2 = \mathbf{G} - \left(\frac{m_1}{m_c}\right)\mathbf{g}_{12} \tag{4.136}$$

Following the concepts outlined by Chapman and Cowling [25], it can be seen that the Jacobian determinant of transformation using (4.135) is:

$$\begin{aligned}
 J &= \det \left( \frac{\partial(\mathbf{G}, \mathbf{g}_{12})}{\partial(\mathbf{c}_1, \mathbf{c}_2)} \right) = \det \left( \frac{\partial(\mathbf{c}_1 + m_2/m_c \mathbf{g}_{12}, \mathbf{c}_2 - \mathbf{c}_1)}{\partial(\mathbf{c}_1, \mathbf{c}_2)} \right) \\
 &= \det \left( \frac{\partial(\mathbf{c}_1, \mathbf{c}_2)}{\partial(\mathbf{c}_1, \mathbf{c}_2)} \right) = 1
 \end{aligned} \tag{4.137}$$

Due to spherical symmetry, the  $d\mathbf{c}_1, d\mathbf{c}_2$  were replaced by  $d\mathbf{g}_{12}, d\mathbf{G}$  to simplify the integration. Moreover, the  $d\mathbf{g}_{12}, d\mathbf{G}$  were related to the corresponding speeds as [49]:

$$d\mathbf{G} = 4\pi G^2 dG \tag{4.138}$$

$$d\mathbf{g}_{12} = 4\pi g_{12}^2 dg_{12} \tag{4.139}$$

Then, by use of (4.24) and (4.40) it is recognized that the approximation of  $f^{(2)}$  in the integration term in  $\mathbf{p}^{\text{coll},2}$  can be written as:

$$\begin{aligned} f^{(2)} &\approx g_0(\alpha_d) f_1^{(1)} f_2^{(1)} \approx g_0(\alpha_d) f_1^{(0)} f_2^{(0)} \\ &\approx g_0(\alpha_d) \frac{n_1 n_2}{(2\pi\theta)^3} \exp \left[ -\frac{(\mathbf{c}_1 - \mathbf{v})^2 + (\mathbf{c}_2 - \mathbf{v})^2}{2\theta} \right] \\ &\approx g_0(\alpha_d) \frac{n_1 n_2}{(2\pi\theta)^3} \exp \left[ -\frac{2G^2 + \frac{1}{2}g_{12}^2}{2\theta} \right] \end{aligned} \quad (4.140)$$

because for equilibrium flow,  $\mathbf{v}$  is zero.

It follows that the last relation for  $\mathbf{p}^{\text{coll},2}$ , in (4.134), can be expressed as:

$$\begin{aligned} \mathbf{p}_d^{\text{coll},2} &\approx -\frac{d_{12}^4}{768\theta^4\pi^2} g_0(\alpha_d) m(1+e)n_1 n_2 \times \\ &\int \int \exp \left[ -\frac{2G^2}{2\theta} \right] d\mathbf{G} \left[ \nabla \mathbf{v} : \mathbf{g}_{12} \mathbf{g}_{12} (\mathbf{g}_{12} \mathbf{g}_{12} + g_{12}^2 \mathbf{e}) / g_{12} \right. \\ &\quad \left. + g_{12} ((\nabla \mathbf{v} \cdot \mathbf{g}_{12}) \mathbf{g}_{12} + \mathbf{g}_{12} (\nabla \mathbf{v} \cdot \mathbf{g}_{12})) \right] \exp \left[ -\frac{\frac{1}{2}g_{12}^2}{2\theta} \right] d\mathbf{g}_{12} \end{aligned} \quad (4.141)$$

Using (E.6), the integral over  $G$  can be evaluated as:

$$4\pi \int_0^\infty G^2 \exp \left[ -\frac{G^2}{\theta} \right] dG = (\pi\theta)^{3/2} \quad (4.142)$$

Formula (E.6b) with  $r = 5$  produces an estimation of the remaining term in this integral relation considering the term containing  $\nabla \mathbf{v}$  only [25, 30, 49]:

$$4\pi \int_0^\infty g_{12}^5 \exp \left[ -\frac{\frac{1}{2}g_{12}^2}{2\theta} \right] dg_{12} = 4\pi \frac{1}{2} \left( \frac{1}{4\theta} \right)^{-3} 2 = 4\pi (4\theta)^3 \quad (4.143)$$

A typical magnitude for the terms in this integral relation was thus approximated as:

$$\mathbf{p}_d^{\text{coll},2} \propto -\frac{\sqrt{\pi}}{3} g_0(\alpha_d) d_{12}^4 m(1+e)n_1 n_1 \theta^{1/2} \quad (4.144)$$

Ding and Gidaspow [30] used the approaches of Chapman and Cowling [25] Chap. 16.41, and proposed that the  $\mathbf{p}_d^{\text{coll},2}$  should involve the traceless gradient of  $\mathbf{v}$ . The  $\mathbf{p}_d^{\text{coll},2}$  term was thus expressed as:

$$\begin{aligned}
p_d^{\text{coll},2} &= -\frac{4}{3\sqrt{\pi}}\rho_d\alpha_d^2d_{12}g_0(\alpha_d)(1+e)\sqrt{\theta}\left(\frac{6}{5}\mathbf{S}_d + (\nabla \cdot \mathbf{v}_d)\mathbf{e}\right) \\
&= \alpha_d\sigma_d^{\text{coll},2} - \alpha_d\mu_{B,d}^{\text{coll},2}(\nabla \cdot \mathbf{v}_d)\mathbf{e}
\end{aligned} \tag{4.145}$$

The normal component of the collisional deviatoric pressure tensor contains a viscosity that resembles the bulk viscosity term and is thus denoted by  $\mu_{B,d}$ :

$$\mu_{B,d}^{\text{coll},2} = \frac{4}{3}\alpha_d\rho_dd_{12}g_0(\alpha_d)(1+e)\sqrt{\frac{\theta}{\pi}} \tag{4.146}$$

The second part of the collisional deviatoric pressure tensor,  $\sigma_d^{\text{coll},2}$ , is represented by:

$$\alpha_d\sigma_d^{\text{coll},2} = -2\alpha_d\mu_d^{\text{coll},2}\mathbf{S}_d = -\left(\frac{8}{5\sqrt{\pi}}\rho_d\alpha_d^2d_{12}g_0(\alpha_d)(1+e)\sqrt{\theta}\right)\mathbf{S}_d \tag{4.147}$$

The second collisional contribution to the granular viscosity is given by:

$$\mu_d^{\text{coll},2} = \frac{4}{3}\rho_d\alpha_dd_{12}g_0(\alpha_d)(1+e)\sqrt{\frac{\theta}{\pi}} \tag{4.148}$$

The overall collisional deviatoric pressure tensor consists of the viscous terms  $\sigma_d^{\text{coll}} = \sigma_d^{\text{coll},1} + \sigma_d^{\text{coll},2}$  and is thus given by:

$$\begin{aligned}
\sigma_d^{\text{coll}} &= -\frac{16}{5}\mu_d^{\text{dilute}}\left(1 + \frac{4}{5}\alpha_dg_0(\alpha_d)(1+e)\right)\mathbf{S}_d \\
&\quad - \frac{4}{5\sqrt{\pi}}\rho_d\alpha_dd_{12}g_0(\alpha_d)(1+e)\sqrt{\theta}\left(\frac{6}{5}\mathbf{S}_d + (\nabla \cdot \mathbf{v}_d)\mathbf{e}\right).
\end{aligned} \tag{4.149}$$

#### 4.1.5.3 The Frictional Pressure Tensor

It is generally assumed that the KTGF can be applied for granular flows in the *rapid-flow regime* which is sufficiently dilute so that the interparticle collisions can be assumed instantaneous and binary. However, in denser regimes in which the dispersed volume fraction approaches that of maximum packing, the behavior of the granular fluid is dominated by enduring frictional contacts of multiple neighboring particles. In this so-called *quasi-static flow regime*, the underlying assumptions of the KTGF are frequently violated and the theory thus often fails to predict the correct behavior of the multiple particle mixture system. It is thus recognized that in order to overcome these model limitations, a frictional pressure tensor has to be taken into account. Several closures for the frictional pressure tensor of dense particle dispersions,  $p_d^{\text{fric}}$ , have been proposed. Most of these closure models are derived based on the *critical*

*state theory* of solid mechanics [130, 141]. The extended total granular fluid pressure tensor is thus composed of three components as follows:

$$\mathbf{p}_d = \mathbf{p}_d^{\text{kin}} + \mathbf{p}_d^{\text{coll}} + \mathbf{p}_d^{\text{fric}} \quad (4.150)$$

In particular, for dense flows at low shear rates, in which the impact of the long term particle-particle interactions such as sliding or rolling contacts are important, the total solid phase pressure tensor closure is generally extended by a frictional stress contribution. The frictional stress generation mechanism contributes to enlarged energy dissipation. It is noted that the momentum flux closure derived from the kinetic theory of granular flows considers only the contributions from particle translation and short term particle-particle interactions. The semi-empirical frictional pressure tensor closure proposed by Srivastava and Sundaresan [141] is frequently adopted to take these effects into account. Srivastava and Sundaresan [141] considered that the total pressure tensor might be determined as a linear sum of the independent kinetic, collisional, and frictional pressure tensor components. The extended particle pressure and viscosity properties were thus calculated as:

$$p_d = p_d^{\text{kin}} + p_d^{\text{coll}} + p_d^{\text{fric}} \quad (4.151)$$

$$\mu_d = \mu_d^{\text{kin}} + \mu_d^{\text{coll}} + \mu_d^{\text{fric}} \quad (4.152)$$

This model was supposed to capture the two extreme limits of granular flow, which are designating the rapid shear and quasi-static flow regimes. In the rapid shear flow regime, the kinetic pressure tensor component dominates, whereas in the quasi-static flow regime the frictional pressure tensor component dominates [141]. The frictional pressure tensor closure derived by Srivastava and Sundaresan [141] is based on the critical state theory from soil mechanics. Moreover, it was assumed that the granular material is non-cohesive and has a rigid-plastic rheological behavior. At the critical state the granular assembly deforms without volume change,  $\nabla \cdot \mathbf{v}_d = 0$ , and the frictional pressure tensor equals the critical state frictional pressure tensor. This particular frictional pressure tensor closure, which is valid only at the critical state, is often used as a simple representation of these frictional phenomena even when  $\nabla \cdot \mathbf{v}_d \neq 0$ . Notwithstanding, this simple semi-empirical frictional pressure tensor closure might still be adequate for stabilizing the bubbling fluidized bed simulations and providing reasonable flow predictions.

The critical state pressure is given by [76]:

$$p_d^{\text{crit}} = \begin{cases} \zeta \frac{(\alpha_d - \alpha_d^{\min})^r}{(\alpha_d^{\max} - \alpha_d)^s} & \text{if } \alpha_d > \alpha_d^{\min} \\ 0 & \text{if } \alpha_d \leq \alpha_d^{\min} \end{cases} \quad (4.153)$$

where  $\zeta$ ,  $r$  and  $s$  are empirical constants. The model asserts that the frictional interactions do not occur for particle volume fractions less than  $\alpha_d^{\min}$ .

At the critical state, the solids frictional viscosity is given by:

**Table 4.1** Empirical parameters for the frictional pressure and viscosity relations

|                   |                                          | Ocone et al. [112] | Johnson et al. [76] |
|-------------------|------------------------------------------|--------------------|---------------------|
| $\phi$            | Angle of internal friction [°]           | 28                 | 28.5                |
| $\zeta$           | Constant [N/m <sup>2</sup> ]             | 0.5                | 0.5                 |
| $r$               | Constant                                 | 2                  | 2                   |
| $s$               | Constant                                 | 3                  | 5                   |
| $\alpha_d^{\min}$ | Lower volume fraction limit for friction | 0.5                | 0.5                 |

$$\mu_d^{\text{crit}} = \frac{p_d^{\text{crit}} \sqrt{2} \sin \phi}{2\alpha_d \sqrt{\mathbf{S}_d : \mathbf{S}_d + \Theta_d/d_p^2}} \quad (4.154)$$

The solids frictional pressure and viscosity are thus approximated by:

$$p_d^{\text{fric}} \approx p_d^{\text{crit}} \quad (4.155)$$

$$\mu_d^{\text{fric}} \approx \mu_d^{\text{crit}} \quad (4.156)$$

Two representative sets of model parameter values are listed in Table 4.1.

In a very recent study by Farzaneh Kaloorazi [42], it was presumed that the mechanical behavior of dense granular flows is not approximated sufficiently accurately by the soil mechanics theory representing the mechanical behavior of the system as a rate independent *plastic regime* characterized by a constant friction coefficient. It was claimed that somewhat improved model predictions were obtained for bubbling fluidized bed combustors with a somewhat more comprehensive theory proposed by Jop et al. [77]. This alternative frictional pressure tensor closure was derived based on visco-plastic fluid analysis.

#### 4.1.5.4 Total Granular Fluid Pressure Tensor

In a generalized modeling approach, the total granular fluid pressure tensor might be defined in accordance with (4.150) as:
